Abstract: We consider ZZ production in hadronic collisions and present state-of-the-art predictions in QCD perturbation theory matched to parton showers. Next-to-next-to-leading order corrections to the quark-initiated channel are combined with parton showers using the MiNNLO\textsubscript{PS} method, while next-to-leading order corrections to the loop-induced gluon fusion channel are matched using the POWHEG method. Their combination, dubbed nNNLO+PS, constitutes the best theoretical description of ZZ events to date. Spin correlations, interferences and off-shell effects are included by calculating the full process $pp \rightarrow ℓ^+ℓ^-ℓ^{(0)+}ℓ^{(0)-}$. We show the crucial impact of higher-order corrections for both quark- and gluon-initiated processes as well as the relevance of the parton shower in certain kinematical regimes. Our predictions are in very good agreement with recent LHC data.

Keywords: NLO computations, Perturbative QCD, Resummation
1 Introduction

Vector-boson pair production processes provide some of the most relevant signatures in precision measurements, which have evolved to one of the cornerstones of the rich physics programme at the Large Hadron Collider (LHC). The accurate determination of production rates and distributions provides a valuable path towards the observation of deviations from the predictions made by the Standard Model (SM) of particle physics. Observing or constraining anomalous interactions among SM particles is one of the central goals of such analyses. Through diboson signatures the couplings among three vector bosons (triple-gauge couplings) are directly accessible, which are altered by various beyond-the-SM (BSM) theories. Therefore, the observation of small deviations from the expected rates or shapes of distributions would be a clear sign of new physics. Similarly, measurements at high transverse momentum of some of the particles produced in diboson processes provide constraints on the mass range of possible heavy $Z'$ bosons. Apart from that, vector-boson pair final states constitute an irreducible background to on- and off-shell Higgs cross-section measurements, when the Higgs boson decays to four leptons. These measurements are important for the extraction of the Higgs couplings and for constraints of the Higgs width [1–11].

While the cross section for $ZZ$ production is smaller than the one of $W^\pm Z$ or $W^+W^-$ production, experimentally the decay to four charged leptons provides the cleanest signature of the massive diboson processes, since the final state does not involve any missing transverse
momentum. Accordingly, experimental measurements already reach a remarkable level of precision. In particular, both ATLAS and CMS collaborations have performed measurements of the ZZ production cross sections at 5.02 TeV [12], 7 TeV [13–17], 8 TeV [16–22] and 13 TeV [22–27] and used these measurements to test the SM and constrain triple-gauge couplings.

Modern fits of parton distribution functions (PDFs) have started to include more and more LHC data. For instance NNPDF3.1 [28] already includes top-pair production and the transverse momentum of the Drell-Yan pair. Upcoming fits will also include direct photon, dijet and single top production. It is clear that a further step would be the inclusion of diboson production and other processes with more final-state particles such as three jets, provided the accuracy of theory predictions, both at the level of higher-order QCD and electroweak (EW) corrections, is sufficient.

The first next-to-leading order (NLO) QCD corrections to Z-boson pair production started to appear about thirty years ago [29–33]. NLO QCD calculations were later consistently matched with fully exclusive Parton Shower Monte Carlo programmes (NLO+PS) using the POWHEG [34, 35] or aMC@NLO method [36]. Electroweak (EW) effects at NLO were also computed first in the on-shell approximation [37, 38] and later keeping off-shell and spin-correlation effects [39, 40]. The combination of NLO QCD and NLO EW corrections was presented in ref. [41] and recently also their matching to parton showers was performed [42]. Likewise, in the case of polarized Z bosons NLO QCD and NLO EW corrections have been combined very recently [43]. NNLO QCD corrections have been computed for on-shell [44, 45] and off-shell ZZ production [46, 47], and their combination with NLO EW effects was presented in ref. [48]. The loop-induced $gg \to ZZ$ process starts contributing only at $O(\alpha_s^2)$, but it is enhanced by the gluon PDFs. Since higher-order corrections to this process can be formulated as a gauge-invariant set of contributions and their impact was expected to be important, NLO QCD corrections to $gg \to ZZ$ production have also been computed in the recent years [5, 49–51]. The leading order (LO) matching of the loop-induced gluon fusion process was presented in ref. [52], while NLO+PS predictions were first obtained neglecting the quark channels [53] and very recently also including the full NLO QCD corrections with quark-gluon and quark-antiquark channels and the Higgs resonance [54].

The remarkable progress in NNLO QCD calculations\(^1\) triggered considerable advancements in the matching of NNLO QCD corrections and parton showers (NNLO+PS). The first method developed was the NNLOPS method based on MiNLO’ [89, 90], which achieves NNLO QCD accuracy through a reweighting of MiNLO’ events. This method was successfully employed for relatively simple processes, such as Higgs production [90], Drell-Yan production [91] and associated Higgs production [92, 93], i.e. to processes that from a QCD point of view are just $2 \to 1$ processes. The same method was then also employed for $W^+W^-$ production, including the decay of the $W$-bosons [94]. This paper showed explicitly the limitations of the NNLOPS method, because in practice the multi-differential

\(^1\)By now all $2 \to 1$ and $2 \to 2$ colour-singlet processes are available at NNLO QCD [44–47, 55–83] (see e.g. ref. [84] for a review), and even first such calculations for $2 \to 3$ processes are emerging [85–88].
Reweighting cannot easily be applied to more complicated processes, without making certain assumptions or approximations. About ten years ago, two more NNLO+PS methods were proposed: the UNNLOPS one, which has only been applied to Higgs [95] and Drell-Yan production [96], and the GENEVA method [97, 98]. The latter was subsequently modified, as far as the interface to the shower is concerned, and applied to Drell-Yan [99], Higgsstrahlung [100], photon pair production [101], hadronic Higgs decays [102], ZZ production [103], and $W\gamma$ production [104]. Recently, the GENEVA method was reformulated using the transverse momentum of the colour singlet rather than the jettiness variable and applied to Drell-Yan [105].

