Abstract

Solving geometric optimization problems over uncertain data has become increasingly important in many applications and has attracted a lot of attentions in recent years. In this paper, we study two important geometric optimization problems, the $k$-center problem and the $j$-flat-center problem, over stochastic/uncertain data points in Euclidean spaces. For the stochastic $k$-center problem, we would like to find $k$ points in a fixed dimensional Euclidean space, such that the expected value of the $k$-center objective is minimized. For the stochastic $j$-flat-center problem, we seek a $j$-flat (i.e., a $j$-dimensional affine subspace) such that the expected value of the maximum distance from any point to the $j$-flat is minimized. We consider both problems under two popular stochastic geometric models, the existential uncertainty model, where the existence of each point may be uncertain, and the locational uncertainty model, where the location of each point may be uncertain. We provide the first PTAS (Polynomial Time Approximation Scheme) for both problems under the two models. Our results generalize the previous results for stochastic minimum enclosing ball and stochastic enclosing cylinder.
1 Introduction

With the prevalence of automatic information extraction/integration systems, and predictive machine learning algorithms in numerous application areas, we are faced with a huge volume of data which is inherently uncertain and noisy. The most principled way for managing, analyzing and optimizing over such uncertain data is to use stochastic models (i.e., use probability distributions over possible realizations to capture the uncertainty). This has led to a surge of interests in stochastic combinatorial and geometric optimization problems in recent years from several research communities including theoretical computer science, databases, machine learning. In this paper, we study two classic geometric optimization problems, the $k$-center problem and the $j$-flat center problem in Euclidean spaces. Both problems are important in geometric data analysis. We generalize both problems to the stochastic settings. We first introduce the stochastic geometry models, and then formally define our problems.

Stochastic Geometry Models: There are two natural and popular stochastic geometry models, under which most of stochastic geometric optimization problems are studied, such as closest pairs [27], nearest neighbors [6,27], minimum spanning trees [24,28], perfect matchings [24], clustering [13,20], minimum enclosing balls [32], and range queries [1,5,31]. We define them formally as follows:

1. Existential uncertainty model: Given a set $P$ of $n$ points in $\mathbb{R}^d$, each point $s_i \in P$ $(1 \leq i \leq n)$ is associated with a real number (called existential probability) $p_i \in [0,1]$, i.e., point $u_i$ is present independently with probability $p_i$. A realization $P \sim P$ is a point set which is realized with probability
   \[
   \Pr[\succeq P] = \prod_{s_i \in P} p_i \prod_{s_i \not\in P} (1 - p_i).
   \]

2. Locational uncertainty model: Assume that there is a set $F$ of $n$ nodes and the existence of each node is certain. However, the location of each node $u_i \in P$ $(1 \leq i \leq n)$ might be a random point in $\mathbb{R}^d$. We assume that the probability distribution for each $u_i \in P$ is discrete and independent of other points. For a node $u_i \in P$ and a point $s_j \in \mathbb{R}^d$ $(1 \leq j \leq m)$, we define $p_{i,j}$ to be the probability that the location of node $u_i$ is $s_j$.

Stochastic $k$-Center: The deterministic Euclidean $k$-center problem is a central problem in geometric optimization [4,8]. It asks for a $k$-point set $F$ in $\mathbb{R}^d$ such that the maximum distance from any of the $n$ given points to its closest point in $F$ is minimized. Its stochastic version is naturally motivated: Suppose we want to build $k$ facilities to serve a set of uncertain demand points, and our goal is to minimize the expectation of the maximum distance from any realized demand point to its closest facility.

Definition 1. For a set of points $P \in \mathbb{R}^d$, and a $k$-point set $F = \{f_1, \ldots, f_k\} \in \mathbb{R}^d$, 1 \leq i \leq k\), we define $K(P, F) = \max_{s \in P} \min_{1 \leq i \leq k} d(s, f_i)$ as the $k$-center value of $F$ w.r.t. $P$. We use $\mathcal{F}$ to denote the family of all $k$-point sets in $\mathbb{R}^d$. Given a set $\mathcal{P}$ of $n$ stochastic points (in either the existential or locational uncertainty model) in $\mathbb{R}^d$, and a $k$-point set $F \in \mathcal{F}$, we define the expected $k$-center value of $F$ w.r.t $\mathcal{P}$ as

\[
K(\mathcal{P}, F) = \mathbb{E}_{P \sim \mathcal{P}}[K(P, F)].
\]

In the stochastic minimum $k$-center problem, our goal is to find a $k$-point set $F \in \mathcal{F}$ which minimizes $K(\mathcal{P}, F)$. In this paper, we assume that both the dimensionality $d$ and $k$ are fixed constants.

Stochastic $j$-Flat-Center: The deterministic $j$-flat-center problem is defined as follows: given $n$ points in $\mathbb{R}^d$, we would like to find a $j$-flat $F$ (i.e., a $j$-dimensional affine subspace) such that the maximum distance from any given point to $F$ is minimized. It is a common generalization of the minimum enclosing ball ($j = 0$), minimum enclosing cylinder ($j = 1$), and minimum width problems ($j = d - 1$), and has been well studied in computational geometry [8,16,36]. Its stochastic version is also naturally motivated by the
stochastic variant of the $\ell_\infty$ regression problem: Suppose we would like to fit a set of points by an affine subspace. However, those points may be produced by some machine learning algorithm, which associates some confidence level to each point (i.e., each point has an existential probability). This naturally gives rise to the stochastic $j$-flat-center problem. Formally, it is defined as follows.

**Definition 2.** Given a set $P$ of $n$ points in $\mathbb{R}^d$, and a $j$-flat $F \in \mathcal{F}$ ($0 \leq j \leq d - 1$), where $\mathcal{F}$ is the family of all $j$-flats in $\mathbb{R}^d$, we define the $j$-flat-center value of $F$ w.r.t. $P$ to be $J(P, F) = \max_{s \in P} d(s, F)$, where $d(s, F) = \min_{f \in F} d(s, f)$ is the distance between point $s$ and $j$-flat $F$. Given a set $\mathcal{P}$ of $n$ stochastic points (in either the existential or locational model) in $\mathbb{R}^d$, and a $j$-flat $F \in \mathcal{F}$ ($0 \leq j \leq d - 1$), we define the expected $j$-flat-center value of $F$ w.r.t. $\mathcal{P}$ to be $J(\mathcal{P}, F) = \mathbb{E}_{P \sim \mathcal{P}}[J(P, F)]$.

In the stochastic minimum $j$-flat-center problem, our goal is to find a $j$-flat $F$ which minimizes $J(\mathcal{P}, F)$.

### 1.1 Previous Results and Our contributions

Recall that a polynomial time approximation scheme (PTAS) for a minimization problem is an algorithm $A$ that produces a solution whose cost is at most $1 + \varepsilon$ times the optimal cost in polynomial time, for any fixed constant $\varepsilon > 0$.

**Stochastic $k$-Center:** Cormode and McGregor [13] first studied the stochastic $k$-center problem in a finite metric graph under the locational uncertainty model, and obtained a bi-criterion constant approximation. Guha and Munagala [20] improved their result to a single-criterion constant factor approximation. Recently, Wang and Zhang [37] studied the stochastic $k$-center problem on a line, and proposed an efficient exact algorithm. No result better than a constant approximation is known for the Euclidean space $\mathbb{R}^d$ ($d \geq 2$). We obtain the first PTAS for the stochastic $k$-center problem in $\mathbb{R}^d$.

**Theorem 3.** Assume that both $k$ and $d$ are fixed constants. There exists a PTAS for the stochastic minimum $k$-center problem in $\mathbb{R}^d$, under either the existential or the locational uncertainty model.

Our result generalizes the PTAS for stochastic minimum enclosing ball by Munteanu et al. [32]. We remark that the assumption that $k$ is a constant is necessary for getting a PTAS, since even the deterministic Euclidean $k$-center problem is APX-hard for arbitrary $k$ even in $\mathbb{R}^2$ [15].

**Stochastic $j$-Flat-Center:** Our main result for the stochastic $j$-flat-center is as follows.

**Theorem 4.** Assume that the dimensionality $d$ is a constant. There exists a PTAS for the stochastic minimum $j$-flat-center problem, under either the existential or the locational uncertainty model.

This result also generalizes the PTAS for stochastic minimum enclosing ball (i.e., 0-flat-center) by Munteanu et al. [32]. It also generalizes a previous PTAS for the stochastic minimum enclosing cylinder (i.e., 1-flat-center) problem in the existential model where the existential probability of each point is assumed to be lower bounded by a small fixed constant [25].

**Our techniques:** Our techniques for both problems heavily rely on the powerful notion of coresets. In a typical deterministic geometric optimization problem, an instance $P$ is a set of deterministic (weighted) points. A coreset $S$ of $P$ is a set of (weighted) points, such that the solution for the optimization problem over $S$ is a good approximate solution for $P$. Recently, Huang et al. [25] generalized the notion of $\varepsilon$-kernel coreset (for directional width) to stochastic points. However, their technique can only handle directional

---

1It is possible to define coresets for other classes of optimization problems.
width, and extending it to problems such as stochastic minimum enclosing cylinder requires certain technical assumption (see [25] for the detailed discussion).

In this paper, we introduce a new framework for solving geometric optimization problems over stochastic points. For a stochastic instance \( \mathcal{P} \), we consider \( \mathcal{P} \) as a collection of realizations \( \mathcal{P} = \{ P \mid P \sim \mathcal{P} \} \). Each realization \( P \) has a weight \( \Pr[\Pi=P] \), which is its realized probability. Now, we can think the stochastic problem as a certain deterministic problem over (exponential many) all realizations (each being a point set). Our framework constructs an object \( S \) satisfying the following properties.

1. Basically, \( S \) has a constant size description (the constants may depend on \( d, \varepsilon, \) and \( k \)).

2. The objective value for a certain deterministic optimization problem over \( S \) can approximate the objective for the original stochastic problem well. Moreover, the solution to the deterministic optimization over \( S \) is a good approximation for the original problem as well.

In a high level, \( S \) serves very similar roles as the coresets in the deterministic setting. Note that the form of \( S \) may vary for different problems: in stochastic \( k \)-center, it is a collection of weighted point sets (we call \( S \) an SKC-CORESET); in stochastic \( j \)-flat-center, it is a combination of two collections of weighted point sets for two intermediate problems (we call \( S \) an SJFC-CORESET).

For stochastic \( k \)-center under the existential model, we construct an SKC-CORESET \( S \) in two steps. First, we map all realizations to their additive \( \varepsilon \)-coresets (for deterministic \( k \)-centers) [4]. Since there are only a polynomial number of possible additive \( \varepsilon \)-coresets, the above mapping can partition the space of all realizations into a polynomial number of parts, such that the realizations in each part have very similar objective functions. Moreover, for each additive \( \varepsilon \)-coresets, it is possible to compute the total probability of the realizations that are mapped to the coreset. In fact, this requires a subtle modification of the construction in [4] so that we can compute the aforementioned probability efficiently. This step has reduced the exponential number of realizations to a polynomial size representation. Next, we define a generalized shape fitting problem, call the generalized \( k \)-median problem, over the collection of above additive \( \varepsilon \)-coresets. Then, we need to properly generalize the previous definition of coreset and the total sensitivity (a notion proposed in the deterministic coreset context by Langberg and Schulman [30]), and prove a constant upper bound for the generalized total sensitivity by relating it to the total sensitivity of the ordinary \( k \)-median problem. The SKC-CORESET \( S \) is a generalized coreset for the generalized \( k \)-median problem, which consists of a constant number of weighted point sets.

For stochastic \( k \)-center under the locational model, computing the weight for each set in the SKC-CORESET \( S \) is somewhat more complicated. We need to reduce the computational problem to a family of bipartite holant problems, and apply the celebrated result by Jerrum, Sinclair, and Vigoda [26].

For the stochastic minimum \( j \)-flat-center problem, we proposed an efficient algorithm for constructing an SJFC-CORESET. We utilize several ideas in the recent work [25], as well as prior results on the shape fitting problem. We first partition the realizations \( P \sim \mathcal{P} \) into two parts through a construction similar to the \( (\varepsilon, \tau) \)-QUANT KERNEL construction in [25]. Roughly speaking, after linearization, we need to find a convex set \( K \) in a higher dimensional space such that the total probability of any point falling outside \( K \) is small, but not so small such that in each direction the expected directional width of \( \mathcal{P} \) is comparable to that of \( K \). Then, for those points inside \( K \), it is possible to use a slight modification of the construction in [25] to construct a collection of weighted point sets. For the points outside \( K \), since the total probability is small, we reduce the problem to a weighted \( j \)-flat-median problem, and use the coreset in [36] (this step is similar to that in [32]). By combining the two collections, we obtain the SJFC-CORESET \( S \) for the problem, which is of constant size. Then, we can easily obtain a PTAS by solving a constant size polynomial system defined by \( S \).

We remark that our overall approach is very different from that in Munteanu et al. [32] (except one aforementioned step and that they also crucially used some machinery from the coreset literature). Munteanu
et al. \cite{32} defined a near-metric distance measure \( m(A, B) = \max_{a \in A, b \in B} d(a, b) \) for two non-empty point sets \( A, B \). This near-metric measure satisfies many metric properties, like non-negativity, symmetry and the triangle inequality. By lifting the problem to the space defined by such metric and utilizing a previous coreset result for clustering, they obtained a PTAS for the problem. However, in the more general stochastic minimum \( k \)-center problem and stochastic minimum \( j \)-flat-center problem, it is unclear how to translate the distance function between point sets and \( k \)-centers or point sets and \( j \)-flat sets to a near-metric distance (and still satisfies symmetry and triangle inequality).

1.2 Other Related work

Recently, Huang et al. \cite{25} generalized the notion of \( \varepsilon \)-kernel coreset in \cite{7} to stochastic points and applied it to the stochastic minimum spherical shell, minimum enclosing cylinder and minimum cylindrical shell problems. However, the stochasticity introduces certain complications in lifting the problems to higher dimensional space and converting the solution back. Hence, they could only obtain PTAS for those problems under the assumption that the existential probability of each point is lower bounded by a small fixed constant. Abdullah et al. \cite{1} also studied coresets for range queries over stochastic data.

Kamousi, Chan and Suri \cite{28} studied the problem of estimating the expected length of several geometric objects, such as MST, the nearest neighbor graph, the Gabriel graph and the Delaunay triangulation in stochastic geometry models. Huang and Li \cite{24} considered several other problems including closest pair, diameter, minimum perfect matching, and minimum cycle cover. Many stochastic geometry problems have also been studied recently, such as computing the expected volume of a set of probabilistic rectangles in a Euclidean space \cite{38}, convex hulls \cite{3}, and skylines over probabilistic points \cite{2, 10}.

For the deterministic \( k \)-center problem, Gonzalez gave a 2-approximation greedy algorithm in metric space. Hochbaum and Shmoys \cite{23} showed that 2 is optimal in general metric spaces unless \( P = NP \). In Euclidean spaces, the best hardness of approximation known is 1.82 even for \( \mathbb{R}^2 \) \cite{15}. Agarwal and Procopiuc \cite{4} showed that there exists an additive coreset of a constant size if both \( k \) and \( d \) are constants. Har-Peled and Varadarajan \cite{22} studied the minimum enclosing cylinder (1-flat-center) problem in \( \mathbb{R}^d \), and obtained a PTAS running in \( dn^{(1/\varepsilon)O(1)} \) time. Their algorithm can be extended to the \( j \)-flat-center problem, and obtained a PTAS running in \( dn^{(j/\varepsilon)O(1)} \) time. Badouiu, Clarkson and Panigrahy \cite{11, 33} improved their result of the \( j \)-flat-center problem to a linear-time PTAS.

Note that both the \( k \)-center and \( j \)-flat center problems are special cases of the \( \ell_\infty \) version of \((j, k)\)-projective clustering problem, where we want to find \( k \) \( j \)-flats to minimize the maximum distance from any point to its closest \( j \)-flat. Har-Peled and Varadarajan \cite{22} obtained the first PTAS when both \( j \) and \( k \) are constants (\( d \) can be arbitrary).

The \( \ell_1 \) version of the projective clustering problems (with the corresponding coresets) have also been studied extensively (see e.g., \cite{16, 18, 35, 56}). In Euclidean space \( \mathbb{R}^d \), Feldman and Langberg \cite{16} gave a coreset for the \( k \)-median problem, the subspace approximation (i.e., \( j \)-flat median) problem, and the \( k \)-line-median problem. Varadarajan et al. \cite{56} also considered the \( k \)-line-median problem, and gave a coreset of size \( O(kf(k)d\log n^2/\varepsilon^2) \), where \( f(k) \) is a function depending only on \( k \).

2 Preliminaries

**Generalized Shape Fitting Problems and Coresets** As we mentioned in the introduction, an SKC-CORESET \( S \) is a collection of weighted point sets. Hence, we need to define the generalized shape fitting problems, which are defined over a collection of (weighted) point sets, (recall that the traditional

\footnote{The minimum \( k \)-center problem is the \((0, k)\)-projective clustering problem, and the minimum \( j \)-flat-center problem is the \((j, 1)\)-projective clustering problem.}
shape fitting problems (see e.g., [36]) are defined over a set of (weighted) points. We use $\mathbb{R}^d$ to denote the $d$-dimensional Euclidean space. Let $d(p, q)$ denote the Euclidean distance between point $p$ and $q$ and $d(p, F) = \min_{q \in F} d(p, q)$ for any $F \subset \mathbb{R}^d$. Let $\mathbb{U}^d = \{ P \mid P \subset \mathbb{R}^d, |P| \text{ is finite} \}$ be the collection of all finite discrete point sets in $\mathbb{R}^d$.

**Definition 5.** (Generalized shape fitting problems) A generalized shape fitting problem is specified by a triple $(\mathbb{R}^d, \mathcal{F}, \text{dist})$. Here the set $\mathcal{F}$ of shapes is a family of subsets of $\mathbb{R}^d$ (e.g., all k-point sets, or all j-flats), and dist : $\mathbb{U}^d \times \mathcal{F} \to \mathbb{R}^{\geq 0}$ is a generalized distance function, defined as $\text{dist}(P, F) = \max_{s \in P} d(s, F)$ for a point set $P \in \mathbb{U}^d$ and a shape $F \in \mathcal{F}$. An instance $S$ of the generalized shape fitting problem is a (weighted) collection $\{S_1, \ldots, S_m\}$ ($S_i \in \mathbb{U}^d$) of point sets, and each $S_i$ has a positive weight $w_i \in \mathbb{R}^+$. For any shape $F \in \mathcal{F}$, define the total generalized distance from $S$ to $F$ to be $\text{dist}(S, F) = \sum_{S_i \in S} w_i \cdot \text{dist}(S_i, F)$. Given an instance $S$, our goal is to find a shape $F \in \mathcal{F}$, which minimizes the total generalized distance $\text{dist}(S, F)$.

If we replace $\mathbb{U}^d$ with $\mathbb{R}^d$, the above definition reduces to the traditional shape fitting problem defined in e.g., [36]. Now, we define what is a coreset for a generalized shape fitting problem.

**Definition 6.** (Generalized Coreset) Given a (weighted) instance $S$ of a generalized shape fitting problem $(\mathbb{R}^d, \mathcal{F}, \text{dist})$ with a weight function $w : S \to \mathbb{R}^+$, a generalized $\epsilon$-coreset of $S$ is a (weighted) collection $S \subseteq S$ of point sets, together with a weight function $w' : S \to \mathbb{R}^+$, such that for any shape $F \in \mathcal{F}$, we have that

$$\sum_{S_i \in S} w'_i \cdot \text{dist}(S_i, F) \in (1 \pm \epsilon) \sum_{S_i \in S} w_i \cdot \text{dist}(S_i, F)$$

(or more compactly, $\text{dist}(S, F) \in (1 \pm \epsilon)\text{dist}(S, F)$). We denote the cardinality of the coreset $S$ as $|S|$.

Definition 6 also generalizes the prior definition in [36], where each $S_i \in S$ contains only one point.

**Total sensitivity and dimension** To bound the size of the generalized coresets, we need the notion of total sensitivity, originally introduced in [29].

**Definition 7.** (Total sensitivity of a generalized shape fitting instance). Let $\mathbb{U}^d$ be the collection of all finite discrete point sets $P \subset \mathbb{R}^d$, and let dist : $\mathbb{U}^d \times \mathcal{F} \to \mathbb{R}^{\geq 0}$ be a continuous function. Given an instance $S = \{S_i \mid S_i \subset \mathbb{U}^d, 1 \leq i \leq n \}$ of a generalized shape fitting problem $(\mathbb{R}^d, \mathcal{F}, \text{dist})$, with a weight function $w : S \to \mathbb{R}^+$, the sensitivity $S_i \in S$ is $\sigma_S(S_i) := \inf \{ \beta \geq 0 \mid w_i \cdot \text{dist}(S_i, F) \leq \beta \cdot \text{dist}(S, F), \forall F \in \mathcal{F} \}$. The total sensitivity of $S$ is defined by $\sigma_S = \sum_{S_i \in S} \sigma_S(S_i)$.

Note that this definition generalizes the one in [29]. In fact, if each $S_i \in S$ contains only one point and the weight function $w_i = 1$ for all $i$, this definition is equivalent to the definition in [29].

We also need to generalize the definition of dimension defined in [16] (it is in fact the primal shattering dimension (See e.g., [16][21]) of a certain range space. It plays a similar role to VC-dimension).

**Definition 8.** (Generalized dimension) Let $S = \{S_i \mid S_i \subset \mathbb{U}^d, 1 \leq i \leq n \}$ be an instance of a generalized shape fitting problem $(\mathbb{R}^d, \mathcal{F}, \text{dist})$. Suppose $w_i$ is the weight of $S_i$. We consider the range space $(S, \mathcal{R})$, where $\mathcal{R}$ is a family of subsets $R_{F,r}$ of $S$ defined as follows: given an $F \in \mathcal{F}$ and $r \geq 0$, let $R_{F,r} = \{S_i \in S \mid w_i \cdot \text{dist}(S_i, F) \geq r \} \in \mathcal{R}$ consist of the sets $S_i$ whose weighted distance to the shape $F$ is at least $r$. Finally, we denote the generalized dimension of the instance $S$ by $\dim(S)$, to be the smallest integer $m$, such that for any weight function $w$ and $A \subseteq S$ of size $|A| = a \geq 2$, we have $|\{A \cap R_{F,r} \mid F \in \mathcal{F}, r \geq 0\}| \leq a^m$.

Note that dist may not be a metric in general.

The notation $(1 \pm \epsilon)B$ means the interval $[(1 - \epsilon)B, (1 + \epsilon)B]$. 

5
The definition [29] is a special case of the above definition when each $S_i \in S$ contains only one point. On the other hand, the above definition is a special case of Definition 7.2 [16] if thinking each $w_i \cdot \text{dist}(S_i, \cdot) = g_i(\cdot)$ as a function from $F$ to $\mathbb{R}^\geq 0$.

We have the following lemma for bounding the size of generalized coresets by the generalized total sensitivity and dimension. The proof is a straightforward extension of a result in [16]. See Appendix A for the details.

**Lemma 9.** Given any instance $S = \{S_i \mid S_i \subseteq \mathbb{U}^d, 1 \leq i \leq n\}$ of a generalized shape fitting problem $(\mathbb{R}^d, F, \text{dist})$, any weight function $w : S \rightarrow \mathbb{R}^+$, and any $\varepsilon \in (0, 1]$, there exists a generalized $\varepsilon$-coreset for $S$ of cardinality $O((\frac{\text{diam}(S)}{\varepsilon})^2 \text{dim}(S))$.

## 3 Stochastic Minimum $k$-Center

In this section, we consider the stochastic minimum $k$-center problem in $\mathbb{R}^d$ in the stochastic model. Let $F$ be the family of all $k$-point sets of $\mathbb{R}^d$, and let $P$ be the set of stochastic points. Our main technique is to construct an SKC-CORESET $S$ of constant size. For any $k$-point set $F \in F$, $K(S, F)$ should be a $(1 \pm \varepsilon)$-estimation for $K(P, F) = \mathbb{E}_{P \sim \mathcal{P}}[K(P, F)]$. Recall that $K(P, F) = \max_{s \in P} \min_{f \in F} d(s, f)$ is the $k$-center value between two point sets $P$ and $F$. Constructing $S$ includes two main steps: 1) Partition all realizations via additive $\varepsilon$-coresets, which reduces an exponential number of realizations to a polynomial number of point sets. 2) Show that there exists a generalized coreset of constant cardinality for the generalized $k$-median problem defined over the above set of polynomial point sets. Finally, we enumerate polynomially many possible collections $S_i$ (together with their weights). We show that there is an SKC-CORESET $S$ among those candidate. By solving a polynomial system for each $S_i$, and take the minimum solution, we can obtain a PTAS.

We first need the formal definition of an additive $\varepsilon$-coreset [4] as follows.

**Definition 10.** (additive $\varepsilon$-coreset) Let $B(f, r)$ denote the ball of radius $r$ centered at point $f$. For a set of points $P \subseteq \mathbb{U}^d$, we call $Q \subseteq P$ an additive $\varepsilon$-coreset of $P$ if for every $k$-point set $F = \{f_1, \ldots, f_k\}$, we have

$$P \subseteq \cup_{i=1}^k B(f_i, (1 + \varepsilon)K(Q, F)),$$

i.e., the union of all balls $B(f_i, (1 + \varepsilon)K(Q, F))$ ($1 \leq i \leq k$) covers $P$.

### 3.1 Existential uncertainty model

We first consider the existential uncertainty model.

**Step 1: Partitioning realizations**

We first provide an algorithm $\mathcal{A}$, which can construct an additive $\varepsilon$-coreset for any deterministic point set. We can think $\mathcal{A}$ as a mapping from all realizations of $P$ to all possible additive $\varepsilon$-coresets. The mapping naturally induces a partition of all realizations. Note that we do not run $\mathcal{A}$ on every realization.

**Algorithm $\mathcal{A}$ for constructing additive $\varepsilon$-coresets.** Given a realization $P \sim \mathcal{P}$, we build a Cartesian grid $G(P)$ of side length depending on $P$. Let $C(P) = \{C \mid C \in G, C \cap P \neq \emptyset\}$ be the collection of those nonempty cells (i.e., cells that contain at least one point in $P$). In each non-empty cell $C \in C(P)$, we maintain the point $s^C \in C \cap P$ of smallest index. Let $E(P) = \{s^C \mid C \in G\}$, which is an additive $\varepsilon$-coreset of $P$. Finally the output of $\mathcal{A}(P)$ is $E(P), G(P)$, and $C(P)$. The details can be found in Appendix B.

---

5Our definition is slight weaker than that in [4]. The weaker definition suffices for our purpose.
Note that we do not use the construction of additive \( \epsilon \)-coresets [4], because we need the set of additive \( \epsilon \)-coreset to have some extra properties (in particular, Lemma 13 below), which allows us to compute certain probability values efficiently.

We first have the following lemma.

**Lemma 11.** The running time of \( \mathcal{A} \) on any \( n \) point set \( P \) is \( O(kn^{k+1}) \). Moreover, the output \( \mathcal{E}(P) \) is an additive \( \epsilon \)-coreset of \( P \) of size at most \( O(k/\epsilon^d) \).

Denote \( \mathcal{E}(P) = \{ \mathcal{E}(P) \mid P \sim P \} \) be the collection of all possible additive \( \epsilon \)-coresets. By Lemma 11 we know that each \( S \in \mathcal{E}(P) \) is of size at most \( O(k/\epsilon^d) \). Thus, the cardinality of \( \mathcal{E}(P) \) is at most \( n^{O(k/\epsilon^d)} \).

For a point set \( S \), denote \( \Pr_{P \sim P}[\mathcal{E}(P) = S] = \sum_{P: P \sim P, \mathcal{E}(P) = S} \Pr[\models P] \) to be the probability that the additive \( \epsilon \)-coreset of a realization is \( S \). The following simple lemma states that we can have a polynomial size representation for the objective function \( K(P, F) \).

**Lemma 12.** Given \( P \) of \( n \) points in \( \mathbb{R}^d \) in the existential uncertainty model, for any \( k \)-point set \( F \in \mathcal{F} \), we have that

\[
\sum_{S \in \mathcal{E}(P)} \Pr_{P \sim P}[\mathcal{E}(P) = S] \cdot K(S, F) \in (1 \pm \epsilon)K(P, F).
\]

**Proof.** By the definition of \( \Pr_{P \sim P}[\mathcal{E}(P) = S] \), we can see that for any \( k \)-point set \( F \in \mathcal{F} \),

\[
\sum_{S \in \mathcal{E}(P)} \Pr_{P \sim P}[\mathcal{E}(P) = S] \cdot K(S, F) = \sum_{S \in \mathcal{E}(P)} \sum_{P: P \sim P, \mathcal{E}(P) = S} \Pr[\models P] \cdot K(S, F)
\]

\[
\in (1 \pm \epsilon) \sum_{S \in \mathcal{E}(P)} \sum_{P: P \sim P, \mathcal{E}(P) = S} \Pr[\models P] \cdot K(P, F) = (1 \pm \epsilon)K(P, F).
\]

The inequality above uses the definition of additive \( \epsilon \)-coresets (Definition 10). \( \Box \)

We can think \( P \rightarrow \mathcal{E}(P) \) as a mapping, which maps a realization \( P \sim P \) to its additive \( \epsilon \)-coreset \( \mathcal{E}(P) \).