Two years ago, the MiNNLOPS method was proposed [106, 107], whose underlying idea is very similar to the MiNLO′ approach that achieves NLO accuracy for colour singlet plus zero and one jet simultaneously. The MiNNLOPS method exploits the close connection to transverse-momentum resummation to include the relevant logarithmically enhanced and constant terms to reach NNLO accuracy. This method was first used to reproduce known results for Higgs production and Drell-Yan [106, 107] and it was applied more recently to $Z\gamma$ [108] and $W^+W^-$ production [109]. Remarkably, although it was the last NNLO+PS method to appear, the MiNNLOPS method was the first to be extended and applied to the production of a coloured final state, namely top-quark pair production [110].

In this work, we employ the MiNNLOPS method to include NNLO QCD corrections for ZZ production in the Powheg framework. Additionally, we present a NLO+PS Powheg calculation for the loop-induced $gg \rightarrow ZZ$ process. When combined, these predictions, dubbed nNNLO+PS, become the most advanced theoretical predictions for ZZ production at the LHC, since they include the highest perturbative accuracy in QCD available to date. Spin correlations, interferences and off-shell effects are included by considering all contributions to the four-lepton final state. Moreover, the matching to the parton shower renders it possible to achieve a fully exclusive description at the level of hadronic events. In the future, the NNLO+PS predictions of our MiNNLOPS ZZ generator could be compared to those recently obtained in the GENEVA framework [103].

This manuscript is organized as follows: in section 2 we discuss in detail the calculation and implementation of the MiNNLOPS method for the $q\bar{q}$-initiated process and the Powheg implementation for the loop-induced $gg$-initiated process. We also show how to avoid that the two-loop amplitudes, whose numerical evaluation is very time-consuming, slow down our code in a considerable way. Our phenomenological results for both cross sections and distributions in ZZ production are discussed in section 3, where we present a comparison between showered, fixed-order, and analytically resummed results at high accuracy for various observables as well as a comparison of our nNNLO+PS predictions to recent LHC data from CMS. We conclude in section 4.
2 Outline of the calculation

2.1 Description of the process

We study the process

\[ pp \rightarrow \ell^+ \ell^- \ell'^+ \ell'^- \]  \hspace{1cm} (2.1)

for any combination of charged leptons \( \ell, \ell' \in \{e, \mu, \tau\} \). While at the matrix-element level our calculation is based on the different-flavour channel \( \ell \neq \ell' \), at the event-generation level arbitrary combinations of charged leptons can be considered, both with different flavours \( \ell \neq \ell' \) and with same flavours \( \ell = \ell' \) (in the latter case interference effects when exchanging the charged leptons, which are typically at the 1-2% level [46], are neglected). Moreover, lepton masses are included via reshuffling of the momenta in the event generation. For simplicity and without loss of generality we consider only the process \( pp \rightarrow e^+ e^- \mu^+ \mu^- \) here, which we will refer to as ZZ production in the following. By including all resonant and non-resonant topologies leading to this process, off-shell effects, interferences and spin correlations are taken into account. Sample diagrams are shown in figure 1 and they include:

(a) tree-level double-resonant t-channel ZZ production in the \( q\bar{q} \) channel;

(b) tree-level single-resonant s-channel DY topologies in the \( qq \) channel;

(c) loop-induced ZZ production in the \( gg \) channel.

The loop-induced contribution proceeds through a quark loop and enters the cross section at \( O(\alpha_s^2) \), i.e. it is part of the NNLO QCD corrections. Since this contribution is enhanced by the large gluon-gluon luminosity at LHC energies, it yields a relatively large fraction of the NNLO corrections [74, 75]. Moreover, it is known that at NLO QCD [49, 51], i.e. \( O(\alpha_s^3) \), its relative correction is very sizable (about a factor of two), which renders it the most significant contribution to ZZ production at \( O(\alpha_s^3) \).

We include the most accurate currently available information in QCD perturbation theory for both the \( q\bar{q} \)-initiated and the \( gg \)-initiated process, and match them consistently with a parton shower. Thus, we calculate NNLO+PS predictions in the \( q\bar{q} \) channel by means

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{diagram.png}
\caption{Sample Feynman diagrams for ZZ production with four charged leptons in the final state. Panels (a) and (b): tree-level diagrams of the quark annihilation (\( q\bar{q} \)) channel; Panel (c): loop-induced diagram in the gluon fusion (\( gg \)) channel.}
\end{figure}
of the MiNNLO$_{PS}$ method [106–108] and NLO+PS predictions in the $gg$ channel using the Powheg approach [111–113]. Our ensuing result is dubbed as nNNLO+PS, as the NLO corrections to the loop-induced gluon-fusion contribution are of $\mathcal{O}(\alpha^3_s)$. These corrections are separately gauge-invariant and constitute the most significant $N^3$LO corrections, as pointed out before.