The mapping partitions all realizations \( P \sim P \) into a polynomial number of additive \( \epsilon \)-coresets. For each possible additive \( \epsilon \)-coreset \( S \in \mathcal{E}(P) \), we denote \( \mathcal{E}^{-1}(S) = \{ P \sim P \mid \mathcal{E}(P) = S \} \) to be the collection of all realizations mapping to \( S \). By the definition of \( \mathcal{E}(P) \), we have that \( \cup_{S \in \mathcal{E}(P)} \mathcal{E}^{-1}(S) = \mathcal{P} \).

Now, we need an efficient algorithm to compute \( \Pr_{P \sim P}[\mathcal{E}(P) = S] \) for each additive \( \epsilon \)-coreset \( S \in \mathcal{E}(P) \). The following lemma states that the mapping constructed by algorithm \( \mathcal{A} \) has some nice properties that allow us to compute the probabilities. This is also the reason why we cannot directly use the original additive \( \epsilon \)-coreset construction algorithm in [4]. The proof is somewhat subtle and can be found in Appendix [3].

**Lemma 13.** Consider a subset \( S \) of at most \( O(k/\epsilon^d) \) points. Run algorithm \( \mathcal{A}(S) \), which outputs an additive \( \epsilon \)-coreset \( \mathcal{E}(S) \), a Cartesian grid \( G(S) \), and a collection \( \mathcal{C}(S) \) of nonempty cells. If \( \mathcal{E}(S) \neq S \), then \( S \notin \mathcal{E}(P) \) (i.e., \( S \) is not the output of \( \mathcal{A} \) for any realization \( P \sim P \)). If \( |S| \leq k \), then \( \mathcal{E}^{-1}(S) = \{ S \} \). Otherwise if \( \mathcal{E}(S) = S \) and \( |S| \geq k + 1 \), then a point set \( P \sim P \) satisfies \( \mathcal{E}(P) = S \) if and only if

\( P \). For any cell \( C \notin \mathcal{C}(S) \), \( C \cap P = \emptyset \).

\( P \). For any cell \( C \in \mathcal{C}(S) \), assume that point \( s^C = C \cap S \). Then \( s^C \in P \), and any point \( s' \in C \cap P \) with a smaller index than that of \( s^C \) does not appear in the realization \( P \).

Thanks to Lemma 13 now we are ready to show how to compute \( \Pr_{P \sim P}[\mathcal{E}(P) = S] \) efficiently for each \( S \in \mathcal{E}(P) \). We enumerate every point set of size \( O(k/\epsilon^d) \). For a set \( S \), we first run \( \mathcal{A}(S) \) and output a Cartesian grid \( G(S) \) and a point set \( \mathcal{E}(S) \). We check whether \( S \in \mathcal{E}(P) \) by checking whether \( \mathcal{E}(S) = S \) or...
Algorithm 1: Computing $\Pr_{P \sim P}[E(P) = S]$

1. For each point set $S \sim P$ of size $|S| = O(k/\varepsilon^d)$, run algorithm $\mathcal{A}(S)$. Assume that the output is a point set $E(S)$, a Cartesian grid $G(S)$, and a cell collection $C(S) = \{C \mid C \in G, C \cap S \neq \emptyset\}$.

2. If $E(S) \neq S$, output $\Pr_{P \sim P}[E(P) = S] = 0$. If $|S| \leq k$, output $\Pr_{P \sim P}[E(P) = S] = \Pr[\models S]$.

3. For a cell $C \notin C(S)$, suppose $C \cap P = \{t_1, t_2, \ldots, t_m\}$. W.l.o.g., assume that $t_1, \ldots, t_m$ are in increasing order of their indices. For $C \notin C(S)$, let

\[
Q(C) = \Pr_{P \sim P}[P \cap C = \emptyset] = \prod_{i=1}^{m}(1 - p_i)
\]

be the probability that no point in $C$ is realized. If $C \in C(S)$, assume that point $t_j \in C \cap S$, and let

\[
Q(C) = \Pr_{P \sim P}[t_j \in P \text{ and } \{t_1, \ldots, t_{j-1}\} \cap P = \emptyset] = p_j \cdot \prod_{i=1}^{j-1}(1 - p_i)
\]

be the probability that $t_j$ appears, but $t_1, \ldots, t_{j-1}$ do not appear.

4. Output $\Pr_{P \sim P}[E(P) = S] = \prod_{C \in G(S)} Q(C)$.

$|S| \leq k$. If $S \in \mathcal{E}(P)$, we can compute $\Pr_{P \sim P}[E(P) = S]$ using the Cartesian grid $G(S)$. See Algorithm 1 for details.

The following lemma asserting the correctness of Algorithm 1 is a simple consequence of Lemma 13.

Lemma 14. For any point set $S$, Algorithm 1 computes exactly the total probability

\[
\Pr_{P \sim P}[E(P) = S] = \sum_{P : P \sim P, E(P) = S} \Pr[\models P]
\]

in $O(n^{O(k/\varepsilon^d)})$ time.

Proof. Run $\mathcal{A}(S)$, and we obtain a point set $E(S)$. If $E(S) \neq S$, we have that $S \notin \mathcal{E}(P)$ by Lemma 13. Thus, $\Pr_{P \sim P}[E(P) = S] = 0$. If $|S| \leq k$, we have that $E^{-1}(S) = \{S\}$ by Lemma 13. Thus, $\Pr_{P \sim P}[E(P) = S] = \Pr[\models S]$.

Otherwise if $E(S) = S$ and $|S| \geq k + 1$, by Lemma 13 each realization $P \in E^{-1}(S)$ satisfies P1 and P2. Then combining the definition of $Q(C)$, and the independence of all cells, we can see that $\prod_{C \in \mathcal{E}} Q(C)$ is equal to $\sum_{P \in E^{-1}(S)} \Pr[\models P] = \Pr_{P \sim P}[E(P) = S]$.

For the running time, note that we only need to consider at most $n^{O(k/\varepsilon^d)}$ point sets $S \sim P$. For each $S$, Algorithm 1 needs to run $\mathcal{A}(S)$, which costs $O(kn^{k+1})$ time by Lemma 11. Step 2 and 3 only cost linear time. Thus, we can compute all probabilities $\Pr_{P \sim P}[E(P) = S]$ in $O(n^{O(k/\varepsilon^d)})$ time.

Step 2: Existence of generalized coreset via generalized total sensitivity

Recall that $E(P)$ is a collection of polynomially many point sets of size $O(k/\varepsilon^d)$. By Lemma 12, we can focus on a generalized $k$-median problem: finding a $k$-point set $F \in \mathcal{F}$ which minimizes $K(E(P), F) = \sum_{S \in E(P)} \Pr_{P \sim P}[E(P) = S] \cdot K(S, F)$. In fact, the generalized $k$-median problem is a special case of the generalized shape fitting problem we defined in Definition 5. Here, we instantiate the shape family $\mathcal{F}$ to be the collection of all $k$-point sets. Note that the $k$-center objective $K(E(P), F)$ is indeed a generalized $k$-median objective.

\footnote{It is possible that some point set $S$ satisfies Definition 10 for some realization $P$, but is not the output of $\mathcal{A}(S)$.}
distance function in Definition\textsuperscript{5} To make things concrete, we formalize it below. Recall that \( \mathbb{U}^d \) is the collection of all finite discrete point sets in \( \mathbb{R}^d \).

**Definition 15.** A generalized k-median problem is specified by a triple \((\mathbb{R}^d, \mathcal{F}, K)\). Here \( \mathcal{F} \) is the family of all k-point sets in \( \mathbb{R}^d \), and \( K: \mathbb{U}^d \times \mathcal{F} \to \mathbb{R}_{\geq 0} \) is a generalized distance function defined as follows: for a point set \( P \in \mathbb{U}^d \) and a k-point set \( F \in \mathcal{F} \), \( K(P, F) = \max_{s \in P} d(s, F) = \max_{s \in P} \min_{f \in F} d(s, f) \). An instance \( S \) of the generalized k-median problem is (a weighted) collection \( \{S_1, \ldots, S_m\} \subseteq \mathbb{U}^d \) of point sets, and each \( S_i \) has a positive weight \( w_i \in \mathbb{R}^+ \). For any k-point set \( F \in \mathcal{F} \), the total generalized distance from \( S \) to \( F \) is \( K(S, F) = \sum_{i \in S} w_i \cdot K(S_i, F) \). The goal of the generalized k-median problem (GKM) is to find a k-point set \( F \) which minimizes the total generalized distance \( K(S, F) \).

Recall that a generalized \( \varepsilon \)-coreset is a sub-collection \( \mathcal{S} \subseteq S \) of point sets, together with a weight function \( w' : S \to \mathbb{R}^+ \), such that for any k-point set \( F \in \mathcal{F} \), we have \( \sum_{S \in \mathcal{S}} w'(S) \cdot K(S, F) \in (1 \pm \varepsilon) \sum_{S \in S} w(S) \cdot K(S, F) \) (or \( K(S, F) \in (1 \pm \varepsilon)K(S, F) \)). This generalized coreset will serve as the SKC-CORESET for the original stochastic k-center problem.

Our main lemma asserts that a constant sized generalized coreset exists, as follows.

**Lemma 16.** (main lemma) Given an instance \( P \) of \( n \) stochastic points in \( \mathbb{R}^d \), let \( \mathcal{E}(P) \) be the collection of all additive \( \varepsilon \)-coresets. There exists a generalized \( \varepsilon \)-coreset \( S \subseteq \mathcal{E}(P) \) of cardinality \( |S| = O(\varepsilon^{-(d+2)} d k^4) \), together with a weight function \( w' : S \to \mathbb{R}^+ \), which satisfies that for any k-point set \( F \in \mathcal{F} \),

\[
\sum_{S \in S} w'(S) \cdot K(S, F) \in (1 \pm \varepsilon) \sum_{S \in \mathcal{E}(P)} \Pr_{P \sim \mathcal{E}(P)}[\mathcal{E}(P) = S] \cdot K(S, F).
\]

Now, we prove Lemma\textsuperscript{16} by showing a constant upper bound on the cardinality of a generalized \( \varepsilon \)-coreset. This is done by applying Lemma\textsuperscript{9} and providing constant upper bounds for both the total sensitivity and the generalized dimension of the generalized k-median instance.

Given an instance \( S = \{S_i \mid S_i \in \mathbb{U}^d, 1 \leq i \leq n\} \) of a generalized k-median problem with a weight function \( w : S \to \mathbb{R}^+ \), denote \( F^* \) to be the k-point set which minimizes the total generalized distance \( K(S, F) = \sum_{S \in S} w(S) \cdot K(S, F) \) over all \( F \in \mathcal{F} \). W.l.o.g., we assume that \( K(S, F^*) > 0 \). Since if \( K(S, F^*) = 0 \), there are at most \( k \) different points in the instance.

We first construct a projection instance \( P^* \) of a weighted k-median problem for \( S \), and relate the total sensitivity \( \mathcal{G}_S \) to \( \mathcal{G}_{P^*} \). Recall that \( \mathcal{G}_S = \sum_{S \in S} \sigma_S(S) \) is the total sensitivity of \( S \). Our construction of \( P^* \) is as follows. For each point set \( S_i \in \mathcal{S} \), assume that \( F_i^* \subseteq \mathcal{F} \) is the k-point set satisfying that \( F_i^* = \arg\max_{F \subseteq \mathcal{F}} \frac{w(S_i) \cdot K(S_i, F)}{R(S_i, F)} \), i.e., the sensitivity \( \sigma_S(S_i) \) of \( S_i \) is equal to \( w(S_i) \cdot K(S_i, F_i^*) \). Let \( S_i^* \subseteq S_i \) denote the point farthest to \( F_i^* \). Let \( f_i^* \in F^* \) denote the point closest to \( s_i^* \). Denote \( P^* \) to be the multi-set \( \{f_i^* \mid S_i \in \mathcal{S}\} \), and denote the weight function \( w' : P^* \to \mathbb{R}^+ \) to be \( w'(f_i^*) = w(S_i) \) for any \( i \in [n] \). Thus, \( P^* \) is a weighted k-median instance in \( \mathbb{R}^d \) with a weight function \( w' \). See Figure\textsuperscript{4} for an example of the construction of \( P^* \).

**Lemma 17.** Given an instance \( S = \{S_i \mid S_i \in \mathbb{U}^d, 1 \leq i \leq n\} \) of a generalized k-median problem in \( \mathbb{R}^d \) with a weight function \( w : S \to \mathbb{R}^+ \), let \( P^* \) be its projection instance. Then, we have \( \mathcal{G}_S \leq 2\mathcal{G}_{P^*} + 1 \).

**Proof.** First note that we have the following fact. Given \( i, j \in [n] \), recall that \( s_i^* \in S_j \) is the farthest point to \( F_j^* \), and \( f_j^* \in F^* \) is the closest point to \( s_j^* \). Let \( f \in F_i^* \) be the point closest to \( s_i^* \).

\[
K(S_j, F_i^*) + K(S_j, F^*) \geq d(s_i^*, F_i^*) + d(s_j^*, F^*) = d(s_j^*, F_i^*) + d(s_i^*, f_j^*) = d(s_j^*, f_j^*) \geq d(f_j^*, F_i^*),
\]

\[
(1)
\]

\footnote{If more than 1 points in \( S_i \) have this property, we arbitrarily choose one.}
The first inequality follows from the definition of equality, and the last inequality follows from the definition of $s^*_i$.

Finally, we bound the total sensitivity as follows:

$$
\mathcal{E}_S = \sum_{S_i \in S} \sigma_{S_i} \leq \sum_{S_i \in S} \left( \frac{w(S_i) \cdot K(S_i, F^*)}{K(S, F^*)} + 2\sigma_{P^*}(f^*_i) \right) = 1 + 2\mathcal{E}_P.
$$

This finishes the proof of the lemma.
Since $P^*$ is an instance of a weighted $k$-median problem, we know that the total sensitivity $\Theta_{P^*}$ is at most $2k + 1$, by [29, Theorem 9]. Then combining Lemma [17] we have the following lemma which bounds the total sensitivity of $\Theta_S$.

**Lemma 18.** Consider an instance $S$ of a generalized $k$-median problem $(\mathbb{R}^d, \mathcal{F}, \mathcal{K})$. The total sensitivity $\Theta_S$ is at most $4k + 3$.

Now the remaining task is to bound the generalized dimension $\dim(S)$. Consider the range space $(S, \mathcal{R})$, where $\mathcal{R}$ is a family of subsets $R_{i,F,r} \subseteq S$ defined as follows: given an $F \in \mathcal{F}$ and $r \geq 0$, let $R_{i,F,r} = \{S_i \in S \mid w_i \cdot \mathcal{K}(S_i, F) \geq r\} \in \mathcal{R}$. Here $w_i$ is the weight of $S_i \in S$. We have the following lemma.

**Lemma 19.** Consider an instance $S$ of a generalized $k$-median problem in $\mathbb{R}^d$. If each point set $S \in S$ is of size at most $L$, then the generalized dimension $\dim(S)$ is $O(dkL)$.

*Proof.* Consider a mapping $g : S \rightarrow \mathbb{R}^{dL}$ constructed as follows: suppose $S_i = \{x^1 = (x^1_1, \ldots, x^1_d), \ldots, x^L = (x^L_1, \ldots, x^L_d)\}$ (if $|S_i| < L$, we pad it with $x^1 = (x^1_1, \ldots, x^1_d)$). We let

$$g(S_i) = (x^1_1, \ldots, x^1_d, \ldots, x^L_1, \ldots, x^L_d) \in \mathbb{R}^{dL}.$$ 

For any $t \geq 0$ and any $k$-point set $F \in \mathcal{F}$, we observe that $w_i \cdot \mathcal{K}(S_i, F) \geq r$ holds if and only if there exists some $1 \leq j \leq L$ satisfying that $w_i \cdot d(x^j, F) \geq r$, which is equivalent to saying that point $g(S_i)$ is in the union of the following $L$ sets $\{(x^1_1, \ldots, x^1_d, \ldots, x^L_1, \ldots, x^L_d) \mid d(x^j, F) \geq r/w_i\} (j \in [L])$.

Let $X$ be the image set of $g$. Let $(X, \mathcal{R}^j) (1 \leq j \leq L)$ be $L$ range spaces, where each $\mathcal{R}^j$ consists of all subsets $R_{i,F,r} = \{(x^1_1, \ldots, x^1_d, \ldots, x^L_1, \ldots, x^L_d) \in X \mid d(x^j, F) \geq r\}$ for all $F \in \mathcal{F}$ and $r \geq 0$. Note that each $(X, \mathcal{R}^j)$ has VC-dimension $dk$ by [16]. Thus, we have that each $(X, \mathcal{R}^j)$ has shattering dimension at most its VC-dimension $dk$ by Corollary 5.12 in [21]. Let $\mathcal{R}' = \{\cup R_{i,F,r} \mid R_{i,F,r} \in \mathcal{R}^j, i \in [L]\}$. Using the standard result for bounding the shattering dimension of the union of set systems (e.g., [21 Thm 5.22]), we can see that the shattering dimension of $(X, \mathcal{R}')$ (which is the generalized dimension of $S$) is bounded by $O(dkL)$.

Note that an additive $\varepsilon$-coreset is of size at most $O(k/\varepsilon^d)$. Then combining Lemma [9] 18 and 19 we directly obtain Lemma [16] Combining Lemma 12 and 16 we have the following theorem.

**Theorem 20.** Given an instance $\mathcal{P}$ of $n$ points in $\mathbb{R}^d$ in the existential uncertainty model, there exists an SKC-CORESET $S$ of $O(\varepsilon^{-2(d+2)}dk^4)$ point sets with a weight function $w' : S \rightarrow \mathbb{R}^+$, which satisfies that,

1. For each point set $S \in \mathcal{S}$, we have $S \subseteq \mathcal{P}$ and $|S| = O(k/\varepsilon^d)$.
2. For any $k$-point set $F \in \mathcal{F}$, we have $\sum_{S \in S} w'(S) \cdot \mathcal{K}(S, F) \in (1 \pm \varepsilon)\mathcal{K}(\mathcal{P}, F)$.

**PTAS for stochastic minimum $k$-center.** It remains to give a PTAS for the stochastic minimum $k$-center problem. For an instance $\mathcal{E}(\mathcal{P})$ of a generalized $k$-median problem, if we can compute the sensitivity $\sigma_{\mathcal{E}(\mathcal{P})}(S)$ efficiently for each point set $S \in \mathcal{E}(\mathcal{P})$, then we can construct an SKC-CORESET by importance sampling (The details of importance sampling can be found in Theorem 4.9 in [9]). However, it is unclear how to compute the sensitivity $\sigma_{\mathcal{E}(\mathcal{P})}(S)$ efficiently. Instead, we enumerate all weighted sub-collections $S_i \subseteq \mathcal{E}(\mathcal{P})$ of cardinality at most $O(\varepsilon^{-2(d+2)}dk^4)$. We claim that we only need to enumerate $O(\mathcal{P}O(\varepsilon^{-2(d+2)}dk^5))$ polynomially many sub-collections $S_i$ together with their weight functions, such that there exists a generalized $\varepsilon$-coreset of $\mathcal{E}(\mathcal{P})$. The details can be found in Appendix C.

---

8Theorem 9 in [29] bounds the total sensitivity for the unweighted version. However, the proof can be extended to the weighted version in a straightforward way.

9We remark that even though we enumerate the weight function, computing $\Pr_{\mathcal{P}, \mathcal{P}}[\mathcal{E}(\mathcal{P}) = S]$ is still important for our algorithm. See Lemma 44 for the details of the enumeration algorithm.
In the next step, for each weighted sub-collection $S \subseteq \mathcal{E}(P)$ with a weight function $w^i : S \rightarrow \mathbb{R}^+$, we briefly sketch how to compute the optimal $k$-point set $F$ such that $K(S, F)$ is minimized. We cast the optimization problem as a constant size polynomial system.

Denote the space $\mathcal{F} = \{ (y^1, \ldots, y^k) \mid y^i \in \mathbb{R}^d, 1 \leq i \leq k \}$ to be the collection of ordered $k$-point sets $((y^1, y^2, \ldots, y^k) \in \mathcal{F}$ and $(y^2, y^1, \ldots, y^k) \in \mathcal{F}$ to be two different $k$-point sets if $y^1 \neq y^2$). We first divide the space $\mathcal{F}$ into pieces $\{ \mathcal{F}^i \}$, as follows: Let $L = O(k/\varepsilon^d)$ and $\mathcal{L} = (l_1, \ldots, l_L)$ $(1 \leq l_j \leq k, \forall j \in [L])$ be a sequence of integers, and let $b \in [L]$ be an index. Consider a point set $S = \{ x_1^1 = (x_{11}^1, \ldots, x_{1d}^1), \ldots, x^L = (x_{11}^L, \ldots, x_{1d}^L) \} \in S$ and a $k$-point set $F = \{ y^1 = (y_{11}^1, \ldots, y_{1d}^1), \ldots, y^k = (y_{11}^k, \ldots, y_{1d}^k) \} \in \mathcal{F}$. We give the following definition.

**Definition 21.** The $k$-center value $K(S, F)$ is decided by $\mathcal{L}$ and $b$ if the following two properties hold.

1. For any $i \in [L]$ and any $j \in [k]$, $d(x^i, y^j) \leq d(x^i, y^i)$, i.e., the closest point to $x^i$ is $y^i \in F$.

2. For any $i \in [L]$, $d(x^i, y^i) \leq d(x^b, y^b)$, i.e., the $k$-center value $K(S, F) = d(x^b, y^b)$.

For each point set $S_i \in S$, we enumerate an integer sequence $\mathcal{L}_i$ and an index $b_i$. Given a collection $\{ \mathcal{L}_i, b_i \}_{i \in S}$ (index $i$ ranges over all $S_i$ in $S$), we construct a piece $\mathcal{F}^{(\mathcal{L}_i, b_i)} \subseteq \mathcal{F}$ as follows: for any point set $S_i \in S$ and any $k$-point set $F \in \mathcal{F}^{(\mathcal{L}_i, b_i)}$, the $k$-center value $K(S_i, F)$ is decided by $\mathcal{L}_i$ and $b_i$. According to [Definition 21], $\mathcal{F}^{(\mathcal{L}_i, b_i)}$ is defined by a polynomial system.

Then, we solve our optimization problem in each piece $\mathcal{F}^{(\mathcal{L}_i, b_i)}$. By [Definition 21] for any point set $S_i \in S$ and any $k$-point set $F \in \mathcal{F}^{(\mathcal{L}_i, b_i)}$, the $k$-center value $K(S_i, F) = d(x^{b_i}, y^{L_i(b_i)})$ ($x^{b_i} \in S_i$, $y^{L_i(b_i)} \in F$). Here, the index $L_i(b_i)$ is the $b_i$-th item of $\mathcal{L}_i$. Hence, our problem can be formulated as the following optimization problem:

$$
\min_F \sum_{S_i \in S} w^i(S_i) \cdot g_i, \text{ s.t. } g_i^2 = \| x^{b_i} - y^{L_i(b_i)} \|^2, g_i \geq 0, \forall i \in [L]; y^{L_i(b_i)} \in F; F \in \mathcal{F}^{(\mathcal{L}_i, b_i)}.
$$

By [Definition 21] there are at most $kL|S|$ constraints, which is a constant. Thus, the polynomial system has $dk$ variables and $O(kL|S|)$ constraints, hence can be solved in constant time. Note that there are at most $O(k^L|S|)$ different pieces $\mathcal{F}^{(\mathcal{L}_i, b_i)} \subseteq \mathcal{F}$, which is again a constant. Thus, we can compute the optimal $k$-point set for the weighted sub-collection $S$ in constant time.

Now we return to the stochastic minimum $k$-center problem. Recall that we first enumerate all possible weighted sub-collections $S_i \subseteq \mathcal{E}(P)$ of cardinality at most $O(\varepsilon^{-(d+2)}dk^4)$. Then we compute the optimal $k$-point set $F^i$ for each weighted sub-collection $S_i$ as above, and compute the expected $k$-center value $K(P, F^i)$. [10] Let $F^* \in \mathcal{F}$ be the $k$-point set which minimizes the expected $k$-center value $K(P, F^i)$ over all $F^i$. By [Lemma 44] there is one sub-collection $S_i$ with a weight function $w^i$ satisfying that $K(S_i, F^i) \leq (1 + \varepsilon)\min_{F \in \mathcal{F}} K(P, F)$. Thus, we conclude that $F^*$ is a $(1 + \varepsilon)$-approximation for the stochastic minimum $k$-center problem. For the running time, we enumerate at most $O(n^{O(log \varepsilon^{-2d+2})})$ weighted sub-collections. Moreover, computing the optimal $k$-point set for each sub-collection costs constant time. Then the total running time is at most $O(n^{O(log \varepsilon^{-2d+2})})$. Thus, we have the following corollary.

**Corollary 22.** If both $k$ and $d$ are constants, given an instance $P$ of $n$ stochastic points in $\mathbb{R}^d$ in the existential uncertainty model, there exists a PTAS for the stochastic minimum $k$-center problem in $O(n^{O(log \varepsilon^{-2d+2})})$ time.

---

[10] It is not hard to compute $K(P, F^i)$ in $O(n \log n)$ time by sorting all points in $P$ in non-increasing order according to their distances to $F^i$. 

3.2 Locational uncertainty model

Next, we consider the stochastic minimum $k$-center problem in the locational uncertainty model. Given an instance of $n$ nodes $u_1, \ldots, u_n$ which may locate in the point set $P = \{s_1, \ldots, s_m \mid s_i \in \mathbb{R}^d, 1 \leq i \leq m\}$, our construction of additive $\varepsilon$-coresets and the method for bounding the total sensitivity is exactly the same as in the existential uncertainty model. The only difference is that for an additive $\varepsilon$-coreset $S$, how to compute the probability $\Pr_{T \sim \mathcal{P}}[\mathcal{E}(P) = S] = \sum_{P \sim \mathcal{P}, \mathcal{E}(P) = S} \Pr[T = P]$. Here, $P \sim \mathcal{P}$ is a realized point set according to the probability distribution of $\mathcal{P}$. Run $\mathcal{A}(S)$, and construct a Cartesian grid $G(S)$. Denote $T(S) = (\cup_{P \sim \mathcal{P}, \mathcal{E}(P) = S} P) \setminus S$ to be the collection of all points $s$ which might be contained in some realization $P \sim \mathcal{P}$ with $\mathcal{E}(P) = S$. Recall that $\mathcal{C}(S) = \{C \in G \mid |C \cap S| = 1\}$ is the collection of $d$-dimensional Cartesian cells $C$ which contains a point $s \in S$. By Lemma $[13]$ for any realization $P$ with $\mathcal{E}(P) = S$, we have the following observations.

1. For any cell $C \notin \mathcal{C}(S), C \cap P = \emptyset$. It means that for any point $s \in C \cap \mathcal{P}$, we have $s \notin T(S)$.

2. For any cell $C \in \mathcal{C}(S)$ and any point $s' \in C \cap \mathcal{P}$ with a smaller index than that of $s$, we have $s' \notin \mathcal{P}$. It means that $s' \notin T(S)$.

By the above observations, we conclude that $T(S)$ is the collection of those points $s'$ belonging to some cell $C \in \mathcal{C}(S)$ and with a larger index than that of $s$.

Then we reduce the counting problem $Pr_{T \sim \mathcal{P}}[\mathcal{E}(P) = S]$ to a family of bipartite holant problems. We first give the definition of holant problems.

**Definition 23.** An instance of a holant problem is a tuple $\Lambda = (G(V, E), (g_v)_{v \in V}, (w_e)_{e \in E})$, where for every $v \in V$, $g_v : \{0, 1\}^{E_v} \rightarrow \mathbb{R}^+$ is a function, where $E_v$ is the set of edges incident to $v$. For every assignment $\sigma \in \{0, 1\}^E$, we define the weight of $\sigma$ as

$$w_\Lambda(\sigma) \triangleq \prod_{v \in V} g_v(\sigma |_{E_v}) \prod_{e \in \sigma} w_e.$$

Here $\sigma |_{E_v}$ is the assignment of $E_v$ with respect to the assignment $\sigma$. We denote the value of the holant problem $Z(\Lambda) \triangleq \sum_{\sigma \in \{0, 1\}^E} w_\Lambda(\sigma)$.