2.2 MiNNLO$_{PS}$ for $q\bar{q} \rightarrow ZZ$ production

In this section we present the implementation of a NNLO+PS generator for $ZZ$ production in the $q\bar{q}$ channel by means of the MiNNLO$_{PS}$ method. We first sketch the MiNNLO$_{PS}$ method by introducing its essential ingredients and then discuss its practical implementation within the Powheg-Box-Res framework [114] and linking Matrix [115].

2.2.1 The MiNNLO$_{PS}$ method for colour-singlet production

MiNNLO$_{PS}$ has been formulated in ref. [106], optimised for $2 \rightarrow 1$ processes in ref. [107] and later extended to generic colour-singlet processes in ref. [108] and to heavy-quark pair production in ref. [110]. We refer to those publications for a detailed description of the MiNNLO$_{PS}$ method and here we only sketch the procedure adopting a simplified notation.

The MiNNLO$_{PS}$ method includes NNLO corrections in the event generation of a system $F$ of colour-singlet particles. It involves essentially three steps: in the first one (Step I) $F$ is generated in association with one light parton at NLO according to the Powheg method [111–113, 116], inclusively over the radiation of a second light parton. The second step (Step II) characterizes the MiNNLO$_{PS}$ approach, and it corrects the limit in which the light partons become unresolved by supplementing the appropriate Sudakov form factor and higher-order terms, such that the simulation remains finite as well as NNLO accurate for inclusive $F$ production. In the third step (Step III), the kinematics of the second radiated parton (accounted for inclusively in Step I) is generated through the Powheg method to preserve the NLO accuracy of the $F+1$-jet cross section, and subsequent radiation is included through the parton shower. In these three steps all emissions are appropriately ordered (when using a $p_T$-ordered shower) and the applied Sudakov matches the leading logarithms resummed by the parton shower. Thus, the MiNNLO$_{PS}$ approach preserves the (leading logarithmic) accuracy of the parton shower.

The fully differential MiNNLO$_{PS}$ cross section can be expressed through the Powheg formula for the production of a colour singlet plus one light parton ($FJ$) with a modified content of the $\tilde{B}$ function:

$$d\sigma_{FJ}^{\text{MiNNLO}_PS} = \tilde{B}^{\text{MiNNLO}_PS} \times \left\{ \Delta_{\text{pwg}}(\Lambda_{\text{pwg}}) + \int d\Phi_{\text{rad}} \Delta_{\text{pwg}}(p_{T,\text{rad}}) \frac{R_{FJ}}{B_{FJ}} \right\}, \quad (2.2)$$

where $\Delta_{\text{pwg}}$ is the Powheg Sudakov form factor, $\Phi_{\text{rad}}$ and $p_{T,\text{rad}}$ are the phase space and the transverse momentum of the second radiation, respectively, and $B_{FJ}$ and $R_{FJ}$ denote the squared tree-level matrix elements for $FJ$ and $FJJ$ production, respectively. The content of the curly brackets generates the second QCD emission according to the Powheg method, as described in Step III above, with a default cutoff of $\Lambda_{\text{pwg}} = 0.89$ GeV. The $\tilde{B}$ function contains the same contributions to generate the first emission (and inclusively the second
phase space, which is necessary to include those corrections in the context of an

\[ e^{S} \{ 1 + S^{(1)} + \sigma_{\text{FJ}}^{(2)} + (D - D^{(1)} - D^{(2)}) \times F_{\text{corr}} \} , \]  

(2.3)

with \( \sigma_{\text{FJ}}^{(1,2)} \) being the first- and second-order contribution to the differential FJ cross section and \( e^{-S} \) denoting the Sudakov form factor for the transverse momentum of F. Note that in the MiNNLOPS approach the renormalization and factorization scales are evaluated as \( \mu_{R} \sim \mu_{F} \sim p_{T} \), where \( p_{T} \) is the transverse momentum of F. The third term in eq. (2.3) is of order \( \alpha_{s}^{3}(p_{T}) \) and it adds the relevant (singular) contributions so that the integration over \( p_{T} \) yields a NNLO accurate result [106]. Regular contributions at this order are of subleading nature. The function \( D \) is derived from the transverse-momentum resummation formula, which can be expressed fully differentially in the Born phase space of F as

\[ d\sigma_{F}^{\text{res}} = \frac{d}{dp_{T}} \{ e^{-S} L \} = e^{-S} \left\{ -S' L + L' \right\} , \]  

(2.4)

with \( L \) being the luminosity factor up to NNLO that includes the squared hard-virtual matrix elements for F production and the convolution of the collinear coefficient functions with the parton distribution functions (PDFs). In fact, eq. (2.3) follows directly from matching eq. (2.4) with the fixed-order cross section \( \sigma_{\text{FJ}} \), when using a matching scheme where the Sudakov form factor is factored out, i.e.

\[ d\sigma_{F}^{\text{res}} + [d\sigma_{FJ}]_{\text{f.o.}} - [d\sigma_{F}]_{\text{f.o.}} = e^{-S} \left\{ D + [d\sigma_{FJ}]_{\text{f.o.}} - \frac{1}{e^{-S}]_{\text{f.o.}}} - [d\sigma_{F}]_{\text{f.o.}} \right\} \]  

(2.5)

\[ = e^{-S} \left\{ \sigma_{\text{FJ}}^{(1)} (1 + S^{(1)}) + \sigma_{\text{FJ}}^{(2)} + (D - D^{(1)} - D^{(2)}) + O(\alpha_{s}^{4}) \right\} , \]

where \([\cdots]_{\text{f.o.}}\) denotes the expansion up to a given fixed order in \( \alpha_{s} \). Finally, \( F_{\text{corr}} \) in eq. (2.3) determines the appropriate function to spread the NNLO corrections in the FJ phase space, which is necessary to include those corrections in the context of an FJ POWHEG calculation. Note also that one could either truncate the third term in eq. (2.3) at the third order \( (D - D^{(1)} - D^{(2)}) = D^{(3)} + O(\alpha_{s}^{4}) \) [106], or keep the terms of \( O(\alpha_{s}^{4}) \) and higher [107], which are beyond accuracy, in order to preserve the total derivative in eq. (2.4). We employ the latter option here.