For a counting problem $Pr_{T \sim \mathcal{P}}[\mathcal{E}(P) = S]$, w.l.o.g., we assume that $S = \{s_1, \ldots, s_{|S|}\}$. Then we construct a family of holant instance $\Lambda_\mathcal{L}$ as follows.

1. Enumerate all integer sequences $\mathcal{L} = (l_1, \ldots, l_{|S|}, l_t)$ such that $\sum_{1 \leq i \leq |S|} l_i + l_t = n, l_i \geq 1 (1 \leq i \leq |S|)$, and $l_t \geq 0$. Let $\mathbf{L}$ be the collection of all these integer sequences $\mathcal{L}$.

2. For a sequence $\mathcal{L}$, assume that $\Lambda_\mathcal{L} = (G(U, V, E), (g_v)_{v \in U \cup V})$ is a holant instance on a bipartite graph, where $U = \{u_1, \ldots, u_n\}$, and $V = S \cup \{t\}$ (we use vertex $t$ to represent the collection $T(S)$).

3. The weight function $w : E \rightarrow \mathbb{R}^+$ is defined as follows:

   (a) For a vertex $u_i \in U$ and a vertex $s_j \in S$, $w_{ij} = p_{ij}$.

   (b) For a vertex $u_i \in U$ and $t \in V$, $w_{it} = \sum_{s_j \in T(S)} p_{ij}$.

4. For each vertex $u \in U$, the function $g_u = (= 1)$.[13] For each vertex $s_i \in S$, the function $g_{s_i} = (= l_i)$, and the function $g_t = (= l_t)$.

---

[13]Here the function $g_u = (= i)$ means that the function value $g_u$ is 1 if exactly $i$ edges incident to $u$ are of value 1 in the assignment. Otherwise, $g_u = 0$.
Since each $S \in \mathcal{E}(\mathcal{P})$ is of constant size, we only need to enumerate at most $O(n^{|S|+1}) = \text{poly}(n)$ integer sequences $\mathcal{L}$. Given an integer sequence $\mathcal{L} = (l_1, \ldots, l_{|S|}, l_t)$, we can see that $Z(\Lambda_{\mathcal{L}})$ is exactly the probability that $l_i$ nodes are realized at point $s_i \in S$ ($\forall 1 \leq i \leq |S|$), and $l_t$ nodes are realized inside the point set $T(S)$. Then by Lemma~[13] we have the following equality:

$$\Pr_{\mathcal{P} \sim \mathcal{P}}[\mathcal{E}(\mathcal{P}) = S] = \sum_{\mathcal{L} \in \mathcal{L}} Z(\Lambda_{\mathcal{L}}).$$

It remains to show that we can compute each $Z(\Lambda_{\mathcal{L}})$ efficiently. Fortunately, we have the following lemma.

**Lemma 24.** ([26],[34]) For any bipartite graph $\Lambda_{\mathcal{L}}$ with a specified integer sequence $\mathcal{L}$, there exists an FPRAS to compute the holant value $Z(\Lambda_{\mathcal{L}})$.

Thus, we have the following theorem.

**Theorem 25.** If both $k$ and $d$ are constants, given an instance of $n$ stochastic nodes in $\mathbb{R}^d$ in the locational uncertainty model, there exists a PTAS for the stochastic minimum $k$-center problem.

Combining Theorem 20 and 25 we obtain the main result Theorem 8.

## 4 Stochastic Minimum $j$-Flat-Center

In this section, we consider a generalized shape fitting problem, the minimum $j$-flat-center problem in the stochastic models. Let $\mathcal{F}$ be the family of all $j$-flats in $\mathbb{R}^d$. Our main technique is to construct an SJFC-CORESET of constant size, which satisfies that for any $j$-flat $F \in \mathcal{F}$, we can use the SJFC-CORESET to obtain a $(1 \pm \varepsilon)$-estimation for the expected $j$-flat-center value $J(\mathcal{P}, F)$. Then since the SJFC-CORESET is of constant size, we have a polynomial system of constant size to compute the optimum in constant time.

Let $B = \sum_{1 \leq i \leq n} p_i$ be the total probability. We discuss two different cases. If $B < \varepsilon$, we reduce the problem to a weighted $j$-flat-median problem, which has been studied in [36]. If $B \geq \varepsilon$, the construction of an SJFC-CORESET can be divided into two parts. We first construct a convex hull, such that with high probability (say $1 - \varepsilon$) that all points are realized inside the convex hull. Then we construct a collection of point sets to estimate the contribution of points insider the convex hull. On the other hand, for the case that some point appears outside the convex hull, we again reduce the problem to a weighted $j$-flat-median problem. The definition of the weighted $j$-flat-median problem is as follows.

**Definition 26.** For some $0 \leq j \leq d - 1$, let $\mathcal{F}$ be the family of all $j$-flats in $\mathbb{R}^d$. Given a set $\mathcal{P}$ of $n$ points in $\mathbb{R}^d$ together with a weight function $w : \mathcal{P} \rightarrow \mathbb{R}^+$, denote $\text{cost}(\mathcal{P}, F) = \sum_{s_i \in \mathcal{P}} w_i \cdot d(s_i, F)$. A weighted $j$-flat-median problem is to find a shape $F \in \mathcal{F}$ which minimizes the value $\text{cost}(\mathcal{P}, F)$.

### 4.1 Case 1: $B < \varepsilon$

In the first case, we show that the minimum $j$-flat-center problem can be reduced to a weighted $j$-flat-median problem. We need the following lemmas.

**Lemma 27.** If $B < \varepsilon$, for any $j$-flat $F \in \mathcal{F}$, we have $\sum_{s_i \in \mathcal{P}} p_i \cdot d(s_i, F) \in (1 \pm \varepsilon) \cdot J(\mathcal{P}, F)$.

**Proof.** For a $j$-flat $F \in \mathbb{R}^d$, w.l.o.g., we assume that $d(s_i, F)$ is non-decreasing in $i$. Thus, we have

$$J(\mathcal{P}, F) = \sum_{i \in [n]} p_i \cdot d(s_i, F) \cdot \prod_{j>i}(1 - p_j)$$

Since $B < \varepsilon$, for any $i \in [n]$, we have that $1 - \varepsilon \leq 1 - \sum_{j \in [n]} p_i \leq \prod_{j>i}(1 - p_j) \leq 1$. So we prove the lemma. 

\[\square\]
By Lemma [27] we reduce the original problem to a weighted j-flat-median problem, where each point $s_i \in \mathcal{P}$ has weight $p_i$. We then need the following lemma to bound the total sensitivity.

**Lemma 28.** (Theorem 18 in [36]) Consider the weighted j-flat-median problem where $\mathcal{F}$ is the set of all j-flats in $\mathbb{R}^d$. The total sensitivity of any weighted n-point set is $O(j^{1.5})$.

On the other hand, we know that the dimension of the weighted j-flat-median problem is $O(jd)$ by [16]. Then by Lemma 9, there exists an $\varepsilon$-coreset $\mathcal{S} \subseteq \mathcal{P}$ of cardinality $O(j^d \varepsilon^{-2})$ to estimate the j-flat-median value $\sum_{s_i \in \mathcal{P}} p_i \cdot d(s_i, F)$ for any j-flat $F \in \mathcal{F}$. Moreover, we can compute a constant approximation j-flat in $O(ndj^2 \varepsilon^{-2})$ time by [17]. Then by [36], we can construct an $\varepsilon$-coreset $\mathcal{S}$ in $O(ndj^2 \varepsilon^{-2})$ time. Combining Lemma [27] we conclude the main lemma in this subsection.

**Lemma 29.** Given an instance $\mathcal{P}$ of n stochastic points in $\mathbb{R}^d$, if the total probability $\sum_i p_i < \varepsilon$, there exists an SJFC-CORESET of cardinality $O(j^d \varepsilon^{-2})$ for the minimum j-flat-center problem. Moreover, we have an $O(ndj^2 \varepsilon^{-2})$ time algorithm to compute the SJFC-CORESET.

### 4.2 Case 2: $B \geq \varepsilon$

Note that if $F$ is a j-flat, the function $d(x, F)^2$ has a linearization. Here, a linearization is to map the function $d(x, F)^2$ to a k-variate linear function through variate embedding. The number $k$ is called the dimension of the linearization, see [8]. We have the following lemma to bound the dimension of the linearization.

**Lemma 30.** ([13]) Suppose $F$ is a j-flat in $\mathbb{R}^d$, the function $d(x, F)^2 (x \in \mathbb{R}^d)$ has a linearization. Let $D$ be the dimension of the linearization. If $j = 0$, we have $D = d + 1$. If $j = 1$, we have $D = O(d^2)$. Otherwise, for $2 \leq j \leq d - 1$, we have $D = O(j^2 d^3)$.

Suppose $\mathcal{P}$ is an instance of n stochastic points in $\mathbb{R}^d$. For each j-flat $F \in \mathbb{R}^d$, let $h_F(x) = d(x, F)^2 (x \in \mathbb{R}^d)$, which admits a linearization of dimension $O(j^2 d^3)$ by Lemma 30. Now, we map each point $s \in \mathcal{P}$ into an $O(j^2 d^3)$ dimensional point $s'$ and map each j-flat $F \in \mathbb{R}^d$ into an $O(j^2 d^3)$ dimensional direction $u$, such that $d(s, F) = \langle s', u \rangle^{1/2}$. For convenience, we still use $\mathcal{P}$ to represent the collection of points after linearization. Recall that $\Pr[P]$ is the realized probability of the realization $P \sim \mathcal{P}$. By this mapping, we translate our goal into finding a direction $u \in \mathbb{R}^{O(j^2 d^3)}$, which minimizes the expected value $\mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in \mathcal{P}} \langle u, x \rangle^{1/2}] = \sum_{P \sim \mathcal{P}} \Pr[P] \cdot \max_{x \in \mathcal{P}} \langle u, x \rangle^{1/2}$. We also denote $\mathcal{P}^* = \{ u \in \mathbb{R}^d \mid \langle u, s \rangle \geq 0, \forall s \in \mathcal{P} \}$ to be the polar set of $\mathcal{P}$. We only care about the directions in the polar set $\mathcal{P}^*$ for which $\langle u, s \rangle^{1/2}$, $\forall s \in \mathcal{P}$ is well defined.

We first construct a convex hull $\mathcal{H}$ to partition the realizations into two parts. Our construction uses the method of $(\varepsilon, \tau)$-QUANT-KERNEL construction in [25]. For any normal vector (direction) $u$, we move a sweep line $l_u$ orthogonal to $u$, along the direction $u$, to sweep through the points in $\mathcal{P}$. Stop the movement of $l_u$ at the first point such that $\Pr[P \cap \overline{l_u}] \geq \varepsilon'$, where $\varepsilon' = \varepsilon O(j^2 d^3)$ is a fixed constant. Denote $H_u$ to be the halfplane defined by the sweep line $l_u$ (orthogonal to the normal vector $u$) and $\overline{l_u}$ to be its complement. Denote $\mathcal{P}(\overline{l_u}) = \mathcal{P} \cap \overline{l_u}$ to be the set of points swept by the sweep line $l_u$. We repeat the above process for all normal vectors (directions) $u$, and let $\mathcal{H} = \bigcap_u H_u$. Since the total probability $B \geq \varepsilon$, $\mathcal{H}$ is nonempty by Helly’s theorem. We also know that $\mathcal{H}$ is a convex hull by [24]. Moreover, we have the following lemma.

**Lemma 31.** (Lemma 33 and Theorem 6 in [25]) Suppose the dimensionality is d. There is a convex set $\mathcal{K}$, which is an intersection of $O(\varepsilon^{-d(d-1)/2})$ halfspaces and satisfies $(1 - \varepsilon)\mathcal{K} \subseteq \mathcal{H} \subseteq \mathcal{K}$. Moreover, $\mathcal{K}$ can be constructed in $O(n \log O(d) n)$ time.

---

[12] Theorem 18 in [36] bounds the total sensitivity for the unweighted version. However, the proof can be extended to the weighted version in a straightforward manner.

[13] We remark that for the j-flat-median problem, Feldman and Langberg [16] showed that there exists a coreset of size $O(jd \varepsilon^{-2})$. However, it is unclear how to generalize their technique to weighted version.
By the above lemma, we construct a convex set $K = \cap_u K_u$, which is the intersection of $O(\varepsilon^{-O(j^2d^3)})$ halfspaces $K_u$ ($u$ is the direction orthogonal to the halfspace $K_u$). Let $\overline{K}_u$ be the complement of $K_u$, and let $\mathcal{P}(\overline{K}_u) = \mathcal{P} \cap \overline{K}_u$ be the set of points in $\overline{K}_u$. Denote $\mathcal{P}(\overline{K})$ to be the set of points outside the convex set $K$. Then we have the following lemma, which shows that the total probability outside $K$ is very small.

**Lemma 32.** Let $K$ be a convex set constructed as in Lemma [31] The total probability $\Pr[\mathcal{P}(\overline{K})] \leq \varepsilon$.

**Proof.** Assume that $K = \cap_u K_u$. Consider a halfspace $K_u$. By Lemma [31] the convex set $K$ satisfies that $\mathcal{H} \subseteq K$. Thus, we have that $\Pr[\mathcal{P}(\overline{K}_u)] \leq \Pr[\mathcal{P}(\overline{K}_u)] \leq \varepsilon'$ by the definition of $\overline{P}_u$.

Note that $\Pr[\mathcal{P}(\overline{K}_u)]$ is upper bounded by the multiplication of $\varepsilon'$ and the number of halfspaces of $K$. By Lemma [31] there are at most $O(\varepsilon^{-O(j^2d^3)})$ halfspaces $K_u$. Thus, we have that $\Pr[\mathcal{P}(\overline{K})] \leq \varepsilon$. \hfill \Box

Our construction of SJFC-CORESET is consist of two parts. For points inside $K$, we construct a collection $S_1$. Our construction is almost the same as $(\varepsilon, r)$-FPower-Kernel construction in [25], except that the cardinality of the collection $S_1$ is different. For completeness, we provide the details of the construction here. Let $\mathcal{P}(K)$ be the collection of points in $K \cap \mathcal{P}$, then $\mathcal{P}(K)$ is also an instance of a stochastic minimum $j$-flat-center problem. We show that we can estimate $\mathbb{E}_{P \sim \mathcal{P}(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}]$ by $S_1$. For the rest points outside $K$, we show that the contribution for the objective function $\mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in P} \langle u, x \rangle^{1/2}]$ is almost linear and can be reduced to a weighted $j$-flat-median problem as in Case 1.

We first show how to construct $S_1$ for points inside $K$ as follows.

1. Sample $N = O((\varepsilon')^{-2}\varepsilon^{-O(j^2d^3)} \log(1/\varepsilon)) = O(\varepsilon^{-O(j^2d^3)})$ independent realizations restricted to $\mathcal{P}(K)$.

2. For each realization $S_1$, use the algorithm in [7] to find a deterministic $\varepsilon$-kernel $\mathcal{E}_i$ of size $O(\varepsilon^{-O(j^2d^3)})$. Here, a deterministic $\varepsilon$-kernel $\mathcal{E}_i$ satisfies that $(1 - \varepsilon)\mathcal{C}(S_i) \subseteq \mathcal{C}(\mathcal{E}_i) \subseteq \mathcal{C}(S_i)$, where $\mathcal{C}(\cdot)$ is the convex hull of the point set.

3. Let $S_1 = \{\mathcal{E}_i \mid 1 \leq i \leq N\}$ be the collection of all $\varepsilon$-kernels, and each $\varepsilon$-kernel $\mathcal{E}_i$ has a weight $1/N$.

Hence, the total size of $S_1$ is $O(\varepsilon^{-O(j^2d^3)})$. For any direction $u \in \mathcal{P}^*$, we use $\frac{1}{N} \sum_{i \in S_1} \max_{x \in \mathcal{E}_i} \langle u, x \rangle^{1/2}$ as an estimation of $\mathbb{E}_{P \sim \mathcal{P}(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}]$. By [25], we have the following lemma.

**Lemma 33.** (Lemma 38-40 in [25]) For any direction $u \in \mathcal{P}^*$, let $M_u = \max_{x \in \mathcal{P}(K)} \langle u, x \rangle^{1/2}$. We have that

$$\frac{1}{N} \sum_{i \in S_1} \max_{x \in \mathcal{E}_i} \langle u, x \rangle^{1/2} \in \left(1 \pm \varepsilon/2\right)\mathbb{E}_{P \sim \mathcal{P}(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}] \pm \varepsilon'\varepsilon(1 - \varepsilon)M_u/4$$

Now we are ready to prove the following lemma.

**Lemma 34.** For any direction $u \in \mathcal{P}^*$, we have the following property.

$$\frac{1}{N} \sum_{i \in S_1} \max_{x \in \mathcal{E}_i} \langle u, x \rangle^{1/2} + \sum_{s_i \in \mathcal{P}(K)} p_i \cdot \langle u, s_i \rangle^{1/2} \in (1 \pm 4\varepsilon)\mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in P} \langle u, x \rangle^{1/2}]$$

**Proof.** Let $E$ be the event that no point is present in $\overline{K}$. By the fact $\Pr[\overline{K}] \leq \varepsilon$, we have that $\Pr[E] = \prod_{s_i \in \mathcal{P}(\overline{K})} (1 - p_i) \geq 1 - \sum_{s_i \in \mathcal{P}(\overline{K})} p_i \geq 1 - \varepsilon$. Thus, we conclude that $1 - \varepsilon \leq \Pr[E] \leq 1$. We first rewrite $\mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in P} \langle u, x \rangle^{1/2}]$ as follows:

$$\mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in P} \langle u, x \rangle^{1/2}] = \Pr[E] \cdot \mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid E] + \Pr[\overline{E}] \cdot \mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid \overline{E}]$$

$$= \Pr[E] \cdot \mathbb{E}_{P \sim \mathcal{P}(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}] + \Pr[\overline{E}] \cdot \mathbb{E}_{P \sim \mathcal{P}}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid \overline{E}]$$
For event $E$, we bound the term $\Pr[E] \cdot \mathbb{E}_{P \sim P(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}]$ via the collection $S_1$. Let $M_u = \max_{x \in P(K)} \langle u, x \rangle^{1/2}$. By Lemma 33 for any direction $u \in P^*$, we have that

$$\frac{1}{N} \sum_{\varepsilon_i \in S_1} \max_{x \in \varepsilon_i} \langle u, x \rangle^{1/2} \leq (1 + \varepsilon/2) \mathbb{E}_{P \sim P(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}] \pm \varepsilon' \varepsilon(1 - \varepsilon) M_u/4$$

By Lemma 31, we have that $(1 - \varepsilon)\mathcal{K} \subseteq \mathcal{H}$. Then by the construction of $\mathcal{H}_u$, we have that $\Pr[\mathcal{P} \cap (1 - \varepsilon)\mathcal{K}_u] \geq \varepsilon$. Thus, we obtain that

$$\mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2}] \geq \varepsilon'(1 - \varepsilon) \max_{x \in P(K)} \langle u, x \rangle^{1/2} = \varepsilon'(1 - \varepsilon) M_u.$$

So we conclude that

$$(1 - 2\varepsilon) \Pr[E] \cdot \mathbb{E}_{P \sim P(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}] - \varepsilon \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2}] \leq \frac{1}{N} \sum_{\varepsilon_i \in S_1} \max_{x \in \varepsilon_i} \langle u, x \rangle^{1/2},$$

(4)

since $1 - \varepsilon \leq \Pr[E] \leq 1$.

For event $\overline{E}$, without loss of generality, we assume that the $n$ points $s_1, \ldots, s_n$ in $\mathcal{P}$ are sorted in nondecreasing order according to the inner product $\langle u, s_i \rangle$. Assume that $s_{i_1}, \ldots, s_{i_l}$ ($i_1 < i_2 < \ldots < i_l$) are points in $P(\mathcal{K})$. Let $E_j$ be the event that point $s_{i_j}$ is present and all points $s_{i_k}$ are not present for $k > j$. We have that

$$\Pr[\overline{E}] \cdot \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid \overline{E}] = \sum_{j \in [l]} \Pr[E_j] \cdot \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid E_j]$$

$$= \sum_{j \in [l]} p_{i_j} \cdot \left( \prod_{j+1 \leq k \leq l} (1 - p_{i_k}) \right) \cdot \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid E_j].$$

By the above equality, on one hand, we have that

$$\Pr[\overline{E}] \cdot \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid \overline{E}] \geq (1 - \varepsilon) \sum_{j \in [l]} p_{i_j} \cdot \langle u, s_{i_j} \rangle^{1/2},$$

(5)

since $\max_{x \in P} \langle u, x \rangle^{1/2} \geq \langle u, s_{i_j} \rangle^{1/2}$ if event $E_j$ happens. On the other hand, the following inequality also holds.

$$\Pr[\overline{E}] \cdot \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid \overline{E}] = \sum_{j \in [l]} \Pr[E_j] \cdot \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2} \mid E_j]$$

$$\leq \sum_{j \in [l]} \Pr[E_j] \cdot \mathbb{E}_{P \sim P}[\langle u, s_{i_j} \rangle^{1/2} + \max_{x \in P \cap P(K)} \langle u, x \rangle^{1/2} \mid E_j]$$

$$\leq \sum_{j \in [l]} p_{i_j} \cdot \langle u, s_{i_j} \rangle^{1/2} + \mathbb{E}_{P \sim P}[\max_{x \in P \cap P(K)} \langle u, x \rangle^{1/2} \mid E_j]$$

$$\leq \sum_{j \in [l]} p_{i_j} \cdot \langle u, s_{i_j} \rangle^{1/2} + \sum_{j \in [l]} p_{i_j} \cdot \mathbb{E}_{P \sim P(K)}[\max_{x \in P} \langle u, x \rangle^{1/2}] \leq \sum_{j \in [l]} p_{i_j} \cdot \langle u, s_{i_j} \rangle^{1/2} + \varepsilon \cdot \mathbb{E}_{P \sim P}[\max_{x \in P} \langle u, x \rangle^{1/2}].$$

(6)

The last inequality holds since that $\sum_{j \in [l]} p_{i_j} = \Pr[P(\mathcal{K})] \leq \varepsilon$ by Lemma 32. Combining Inequalities (4), (5) and (6), we prove the lemma. \qed
By Lemma 29, we construct a point set $S_2$ to estimate $\sum_{s_i \in \mathcal{F}(\mathcal{R})} p_i \cdot d(s_i, F)$ with a weight function $w' : S_2 \to \mathbb{R}$. We have that the size of $S_2$ can be bounded by $O(j^4d^2\varepsilon^{-2})$. Then $S = S_1 \cup S_2$ is a collection of constant size, which satisfies the following property:

$$\frac{1}{N} \sum_{x \in S_1} \max_{u \in \mathcal{R}} \{u, x\}^{1/2} + \sum_{s_i \in S_2} w'_i \cdot \max_{u \in \mathcal{R}} \{u, x\}^{1/2} \in (1 + O(\varepsilon))P_{s \sim \mathcal{P}}[\max_{u \in \mathcal{R}} \{u, x\}^{1/2}]$$. (7)

Here $w'_i$ is the weight of $s_i$ in $S_2$. We can think $S_2 = \{\{s_i\} \mid 1 \leq s_i \leq |S_2|\}$ as a collection of singleton point sets $\{s_i\}$. Then by Inequality 7, we have that $S$ is a generalized $\varepsilon$-coreset satisfying Definition 6. We conclude the following lemma.

**Lemma 35.** Given an instance $\mathcal{P}$ of $n$ stochastic points of the stochastic minimum $j$-flat-center problem in the existential model, if the total probability $\sum_i p_i \geq \varepsilon$, there exists an SJFC-CORESET $S$ containing $O(\varepsilon^{-O(j^2d^2)} + j^4d^2\varepsilon^{-2})$ point sets of size at most $O(\varepsilon^{-O(j^2d^2)})$, together with a weight function $w' : S \to \mathbb{R}^+$, which satisfies that for any $j$-flat $F \in \mathcal{F}$, $\sum_{S \in \mathcal{S}} w'(S) \cdot J(S, F) \in (1 \pm \varepsilon)J(\mathcal{P}, F)$.

Combining Lemma 29 and Lemma 35, we can obtain the following theorem.

**Theorem 36.** Given an instance $\mathcal{P}$ of $n$ stochastic points in the existential model, there is an SJFC-CORESET of size $O(\varepsilon^{-O(j^2d^2)} + j^4d^2\varepsilon^{-2})$ for the minimum $j$-flat-center problem. Moreover, we have an $O(n \log^{O(d)} n + \varepsilon^{-O(j^2d^2)n})$ time algorithm to compute the SJFC-CORESET.

**Proof.** We only need to prove the running time. Recall that the SJFC-CORESET $S$ can be divided into two parts $S = S_1 \cup S_2$. For the first part $S_1$, we construct the convex hull $K$ in $O(n \log^{O(d)} n)$ by Lemma 31. Then we construct $S_1$ by taking $O(\varepsilon^{-O(j^2d^2)})$ independent realizations restricted to $\mathcal{P}(K)$. For each sample, we construct a deterministic $\varepsilon$-kernel in $O(n + \varepsilon^{-O(j^2d^2)})$ by [12, 39]. So the total time for constructing $S_1$ is $O(n \log^{O(d)} n + \varepsilon^{-O(j^2d^2)n})$. On the other hand, we can construct $S_2$ in $O(ndj^{O(j^2)})$ time by Lemma 29. Thus, we prove the theorem.

**PTAS for stochastic minimum $j$-flat-center.** Given an SJFC-CORESET $S$ together with a weight function $w' : S \to \mathbb{R}^+$ by Theorem 36, it remains to show how to compute the optimal $j$-flat for $S$. Our goal is to find the optimal $j$-flat $F^*$ such that the total generalized distance $\sum_{S \in \mathcal{S}} w'(S) \cdot J(S, F^*)$ is minimized. The argument is similar to the stochastic minimum $k$-center problem.

We first divide the family $\mathcal{F}$ of $j$-flats into a constant number of sub-families. In each sub-family $\mathcal{F}' \subseteq \mathcal{F}$, we have the following property: for each $S_i \in \mathcal{S}$, and each $j$-flat $F \in \mathcal{F}'$, the point $s_i = \arg \max_{s \in S_i} d(s, F)$ is fixed. By Lemma 41, we have that $h_F(x) = d(x, F)^2$ ($x \in \mathbb{R}^d$) admits a linearization of dimension $O(j^2d^3)$. For each sub-family $\mathcal{F}'$, we can formulate the optimization problem as a polynomial system of constant degree, a constant number of variables, and a constant number of constraints. Then we can compute the optimal $j$-flat in constant time for all sub-families $\mathcal{F}' \subseteq \mathcal{F}$. Thus, we can compute the optimal $j$-flat-center for the SJFC-CORESET $S$ in constant time. We then have the following corollary.

**Corollary 37.** If the dimensionality $d$ is a constant, given an instance of $n$ stochastic points in $\mathbb{R}^d$ in the existential uncertainty model, there exists a PTAS for the stochastic minimum $j$-flat-center problem in $O(n \log^{O(d)} n + \varepsilon^{-O(j^2d^2)n})$ time.

**Locational Uncertainty Model** Note that in the locational uncertainty model, we only need to consider Case 2. We use the same construction as in the existential model. Let $p_i = \sum_j p_{ij}$. Similarly, we make a
linearization for the function $d(x, F)^2$, where $x \in \mathbb{R}^d$ and $F \in \mathcal{F}$ is a $j$-flat. Using this linearization, we also map $\mathcal{P}$ into $O(j^2 d^3)$-dimensional points. For the $j$th node and a set $P$ of points, we denote $p_j(P) = \sum_{s_i \in P} p_{ji}$ to be the total probability that the $j$th node locates inside $P$.

By the condition $\Pr[\mathcal{P}(\mathcal{K})] \leq \varepsilon$, we have that $\Pr[E] = 1 - \prod_{j \in [m]} (1 - p_j(\mathcal{K})) \leq 1 - (1 - \varepsilon) = \varepsilon$, where event $E$ represents that there exists a point present in $\mathcal{K}$. So we can regard those points outside $\mathcal{K}$ independent. On the other hand, for any direction $u$, since $\Pr[\mathcal{P} \cap (1 - \varepsilon)\mathcal{H}_u] \geq \varepsilon'$, we have that $\Pr[E_u] = 1 - \prod_{j \in [m]} (1 - p_j(\mathcal{P} \cap (1 - \varepsilon)\mathcal{H}_u)) \geq 1 - (1 - \frac{\varepsilon'}{m})^m \geq \varepsilon'/2$, where event $E_u$ represents that there exists a point present in $\mathcal{P} \cap (1 - \varepsilon)\mathcal{H}_u$. Moreover, we can use the same method to construct a collection $S_1$ as an estimation for the point set $\mathcal{P}(\mathcal{K})$ in the locational uncertainty model. So Lemma[34] still holds. Then by Lemma[35] we can construct an SJFC-CORESET of constant size.