2.2.2 Practical implementation in POWHEG-BOX-RES+MATRIX

In the following we provide some information on our implementation of a MiNNLOPS generator for ZZ production in the \( q\bar{q} \) channel within the POWHEG-BOX-RES framework [114]. Our NLO+PS generator for the loop-induced \( gg \) channel is discussed in the next section. We stress that, while we distinguish these processes as \( q\bar{q} \) and \( gg \), in their higher-order corrections of course all the relevant partonic initial states are consistently included.
Since no implementation for $ZZ+$jet production was available in Powheg-Box to date, the first step was to implement this process in the Powheg-Box-Res framework. We have implemented all relevant flavour channels and, in addition, adapted the routine build_resonance_histories of Powheg-Box-Res such that it is capable of automatically constructing the correct resonance histories. The tree-level single and double real matrix elements for $e^+e^−\mu^+\mu^−+1,2$-jet production and the one-loop amplitude for $e^+e^−\mu^+\mu^−+1$-jet production are evaluated through OpenLoops [117–119].

In a second step, we have employed the MiNNLOPS method to obtain NNLO+PS predictions for $ZZ$ production in the $q\bar{q}$ channel. In particular, we made use of the implementation of the MiNNLOPS method that was developed and applied to $Z\gamma$ production in ref. [108]. The respective tree-level and one-loop $q\bar{q} \rightarrow e^+e^−\mu^+\mu^−$ amplitudes are also evaluated through OpenLoops, while the two-loop helicity amplitudes have been obtained by extending the interface to Matrix [115] developed in ref. [108] to $ZZ$ production. The evaluation of the two-loop coefficients in this implementation relies on the code VVamp [120] and is based on the calculation of ref. [121].

As discussed in ref. [109] for $W^+W^−$ production, the evaluation of the two-loop helicity amplitudes for massive diboson processes is particularly demanding from a computational point of view. In ref. [109] this problem was circumvented by constructing a set of interpolation grids for the two-loop coefficients that achieves their fast on-the-fly evaluation. In this work we pursue a different strategy: we exploit the possibility of reweighting the events at the generation level (i.e. stage 4 in Powheg-Box) to include the two-loop contribution. In combination with a suitable caching system of the two-loop amplitude that we implemented this allows us to omit the evaluation of the two-loop contribution entirely in the calculation up to stage 4, where it needs to be evaluated only once per event.\footnote{Note that in order for the caching to work properly and not having to reevaluate the two-loop amplitude for every scale variation in the event reweighting, we have set the parameter run_mode 1 in the input file, which ensures that the events are reweighted one-by-one instead of in batches.}

To be more precise, we have implemented a new flag (run_mode), which is accessible from the Powheg input file, and allows the user to switch between four different ways of running the code. Either the full calculation is performed including the two-loop contributions throughout (run_mode 1), or one completely drops the NNLO corrections provided by MiNNLOPS, specifically the terms $(D − D^{(1)} − D^{(2)}) \times F^{corr}$ in eq. (2.3), thus effectively reproducing MiNLO$'$ predictions (run_mode 2). Alternatively, the evaluation of two-loop amplitude can be omitted only in the grid setup, i.e. stage 1 in Powheg-Box, (run_mode 3), or completely (run_mode 4). For all results presented in this manuscript we run the code with the last option run_mode 4, i.e. without evaluating the computationally expensive two-loop amplitude. In this way, also the generation of the events is faster. However, once an event has been accepted, it is reweighted such that the two-loop contribution is included by resetting the run_mode keyword in the event reweight information of the Powheg input file. As a result the two-loop amplitude is evaluated only once for each event, considerably improving the efficiency of the code. Moreover, following the same logic we can also compute MiNLO$'$ weights in parallel to the generation of MiNNLOPS ones using the appropriate setting for run_mode in the event reweight information. We have first validated our implementation in
an inclusive setup, requiring only a suitable $Z$-mass window for the opposite-charge same-flavour dilepton pairs. Here we compared the inclusive cross section at the Les Houches event (LHE) level obtained at stage 4 with the one computed at stage 2 when including the two-loop contribution, finding excellent agreement. Another very robust cross-check of the reweighting procedure is provided by the comparison of the MiNLO’ results obtained directly or through reweighting, which also agree perfectly.

Our calculation involves the evaluation of several convolutions with the PDFs, for which we employ HOPPET [122]. The evaluation of the polylogarithms entering the collinear coefficient functions is done through the HPLOG package [123].