**Theorem 38.** Given an instance $\mathcal{P}$ of $n$ stochastic points in the locational uncertainty model, there is an SJFC-CORESET of cardinality $O(\varepsilon^{-O(j^2 d^3)} + j^4 d \varepsilon^{-2})$ for the minimum $j$-flat-center problem. Moreover, we have a polynomial time algorithm to compute the generalized $\varepsilon$-coreset.

By a similar argument as in the existential model, we can give a PTAS for the locational uncertainty model. Then combining with Corollary[37] we prove the main result Theorem[4].

A Proof of Lemma 9

The following theorem is a restatement of Theorem 4.1 and its proof in [16]. Lemma 9 is a direct corollary from the following theorem.

**Theorem 39.** Let $D = \{g_i \mid 1 \leq i \leq n\}$ be a set of $n$ functions. For each $g \in D$, $g : X \to \mathbb{R}^{\geq 0}$ is a function from a ground set $X$ to $[0, +\infty)$. Let $0 < \varepsilon < 1/4$ be a constant. Let $m : D \to \mathbb{R}^+$ be a function on $D$ such that

$$q(g) \geq \max_{x \in X} \frac{g(x)}{\sum_{g \in D} g(x)}.$$  

(8)
Then there exists a collection $S \subseteq D$ of functions, together with a weight function $w' : S \to \mathbb{R}^+$, such that for every $x \in X$

$$|\sum_{g \in D} g(x) - \sum_{g \in S} w'(g) \cdot g(x)| \leq \varepsilon \sum_{g \in Y} g(x),$$

Moreover, the size of $S$ is

$$O \left( \frac{\left( \sum_{g \in D} q(g) \right)^2}{\varepsilon} \dim(D) \right),$$

where $\dim(D)$ is the generalized shattering dimension of $D$ (see Definition 7.2 in [16]).

Now we are ready to prove Lemma 9.

**Proof.** Suppose that we are given a (weighted) instance $S = \{S_i \mid S_i \subset \mathbb{R}^d, 1 \leq i \leq n\}$ of a generalized shape fitting problem $(\mathbb{R}^d, F, \text{dist})$, with a weight function $w : S \to \mathbb{R}^+$. A generalized $\varepsilon$-coreset is a collection $S' \subseteq S$ of point sets, together with a weight function $w' : S' \to \mathbb{R}^+$ such that, for any shape $F \in F$, we have

$$\sum_{S_i \in S} w'_i \cdot \text{dist}(S_i, F) \in (1 \pm \varepsilon) \sum_{S_i \in S} w_i \cdot \text{dist}(S_i, F). \quad (9)$$

For every $S_i \in S$ and $F \in F$, let $g_i(F) = w_i \cdot \text{dist}(S_i, F)$ and $D = \{g_i \mid S_i \in S\}$. Define

$$q(g_i) = \sigma_S(S_i) + \frac{1}{n} = \inf\{\beta \geq 0 \mid w_i \cdot \text{dist}(S_i, F) \leq \beta : \sum_{S_i \in S} w_i \cdot \text{dist}(S_i, F), \forall F \in F\} + \frac{1}{n}.$$  

It is not hard to verify that this definition satisfies Inequality 8. The additional $1/n$ term will be useful in Appendix C where we need a lower bound of $q(g_i)$. Thus, we have $q_S + 1 = \sum_{S_i \in S}(\sigma_S(S_i) + 1/n) = \sum_{g_i \in D} q(g_i)$. Recall that $\dim(S)$ is the generalized shattering dimension of $S$. By Theorem 39, we conclude that there exists a collection $S$ of cardinality $O((\frac{q_S}{\varepsilon})^2 \dim(S))$ with a weight function $w' : S \to \mathbb{R}^+$ satisfying Inequality 9. \hfill $\Box$

**B Constructing additive $\varepsilon$-coresets**

In this section, we first give the algorithm for constructing an additive $\varepsilon$-coreset. We construct Cartesian grids and maintain one point from each nonempty grid cell, which is similar to [4]. However, our algorithm is more complicated. See Algorithm 2 for details.

Now we analyze the algorithm.

**Observation 40.** $r_P$ is a 2-approximation for the minimum $k$-center problem w.r.t. $P$.

**Proof.** By Gonzalez’s greedy algorithm [19], there exists a subset $F \subseteq P \subseteq P$ of size $k$ such that the $k$-center value $K(P, F)$ is a 2-approximation for the minimum $k$-center problem w.r.t. $P$. Thus, we prove the observation. \hfill $\Box$

By the above observation, we have the following lemma.

**Lemma 11** The running time of $A$ on any $n$ point set $P$ is $O(kn^{k+1})$. Moreover, the output $E(P)$ is an additive $\varepsilon$-coreset of $P$ of size at most $O(k/\varepsilon^d)$.  

22
Algorithm 2: Constructing additive $\varepsilon$-coresets ($\mathcal{A}$)

1. Input: a realization $P \sim \mathcal{P}$. W.l.o.g., assume that $P = \{s_1, \ldots, s_m\}$. 
2. Let $r_P = \min_{F: F \subseteq \mathcal{P}, |F| = k} \mathbb{K}(P, F)$. If $r_P = 0$, output $\mathcal{E}(P) = P$. Otherwise assume that $2^a \leq r_P < 2^{a+1} (a \in \mathbb{Z})$.
3. Draw a $d$-dimensional Cartesian grid $G_1(P)$ of side length $\varepsilon 2^a/4d$ centered at point $0^d$.
4. Let $C_1(P) = \{C \mid C \in G, C \cap P \neq \emptyset\}$ be the collection of those cells which intersect $P$.
5. For each cell $C \in C_1(P)$, let $s^C \in C \cap P$ be the point in $C$ of smallest index. Let $\mathcal{E}_1(P) = \{s^C \mid C \in C_1(P)\}$.
6. Compute $\mathcal{E}_{\mathcal{E}_1}(P) = \min_{F: F \subseteq \mathcal{P}, |F| = k} \mathbb{K}(\mathcal{E}_1(P), F)$. If $r_{\mathcal{E}_1}(P) \geq 2^a$, let $\mathcal{E}(P) = \mathcal{E}_1(P)$, $G(P) = G_1(P)$, and $C(P) = C_1(P)$.
7. If $r_{\mathcal{E}_1}(P) < 2^a$, draw a $d$-dimensional Cartesian grid $G_2(P)$ of side length $\varepsilon 2^a/8d$ centered at point $0^d$. Repeat step 4 and 5, construct $C_2(P)$ and $\mathcal{E}_2(P)$ based on the new Cartesian grid $G_2(P)$. Let $\mathcal{E}(P) = \mathcal{E}_2(P)$, $G(P) = G_2(P)$, and $C(P) = C_2(P)$.
8. Output $\mathcal{E}(P)$, $G(P)$, and $C(P)$.

Proof. Since $r_P$ is a $2$-approximation, $\mathcal{E}(P)$ is an additive $\varepsilon$-coreset of $P$ of size $O(k/\varepsilon^d)$ by Theorem 2.4 in [4]. For the running time, consider computing $r_P$ in Step 2 (also $r_{\mathcal{E}_1}(P)$ in Step 6). There are at most $n^k$ point sets $F \subseteq \mathcal{P}$ such that $|F| = k$. Note that computing $K(P, F)$ costs at most $nk$ time. Thus, it costs $O(kn^{k+1})$ time to compute $r_P$ (also $r_{\mathcal{E}_1}(P)$) for all $k$-point sets $F \subseteq \mathcal{P}$. On the other hand, it only costs linear time to construct the Cartesian grid $G(P)$, the cell collection $C(P)$ and $\mathcal{E}(P)$ after computing $r_P$ and $r_{\mathcal{E}_1}(P)$, which finishes the proof.

We then give the following lemmas, which is useful for proving Lemma 13.

Lemma 41. For two point sets $P, P'$, if $P' \subseteq P$, then $r_{PP'} \leq r_P$. Moreover, if $P'$ is an additive $\varepsilon$-coreset of $P$, then $(1 - \varepsilon)r_P \leq r_{PP'} \leq r_P$.

Proof. Suppose $F \subseteq \mathcal{P}$ is the $k$-point set such that the $k$-center value $K(P, F) = r_P$. Since $P' \subseteq P$, we have $K(P', F) \leq r_P$. Thus, we have $r_{PP'} \leq K(P', F) \leq r_P$.

Moreover, assume that $P'$ is an additive $\varepsilon$-coreset of $P$. Suppose $F' \subseteq \mathcal{P}$ is the $k$-point set such that the $k$-center value $K(P', F') = r_{PP'}$. Then by Definition 10, we have $K(P, F') \leq (1 + \varepsilon)r_{PP'}$. Thus, we have $(1 - \varepsilon)r_P \leq (1 - \varepsilon)K(P, F') < r_{PP'} \leq r_P$.

Lemma 42. Assume that a point set $P' = \mathcal{E}(P)$ for another point set $P \sim \mathcal{P}'$. Running $\mathcal{A}(P')$ and $\mathcal{A}(P)$, assume that we obtain two Cartesian grids $G(P')$ and $G(P)$ respectively. Then we have $G(P') = G(P)$.

Proof. If $r_P = 0$, we have that $r_{PP'} \leq r_P = 0$ by Lemma 41. Thus we do not construct the Cartesian grid for both $P$ and $P'$. Otherwise assume that $2^a \leq r_P < 2^{a+1} (a \in \mathbb{Z})$. Run $\mathcal{A}(P)$. In Step 5, we construct a Cartesian grid $G_1(P)$ of side length $\varepsilon 2^a/4d$, a cell collection $C_1(P)$, and a point set $\mathcal{E}_1(P)$. Since $\mathcal{E}_1(P)$ is an additive $\varepsilon$-coreset of $P$ by [4], we have $2^{a-1} < (1 - \varepsilon)r_P \leq r_{\mathcal{E}_1}(P) \leq r_s < 2^{a+1}$. Then we consider the following two cases.

Case 1: $r_{\mathcal{E}_1}(P) \geq 2^a$. Then $P' = \mathcal{E}(P) = \mathcal{E}_1(P)$, and $G(P) = G_1(P)$ in this case. Running $\mathcal{A}(P')$, we have that $2^a \leq r_{\mathcal{E}_1}(P) = r_{PP'} \leq 2^{a+1}$ by Lemma 41. Thus, we construct a Cartesian grid $G_1(P') = G_1(P)$ of side length $\varepsilon 2^a/4d$, and a point set $\mathcal{E}_1(P')$ in Step 5. Since $G_1(P') = G_1(P)$ and $P' = \mathcal{E}_1(P)$, we have that $\mathcal{E}_1(P') = P'$ by the construction of $\mathcal{E}_1(P')$. Thus, $r_{\mathcal{E}_1}(P') = r_{\mathcal{E}_1}(P) \geq 2^a$, and we obtain that $G(P') = G_1(P')$ in Step 6, which proves the lemma.

Case 2: $2^{a-1} \leq r_{\mathcal{E}_1}(P) < 2^a$. Then in Step 7, we construct a Cartesian grid $G_2(P)$ of side length $\varepsilon 2^a/8d$ for $P$, a cell collection $C_2(P)$, and a point set $\mathcal{E}_2(P)$. In this case, we have that $\mathcal{E}(P) = \mathcal{E}_2(P)$,
Consider the following two cases. If \( 2^a - 1 \leq r_P < 2^a \), we construct a Cartesian grid \( G_1(P') \) of side length \( \varepsilon 2^a / 8d \), and a point set \( E_1(P') \) in Step 5. Since \( G_1(P') = G_2(P) \) and \( P' = E_2(P) \), we have that \( E_1(P') = P' \) by the construction of \( E_1(P') \). Then we let \( G(P') = G_1(P') \) in Step 6. In this case, both \( G(P) \) and \( G(P') \) are of side length \( \varepsilon 2^a / 8d \), which proves the lemma.

Otherwise if \( 2^a \leq r_P < 2^{a+1} \), we construct the Cartesian grid \( G_1(P') = G_1(P) \) of side length \( \varepsilon 2^a / 4d \), a cell collection \( C_1(P') \), and a point set \( E_1(P') \) in Step 5. We then prove that \( E_1(P') = E_1(P) \). Since all Cartesian grids are centered at point \( 0^d \), a cell in \( G_1(P) \) can be partitioned into \( 2^d \) equal cells in \( G_2(P) \).

Rewrite a cell \( C^* \in G_1(P) \) as \( C^* = \bigcup_{1 \leq i \leq 2^a} C_i \) where each \( C_i \in G_2(P) \). Assume that point \( s^* \in C^* \cap P = \bigcup_{1 \leq i \leq 2^a} (C_i \cap P) \) has the smallest index, then point \( s^* \) is also the point in \( C^* \cap E_2(P) \) of smallest index. Consider \( E_1(P') \), note that for each cell \( C^* \in C_1(P') \), \( E_1(P') \) only contains the point in \( C^* \cap P \) of smallest index. Since \( P' = E(P) \), we have that \( E_1(P') = E_1(P) \). Thus, we conclude that \( r_{E_1(P')} = r_{E_1(P)} < 2^a \). Then in Step 7, we construct a Cartesian grid \( G_2(P') = G_2(P) \) of side length \( \varepsilon 2^a / 8d \) for \( P' \). Finally, we output \( G(P') = G_2(P') = G(P) \), which proves the lemma.

We then prove the 'only if' direction. If \( P_1 \) and \( P_2 \) are satisfied, we have that \( \varepsilon x \) does not appear in the realization \( P \).

Recall that we denote \( E(P) = \{ E(P) \mid P \sim P \} \) to be the collection of all possible additive \( \varepsilon \)-coresets. For any \( S \), we denote \( E^{-1}(S) = \{ P \sim P \mid E(P) = S \} \) to be the collection of all realizations mapped to \( S \). Now we are ready to prove Lemma \[\text{Lemma 13} \]

**Lemma 13** (restated) Consider a subset \( S \) of at most \( O(k/\varepsilon^d) \) points. Run algorithm \( \mathcal{A}(S) \), which outputs an additive \( \varepsilon \)-coreset \( E(S) \), a Cartesian grid \( G(S) \), and a collection \( C(S) \) of nonempty cells. If \( E(S) \neq S \), then \( S \notin E(P) \) (i.e., \( S \) is not the output of \( \mathcal{A} \) for any realization \( P \sim P \)). If \( |S| \leq k \), then \( E^{-1}(S) = \{ S \} \). Otherwise if \( E(S) = S \) and \( |S| \geq k + 1 \), then a point set \( P \sim P \) satisfies \( E(P) = S \) if and only if

1. For any cell \( C \notin C(S) \), \( C \cap P = \emptyset \).
2. For any cell \( C \in C(S) \), assume that point \( s^C = C \cap S \). Then \( s^C \in P \), and any point \( s' \in C \cap P \) with a smaller index than that of \( s^C \) does not appear in the realization \( P \).