Finally, let us summarize some of the most relevant (non-standard) settings that we have used to produce NNLO+PS accurate $ZZ$ events in the $q\bar{q}$ channel. For more detailed information on those settings we refer to refs.[107, 110]. To avoid spurious contributions from higher-order logarithmic terms at large $p_T$, we make use of a modified logarithm that is defined such that it smoothly vanishes at $p_T$ equal to or larger than the invariant mass of the system, as used in ref.[110]. As far as the renormalization and factorization scales are concerned, we use the standard MiNNLOPS scale setting in eq.(14) of ref.[107] at small $p_T$, while in the NLO $ZZ+\text{jet}$ cross section at large $p_T$ the scale setting is changed to the one in eq. (19) of ref.[107] by activating the option largeptscales.1. Since those scale settings have been defined with $Q_0 = 0 \text{ GeV}$, the Landau singularity is regulated by freezing the strong coupling and the PDFs for scales below 0.8 GeV. Finally, as recommended for processes with jets in the final state, we turn on the option doublefar 1 of the POWHEG-Box, see ref.[124] for details. For the parton-shower we have used the standard settings, also for the recoil scheme (namely a global recoil scheme for initial state radiation, with SpaceShower:dipoleRecoil 0).

2.3 NLO+PS for $gg \to ZZ$ production

As discussed before, the leading-order contribution to the loop-induced gluon fusion process enters the $ZZ$ cross section at $O(\alpha_s^2)$. Thus, it constitutes a NNLO correction relative to the LO part of the $q\bar{q}$ channel, but it is significantly enhanced by the large gluon-gluon luminosities. It is therefore mandatory to include also the NLO corrections to the loop-induced gluon fusion contribution in any precision study of $ZZ$ production that compares theory and data.

We have implemented a NLO+PS generator for loop-induced $ZZ$ production in the $gg$ channel within the POWHEG-BOX-RES framework. Note that in addition to continuum $ZZ$ production as shown in figure 1 (c) we also include the contribution mediated by a Higgs boson. The calculation of these loop-induced processes is effectively of similar complexity as a NNLO calculation, as far as the amplitude evaluation is concerned. Despite that, the matching to the parton shower through the POWHEG method, which is essentially automated in POWHEG-BOX-RES, can be applied to loop-induced processes as well, without any further conceptual issues. However such an NLO calculation requires the evaluation of both one-loop and two-loop helicity amplitudes and the process at hand is numerically substantially more demanding than a tree-level one, since the evaluation time of the one-loop and two-loop amplitudes is much slower and the stability of the one-loop matrix...
elements with one emitted real parton is challenged in the infrared regions. To cope with these numerical issues, we have implemented and exploited a number of handles within POWHEG-BOX-RES, which will be discussed below.

For the implementation in POWHEG-BOX-RES, we have specified the relevant flavour channels and hard-coded also the resonance channels of the process, as the automatic determination of the latter via the already mentioned routine build_resonance_histories is not available yet for loop-induced processes. At NLO, all relevant partonic channels, namely $gg$, $gq$, $qg$ and the charge-conjugated ones, are included. To unambiguously define the NLO corrections to the loop-induced gluon-fusion process for each of those initial states, we follow the approach introduced in ref. [51] and include all diagrams that involve a closed fermion loop with at least one vector boson attached. The one-loop amplitudes with zero and one jet are evaluated through OPENLOOPS [117–119]. For this purpose, we have adapted the OPENLOOPS interface in POWHEG-BOX-RES developed in ref. [125] to deal with loop-induced processes. As a cross-check, we have also interfaced RECOLA to POWHEG-BOX-RES and found full agreement for all one-loop amplitudes. For the two-loop helicity $gg \to \ell^+\ell^-\ell^{(0)+}\ell^{(0)−}$ amplitudes we exploit their implementation within MATRIX [115], which is based on the evaluation of the two-loop coefficients through VVAMP [121] from their calculation in ref. [126]. To this end, we have extended the interface of POWHEG-BOX-RES to MATRIX developed in ref. [108] to include the $gg \to \ell^+\ell^-\ell^{(0)+}\ell^{(0)−}$ two-loop amplitudes. Also here the evaluation of the two-loop coefficients through VVAMP is very slow, lasting from a few seconds to several tens of seconds. Since this leads to a severe bottleneck in the calculation and especially in the event generation, we have implemented a caching system for the two-loop corrections and we include them only through event reweighting. This is very similar in spirit to the way the two-loop hard function is included in the MiNNLOPS generator in the $q\bar{q}$ channel, as described in the previous section. Our calculation includes the full top-quark mass effects, except for the two-loop $gg \to \ell^+\ell^-\ell^{(0)+}\ell^{(0)−}$ amplitudes, where they are not known to date.\(^3\) Instead, we follow the same approach as ref. [51] and include them approximately through a reweighting of the massless two-loop amplitude with the ratio of the one-loop result including massive loops to the one with only massless loops. Since here we are interested in the ZZ signal region, such reweighting is expected to work extremely well. In fact, ref. [54] recently confirmed that using an asymptotic expansion in the top-quark mass leads to practically identical results as using such reweighting, as long as one sticks to the validity range of the expansion itself.

Very recently, ref. [54] presented a completely independent implementation of a NLO+PS generator for loop-induced ZZ production in the $gg$ channel within the POWHEG-BOX-RES framework. We have compared our calculation to theirs both at the level of individual phase-space points and of the integrated cross sections, and we have found perfect agreement when applying the same approximation for the two-loop virtual corrections.\(^4\) Since, although developed independently, the two calculations are essentially interchangeable (both developed

---

\(^3\)For the case of on-shell $gg \to ZZ$ production the full top-quark mass dependence was recently calculated in refs. [127, 128].