**Proof.** If \( E(S) \neq S \), we have that \( r_S > 0 \). Assume that \( S \in E(P) \). There must exist some point set \( P \sim P \) such that \( E(P) = S \). By Lemma \[\text{Lemma 12} \] running \( \mathcal{A}(P) \) and \( \mathcal{A}(S) \), we obtain the same Cartesian grid \( G(P) = G(S) \). Since \( E(S) \neq S \), there must exist a cell \( C \in C(S) \) such that \( |C \cap S| \geq 2 \) (by the construction of \( E(S) \)). Note that \( C \in G(P) \). We have \( |C \cap E(P)| = 1 \), which is a contradiction with \( E(P) = S \). Thus, we conclude that \( S \notin E(P) \).

If \( |S| \leq k \), assume that there exists another point set \( P \neq S \), such that \( E(P) = S \). By Lemma \[\text{Lemma 11} \] we know that \( S \) is an additive \( \varepsilon \)-coreset of \( P \). By Definition \[\text{Definition 10} \] we have \( S \subseteq P \) and \( K(P,S) \leq (1 + \varepsilon)K(S,S) = 0 \). Thus we conclude that \( P = S \). On the other hand, we have \( E(S) = S \) since \( r_S = 0 \). So we conclude that \( E^{-1}(S) = \{ S \} \).

If \( |S| \geq k + 1 \) and \( E(S) = S \), we have that \( r_S > 0 \). Running \( \mathcal{A}(P) \) and \( \mathcal{A}(S) \), assume that we obtain two Cartesian grids \( G(P) \) and \( G(S) \) respectively. By Lemma \[\text{Lemma 12} \] if \( E(P) = S \), then we have \( G(P) = G(S) \). Moreover, by the construction of \( E(P) \), P1 and P2 must be satisfied.

We then prove the 'only if' direction. If P1 and P2 are satisfied, we have that \( S \) is an additive \( \varepsilon \)-coreset of \( P \) satisfying Definition \[\text{Definition 10} \] by \[\text{Lemma 41} \]. Then by Lemma \[\text{Lemma 41} \] we have that \( (1 - \varepsilon)r_P \leq r_S \leq r_P \). Assume that \( 2^a \leq r_S < 2^{a+1} \), we conclude \( 2^a \leq r_P < 2^{a+2} \). Now run \( \mathcal{A}(P) \) in Step 5, assume that we construct a Cartesian grid \( G_1(S) \) of side length \( \varepsilon 2^a / 4d \), a cell collection \( C_1(S) \), and a point set \( E_1(S) \). Since \( E_1(S) \) is an additive \( \varepsilon \)-coreset of \( S \) by \[\text{Lemma 41} \], we have \( 2^a - 1 \leq (1 - \varepsilon)r_S \leq r_{E_1(S)} \leq r_S < 2^{a+1} \). Then we consider the following two cases.
Case 1: \( 2^a \leq r_{E_1(S)} < 2^{a+1} \). In this case, we have that \( G(S) = G_1(S), C(S) = C_1(S) \), and \( S = E(S) = E_1(S) \). Running \( A(P) \), assume that we obtain \( G(P), C(P), \) and \( E(P) \). Consider the following two cases. If \( 2^a \leq r_P < 2^{a+1} \), we construct a Cartesian grid \( G_1(P) = G(S) \) of side length \( \varepsilon 2^a/4d \), and a point set \( E_1(P) \) in Step 5. Since \( P_1 \) and \( P_2 \) are satisfied, we know that \( E_1(P) = S \). Then since \( 2^a \leq r_{E_1(P)} = r_S < 2^{a+1} \), we obtain that \( E(P) = E_1(P) = S \) in this case. Otherwise if \( 2^{a+1} \leq r_S < 2^{a+2} \), run \( A(P) \). We construct a Cartesian grid \( G_1(P) \) of side length \( \varepsilon 2^a/2d \), and a point set \( E_1(P) \) in Step 5. Since \( P_1 \) and \( P_2 \) are satisfied, we have that \( E_1(P) \subseteq S \). Thus, we have \( r_{E_1(P)} \leq r_S < 2^{a+1} \) by Lemma \[41\]. Then in Step 7, we construct a Cartesian grid \( G_2(P) = G_1(S) \) of side length \( \varepsilon 2^a/4d \), and a point set \( E_2(P) \). In this case, we have that \( G(P) = G_2(P) = G_1(S) \), and \( E(P) = E_2(P) \). By \( P_1 \) and \( P_2 \), we have that \( E(P) = E_2(P) = S \).

Case 2: \( 2^{a-1} \leq r_{E_1(S)} < 2^a \). Running \( A(S) \), we construct a Cartesian grid \( G_2(S) \) of side length \( \varepsilon 2^a/8d \), and a point set \( E_2(S) \) in Step 7. In this case, we have that \( G(S) = G_2(S) \), and \( S = E(S) = E_2(S) \). Since \( E_1(S) \) is an additive \( \varepsilon \)-coreset of \( S \), we conclude that \( E_1(S) \) is also an additive \( 3\varepsilon \)-coreset of \( P \) satisfying Definition \[10\]. Then we have that \( 2^a \leq r_P \leq (1 + 3\varepsilon)r_{E_1(S)} < 2^{a+1} \) by Lemma \[41\]. Running \( A(P) \), we construct a Cartesian grid \( G_1(P) = G_1(S) \) of side length \( \varepsilon 2^a/4d \), and a point set \( E_1(P) \) in Step 5. Since \( P_1 \) and \( P_2 \) are satisfied, we know that \( E_1(P) = E_1(S) \). Thus, we have \( 2^{a-1} \leq r_{E_1(P)} = r_{E_1(S)} < 2^a \). Then in Step 7, we construct a Cartesian grid \( G_2(P) = G_2(S) \) of side length \( \varepsilon 2^a/8d \), and a point set \( E_2(P) \). Again by \( P_1 \) and \( P_2 \), we have that \( E_2(P) = E_2(S) \). Thus, we output \( E(P) = E_2(P) = S \), which finishes the proof.

C PTAS for Stochastic Minimum \( k \)-Center

Given an instance \( S = \{ S_i \mid S_i \in \mathbb{U}^d, 1 \leq i \leq N \} \) of a generalized \( k \)-median problem in \( \mathbb{R}^d \) with a weight function \( w : S \to \mathbb{R}_+ \), we show how to enumerate polynomially many sub-collections \( S_i \subseteq S \) together with their weight functions, such that there exists a generalized \( \varepsilon \)-coreset of \( S \). Recall that \( \sigma_S(S_i) \) is the sensitivity of \( S_i \), and \( \Phi_S = \sum_{i \leq N} \sigma_S(S_i) \) is the total sensitivity. Also recall that \( \dim(S) \) is the generalized dimension of \( S \). Define \( q(S_i) = \sigma_S(S_i) + 1/N \) for \( 1 \leq i \leq M \), and define \( q_S = \sum_{1 \leq i \leq N} q(S_i) \). Note that \( q_S = \Phi_S + 1 \leq 4k + 4 \) by Lemma \[18\]. Our algorithm is as follows.

1. Let \( M = O((\frac{1}{\varepsilon})^2 \dim(S)) \). Let \( L = \frac{M}{k} (\log M + \log N + \log k) \).

2. Enumerate all collections \( S_i \subseteq S \) of cardinality at most \( M \). Note that we only need to enumerate at most \( N^M \) collections.

3. For a collection \( S \subseteq S \), w.l.o.g., assume that \( S = \{ S_1, S_2, \ldots, S_m \} (m \leq M) \). Enumerate all sequences \( ((1 + \varepsilon)^{a_1}, \ldots, (1 + \varepsilon)^{a_m}) \) where each \( 0 \leq a_i \leq L \) is an integer.

4. Given a collection \( S = \{ S_1, S_2, \ldots, S_m \} \) and a sequence \( ((1 + \varepsilon)^{a_1}, \ldots, (1 + \varepsilon)^{a_m}) \), we construct a weight function \( w' : S \to \mathbb{R}_+ \) as follows: for a point set \( S_i \subseteq S \), denote \( w'(S_i) \) to be \( (1 + \varepsilon)^{a_i} \cdot w(S_i)/M \). Recall that \( w(P_i) \) is the weight of \( O_i \subseteq S \).

Analysis. Recall that given an instance \( P \) of a stochastic minimum \( k \)-center problem, we first reduce to an instance \( S = E(P) \) of a generalized \( k \)-median problem. Note that the cardinality of \( S \) is at most \( n^{O(k/\varepsilon^4)} \), and the cardinality of a generalized \( \varepsilon \)-coreset is at most \( M = O(\varepsilon^{-(d+2)}dk^4) \) by Theorem \[20\]. Thus, we enumerate at most \( N^M = n^{O(\varepsilon^{-(d+2)}dk^4)} \) polynomially many sub-collections \( S_i \subseteq S \). For each collection \( S_i \), we construct at most \( M^{L+1} = O(n^{O(k/\varepsilon^4)}) \) polynomially many weight functions. In total, we enumerate \( N^M \cdot M^{L+1} = O(n^{O(\varepsilon^{-(d+2)}dk^4)}) \) polynomially many weighted sub-collections.

It remains to show that there exists a generalized \( \varepsilon \)-coreset of \( S \). We first have the following lemma.

25
Lemma 43. Given an instance $S = \{S_i \mid S_i \in \mathbb{U}^d, 1 \leq i \leq N\}$ of a generalized $k$-median problem in $\mathbb{R}^d$ with a weight function $w : S \rightarrow \mathbb{R}^+$, there exists a generalized $\varepsilon$-coreset $S' \subseteq S$ with a weight function $w' : S \rightarrow \mathbb{R}^+$, such that

$$\sum_{S \in S} w'(S) \cdot K(S, F) \in (1 \pm \varepsilon) \sum_{S \in S} w(S) \cdot K(S, F).$$

The cardinality of $S$ is at most $M = O((\frac{2k}{\varepsilon})^2 \dim(S))$. Moreover, each weight $w'(S) (S \in S)$ has the form that $w'(S) = \frac{c_{\varepsilon} q_S(w(S))}{q(S) M}$, where $1 \leq c \leq M$ is an integer.

Proof. For each $S \in S$, let $g_S : \mathcal{F} \rightarrow \mathbb{R}^+$ be defined as $g_S(F) = w(S) \cdot K(S, F)/q(S)$. Let $D = \{g_S \mid S \in S\}$ be a collection, together with a weight function $w'' : D \rightarrow \mathbb{R}^+$ defined as $w''(g_S) = q(S)$. Then the multi-set $S$ satisfies that for every $F \in \mathcal{F}$,

$$\sum_{g_S \in S} w'(g_S) \cdot g_S(F) \in (1 \pm \varepsilon) \sum_{g_S \in G} w''(g_S) \cdot g_S(F) = (1 \pm \varepsilon)K(S, F).$$

By Theorem 4.1 in [16], we can randomly sample (with replacement) a collection $S \subseteq D$ of cardinality at most $M = O((\frac{2k}{\varepsilon})^2 \dim(S))$, together with a weight function $w' : S \rightarrow \mathbb{R}^+$ defined as $w'(g_S) = q_S/M$. Then the multi-set $S$ satisfies that for every $F \in \mathcal{F}$,

$$\sum_{g_S \in S} w'(g_S) \cdot g_S(F) \in (1 \pm \varepsilon) \sum_{g_S \in G} w''(g_S) \cdot g_S(F) = (1 \pm \varepsilon)K(S, F).$$

By the definition of $g_S$ and $w'$, we prove the lemma. $\square$

We are ready to prove the following lemma.

Lemma 44. Among all sub-collections $S \subseteq S$ of cardinality at most $M = O((\frac{2k}{\varepsilon})^2 \dim(S))$, together with a weight function $w' : S \rightarrow \mathbb{R}^+$ of the form $w'(S_i) = (1 + \varepsilon)^{a_i} \cdot w(S_i)/M (0 \leq a_i \leq \frac{10(\log M + \log N + \log k)}{\varepsilon})$ is an integer, there exists a generalized $\varepsilon$-coreset of $S$.

Proof. By Lemma 43, there exists a generalized $\varepsilon$-coreset $S \subseteq S$ of cardinality at most $M$ together with a weight function $w'' : S \rightarrow \mathbb{R}^+$ defined as follows: each weight $w''(S) (S \in S)$ has the form that $w''(S) = \frac{c_{\varepsilon} q_S(w(S))}{q(S) M}$ for some integer $1 \leq c_S \leq M$. W.l.o.g., we assume that $S = \{S_1, S_2, \ldots, S_m \mid S_i \in S\}$.

By the definition of $q(S)$, we have that $1/\varepsilon \leq q(S) \leq q_S = \Theta_S + 1 \leq 4k + 4$. Then we conclude that for each $S \in S$,

$$1 \leq \frac{c_S \cdot q_S}{q(S)} \leq \frac{1}{4k + 4} M N.$$

For $1 \leq i \leq m$, let $a_i = \lfloor \log_1 \varepsilon \left(\frac{c_S \cdot q_S}{q(S)}\right) \rfloor$. Note that each $a_i$ satisfies that $0 \leq a_i \leq \frac{10(\log M + \log N + \log k)}{\varepsilon}$. Thus, we have enumerated the following sub-collection $S = \{S_1, S_2, \ldots, S_m \mid S_i \in S\}$ with a weight function $w'' : S \rightarrow \mathbb{R}^+$, such that $w''(S_i) = (1 + \varepsilon)^{a_i} \cdot w(S_i)/M$. Moreover, for any $k$-point set $F$, we have the following inequality.

$$\sum_{1 \leq i \leq m} w''(S_i) \cdot K(S_i, F) = \sum_{1 \leq i \leq m} \frac{(1 + \varepsilon)^{a_i} \cdot w(S_i)}{M} \cdot K(S_i, F) \in (1 \pm \varepsilon) \sum_{1 \leq i \leq m} \frac{c_{\varepsilon} q_S \cdot w(S)}{q(S_i) \cdot M} \cdot K(S_i, F)$$

$$= (1 \pm \varepsilon) \sum_{1 \leq i \leq m} w'(S_i) \cdot K(S_i, F) \in (1 \pm 3\varepsilon) \sum_{S \in S} w(S) \cdot K(S, F).$$

The last inequality is due to the assumption that the sub-collection $S$ with a weight function $w'$ is a generalized $\varepsilon$-coreset of $S$. Let $\varepsilon' = \varepsilon/3$, we prove the lemma. $\square$