\(^4\)We would like to thank the authors of ref. [54] for providing the gg4l code and in particular Jonas Lindert for very helpful correspondence.
Figure 2: Predictions for $ZZ$ production in the loop-induced $gg$ channel at LO+PS and NLO+PS. For reference also the LHE-level central result at NLO is plotted. Shown are the distributions in the invariant mass, rapidity and transverse momentum of the four-lepton system, and in the transverse momentum of the leading jet.

in POWHEG-BOX-RES using OPENLOOPS and VVAMP), we advocate that it is equivalent to use either code and combine the results subsequently with our MiNNLOPS generator in the $q\bar{q}$ channel to obtain nNNLO+PS accurate results.

To better control the numerical stability of the calculation we have implemented settings similar to those reported in ref. [54]: in particular we apply small (0.5 GeV) generation cuts on the transverse momentum of the four-lepton system and of each $Z$ boson. Moreover, we
exploit the stability system of OpenLoops and set the parameter `stability_kill 0.01` to remove the remaining unstable points. We have further modified the code in such a way that, whenever the real-emission contribution is set to zero by one of the previous stability checks, also the respective counter terms are set to zero. Finally, we use `withdamp 0` in order not to split the real cross section into a singular and a remnant contribution as the considerably small value of the latter leads to numerical issues when generating events. The same is true for the regular contribution that contains only the $q\bar{q}$ channel: being completely negligible, we have turned it off for all results obtained in this paper.

Since in the upcoming section we study phenomenological results for the full $pp \rightarrow e^+e^-\mu^+\mu^-$ process, we show some plots for the loop-induced $gg$ channel separately in figure 2, both at LO and at NLO. The settings and inputs that we use here correspond to those introduced in section 3.1 in the inclusive setup (setup-inclusive) with just a $Z$-mass window applied between 60 GeV and 120 GeV. The renormalization and factorization scales are set to $\mu_R = \mu_F = \sqrt{m_{4\ell}^2 + p_{T,4\ell}^2}$, where $m_{4\ell}$ and $p_{T,4\ell}$ are the invariant mass and the transverse momentum of the four-lepton system, respectively. The uncertainty bands are obtained through a standard seven-point scale variation. For the genuine NLO-accurate quantities shown in figure 2, namely $m_{4\ell}$ and the rapidity of the four-lepton system ($y_{4\ell}$), we find results that are completely in line with the findings of previous fixed-order calculations [49, 51], which is expected since shower effects are negligible for those observables, as one can see from the LHE results. In particular, NLO corrections are sizable and increase the value of the inclusive cross section by almost a factor of two, with scale uncertainties at the level of 10-15%. In certain phase-space regions, like in the tail of the $m_{4\ell}$ distribution, the NLO corrections can even become significantly larger than a factor of two. However, in those regions the relative impact of the loop-induced $gg$ contribution is reduced. When looking at the transverse-momentum spectrum of the four-lepton system ($p_{T,4\ell}$) and of the leading jet ($p_{T,j_1}$) in figure 2, the importance of matching to the parton shower becomes clear: at LO only the parton shower fills those distributions and at NLO it still provides a substantial correction. In fact, in a fixed-order calculation both observables would diverge, and therefore be unphysical, at small transverse momenta. It is interesting to notice that the LO+PS result is actually higher than the NLO+PS one in the intermediate $p_{T,4\ell}$ region before it falls off steeply. This region is completely filled by the shower, whose starting scale by default is set to $m_{4\ell}$ in the LO calculation. The fact that $m_{4\ell}$ is on average relatively large explains why the shower fills the spectrum even at such high transverse momenta.

3 Phenomenological results

In this section we present phenomenological results for the process $pp \rightarrow e^+e^-\mu^+\mu^-$. After discussing our setup in section 3.1, we compare our MiNNLO_{PS} predictions for integrated cross sections (section 3.2) and at the differential level (section 3.3) against fixed-order predictions at NNLO accuracy, MiNLO’ results and experimental data from the CMS experiment [27].
3.1 Input parameters and setup

We consider proton–proton collisions at the LHC with a center-of-mass energy of 13 TeV and present predictions for $pp \to e^+e^-\mu^+\mu^-$ production. We use the complex-mass scheme [129] throughout and set the electroweak (EW) inputs to their PDG [130] values: $G_F = 1.16639 \times 10^{-5}$ GeV$^{-2}$, $m_W = 80.385$ GeV, $\Gamma_W = 2.0854$ GeV, $m_Z = 91.1876$ GeV, $\Gamma_Z = 2.4952$ GeV, $m_H = 125$ GeV and $\Gamma_H = 0.00407$ GeV. We set the on-shell top-quark mass to $m_t = 173.2$ GeV, and $\Gamma_t = 1.347878$ GeV is used. We determine the other EW parameters in the $G_\mu$ scheme with the EW coupling $\alpha_{\text{EM}} = \sqrt{2}/\pi G_\mu[(m_W^2 - i \Gamma_W m_W)\sin^2 \theta_W]$ and the EW mixing angle $\cos^2 \theta_W = (m_W^2 - i \Gamma_W m_W)/(m_Z^2 - i \Gamma_Z m_Z)$. We use the NNPDF3.1 [28] NNLO set with $\alpha_s = 0.118$ via the LHAPDF interface [131] for all our predictions. For MiNLO$'$ and MiNNLO$_{\text{PS}}$, the PDFs are read by LHAPDF and evolved internally by HOPPET [122] as described in ref.[106]. The central factorization and renormalization scales are set as discussed in section 2.2.2 for the MiNNLO$_{\text{PS}}$ ZZ generator in the $q\bar{q}$ channel and as given in section 2.3 for the loop-induced $gg$ channel. Scale uncertainties are estimated by varying $\mu_F$ and $\mu_R$ around their central value by a factor of two in each direction, while keeping the minimal and maximal values with the constraint $0.5 \leq \mu_R/\mu_F \leq 2$.

By combining the MiNNLO$_{\text{PS}}$ $q\bar{q}$ results and loop-induced $gg$ results at (N)LO+PS, we obtain predictions for ZZ production at (n)NNLO accuracy matched to parton showers. For all (n)NNLO+PS predictions presented in this paper we make use of the PYTHIA8 parton shower [132] with the A14 tune [133] (py8tune 21 in the input card). To validate our calculation and to show where shower effects are crucial, we compare (n)NNLO+PS predictions obtained with MiNNLO$_{\text{PS}}$ and (n)NNLO fixed-order predictions obtained with MATRIX [115]. Additionally, we consider the inclusion of NLO EW effects. In the MATRIX predictions we set $\mu_F = \mu_R = m_{4\ell}$, and we construct the scale-uncertainty bands with the same canonical seven-point scale variation used for our MiNLO$'$ and MiNNLO$_{\text{PS}}$ results.

Moreover, we compare our predictions with the most recent results by the CMS collaboration [27] within the fiducial volume defined in table 1, denoted as setup-fiducial. Note that the reconstructed $Z$ bosons $Z_1$ and $Z_2$ are identified by selecting the opposite-sign same-flavour (OSSF) lepton pair with an invariant mass closest to the $Z$-boson mass as $Z_1$ and identifying the remaining OSSF lepton pair with $Z_2$. Since here we only consider the different-flavour channel ($e^+e^-\mu^+\mu^-$), the two $Z$ bosons are unambiguously reconstructed and this procedure only selects which lepton pair is called $Z_1$ and which $Z_2$. Note that in the

| setup-inclusive | setup-fiducial |
|-----------------|-----------------|
| $Z$-mass window | $60 \text{ GeV} < m_{Z_1}, m_{Z_2} < 120 \text{ GeV}$ | $60 \text{ GeV} < m_{Z_1}, m_{Z_2} < 120 \text{ GeV}$ |
| lepton cuts     | $m_{\ell^+\ell^-} > 4 \text{ GeV}$ | $p_T, \ell_i > 20 \text{ GeV}$, $p_T, \ell_2 > 10 \text{ GeV}$, $p_T, \ell_{3,4} > 5 \text{ GeV}$, $|\eta_\ell| < 2.5$, $m_{\ell^+\ell^-} > 4 \text{ GeV}$ |

Table 1: Inclusive and fiducial cuts used to define the setup-inclusive and setup-fiducial phase space regions [27]. See text for more details.
different-flavour channel the additional \( m_{\ell^+\ell^-} > 4 \text{ GeV} \) cut in table 1 has no effect. Besides the fiducial setup, we also consider an inclusive setup (dubbed setup-inclusive), where we only require a Z-mass window between 60 GeV and 120 GeV for the two resonances.

In order to provide the most realistic comparison to experimental data, our final predictions include effects from hadronization and multi-particle interactions (MPI). We also include QED showering effects as provided by PYTHIA8. In order to prevent charged resonances to radiate photons and photons to branch into lepton- or quark-pairs, we set the two flags \texttt{TimeShower:QEDshowerByOther} and \texttt{TimeShower:QEDshowerByGamma} to \texttt{off}.

Finally, we define dressed leptons by adding to the four-momentum of a lepton the four-momenta of all photons within a distance \( \Delta R_{\gamma\ell} = \sqrt{\Delta \phi^2_{\gamma\ell} + \Delta \eta^2_{\gamma\ell}} < 0.1 \).

### 3.2 Integrated cross sections

We start the discussion of our results by first considering integrated cross sections. In table 2 we report predictions both in the inclusive and in the fiducial setup introduced above for various perturbative calculations. Specifically, we consider MiNLO’ predictions, and a number of predictions including NNLO corrections, both at fixed order and matched to parton showers through MiNNLO\textsubscript{PS}: besides the complete NNLO predictions (that include the LO loop-induced \( gg \) contribution), we provide the NNLO corrections to the \( q\bar{q} \) channel (dubbed NNLO\textsubscript{qq}) and nNNLO cross sections (as defined before). For completeness, we also quote nNNLO predictions combined with NLO EW corrections, computed at fixed-order with \textsc{Matrix}, either using an additive or multiplicative scheme. In the latter predictions we also take into account the photon-induced contribution at LO and beyond. In order to compare our predictions to fixed-order results, all MiNNLO\textsubscript{PS} (and MiNLO’) results of table 2 are obtained at parton level, without including hadronization, MPI or photon radiation effects. We have checked explicitly that those effects have a negligible impact on the integrated cross sections.

The MiNNLO\textsubscript{PS} prediction and the NNLO result are in excellent agreement with each other both in the inclusive and in the fiducial setup. The perturbative uncertainty at (n)NNLO(+PS) is at the 2-3% level. In particular, despite the fact that the loop-induced \( gg \) process at LO (NLO) contributes only \( \sim 6-8\% (\sim 10-15\%) \) to the NNLO (nNNLO) cross section, the uncertainties of the (n)NNLO results are dominated by the gluon-initiated contribution. The NLO correction for the loop-induced \( gg \) channel is particularly sizable, almost doubling the LO contribution entering at \( \alpha_s^2 \), as discussed in section 2.3. Accordingly, the nNNLO central prediction is not included in the NNLO uncertainty band.

The MiNLO’ result is 8-10% smaller than the MiNNLO\textsubscript{PS} result. Its uncertainty band, which is considerably larger than the MiNNLO\textsubscript{PS} one, does not contain the central (n)NNLO+PS prediction, because scale variations cannot account for the additional loop-induced \( gg \) process entering at NNLO. We also note that the MiNLO’ uncertainty band is larger than the NLO one, and it includes the NLO result. On the contrary, the NLO...
In the contrary, in the inclusive setup, without a minimal transverse momentum, the photon-larger than 20 GeV, and all leptons have a transverse momentum larger than 5 GeV. On negligible impact in the fiducial setup, where the leading lepton has a transverse momentum measurement. We note that EW effects include photon-initiated processes. These have a 4-6% in the fiducial region, slightly deteriorating the agreement with the experimental has a non-negligible impact on the nNNLO result and reduces the cross section by about with EW corrections. Their inclusion, using either an additive or multiplicative scheme [48], fiducial cross section measured by CMS, the theoretical predictions should be supplemented it.

Notwithstanding the excellent agreement between the nNNLO(+PS) result and the fiducial cross section measured by the CMS experiment in ref.[27]. Since the measured inclusive cross section corresponds to on-shell \( pp \to ZZ \) production, we have multiplied the measured cross section by a branching fraction of \( BR(Z \to \ell^+\ell^-) = 0.03366 \), as quoted in ref.[27], for each \( Z \) boson and by a factor of two to compare with our predictions for \( pp \to e^+e^-\mu^+\mu^- \) production. For the measured fiducial cross section the CMS analysis includes both different-flavour (\( e^+e^-\mu^+\mu^- \)) and same-flavour (\( e^+e^-\mu^+\mu^- \)) decay channels of the two \( Z \) bosons. We have therefore divided the measured fiducial cross section by a factor of two to compare with our predictions for \( pp \to e^+e^-\mu^+\mu^- \) predictions.

The uncertainty band is very small and neither MiNLO’ nor the NNLO central results lie inside it.

Table 2: Integrated cross sections at various perturbative orders in both the setup-inclusive and setup-fiducial region. In brackets we report the statistical uncertainties, while scale uncertainties are reported in percentages. We also report the inclusive and fiducial cross sections measured by the CMS experiment in ref.[27]. Since the measured inclusive cross section corresponds to on-shell \( pp \to ZZ \) production, we have multiplied the measured cross section by a branching fraction of \( BR(Z \to \ell^+\ell^-) = 0.03366 \), as quoted in ref.[27], for each \( Z \) boson and by a factor of two to compare with our predictions for \( pp \to e^+e^-\mu^+\mu^- \) production. For the measured fiducial cross section the CMS analysis includes both different-flavour (\( e^+e^-\mu^+\mu^- \)) and same-flavour (\( e^+e^-\mu^+\mu^- \)) decay channels of the two \( Z \) bosons. We have therefore divided the measured fiducial cross section by a factor of two to compare with our predictions for \( pp \to e^+e^-\mu^+\mu^- \) predictions.

Notwithstanding the excellent agreement between the nNNLO(+PS) result and the fiducial cross section measured by CMS, the theoretical predictions should be supplemented with EW corrections. Their inclusion, using either an additive or multiplicative scheme [48], has a non-negligible impact on the nNNLO result and reduces the cross section by about 4-6% in the fiducial region, slightly deteriorating the agreement with the experimental measurement. We note that EW effects include photon-initiated processes. These have a negligible impact in the fiducial setup, where the leading lepton has a transverse momentum larger than 20 GeV, and all leptons have a transverse momentum larger than 5 GeV. On the contrary, in the inclusive setup, without a minimal transverse momentum, the photon-
initiated contribution features a collinear divergence. To avoid this divergence, the CMS analysis [27] imposed a transverse momentum cut of 5 GeV on the leptons in the evaluation of the photon-induced component. With this cut, they showed that the photon-induced contribution is less than 1% of the total cross section. For this reason, we set the photon-induced component to zero for the nNNLO+NLO\textsubscript{EW} and nNNLO×NLO\textsubscript{EW} results in the inclusive case.

3.3 Differential distributions

In this section we present our results for differential distributions. We start by comparing the nNNLO+PS predictions obtained with MiNNLO\textsubscript{PS} against MiNLO’ and fixed-order nNNLO predictions in the setup-inclusive in section 3.3.1. In section 3.3.2 we move to consider the setup-fiducial and we compare our MiNNLO\textsubscript{PS} predictions at nNNLO+PS with the data collected and analyzed by the CMS experiment [27].

3.3.1 Comparison against theoretical predictions

In figure 3 we compare nNNLO+PS predictions for MiNNLO\textsubscript{PS} with MiNLO’ and nNNLO predictions at fixed order for four different distributions which are non-zero at LO. In particular, we consider the invariant mass of the $e^+e^-$ pair ($m_{e^+e^-}$), the invariant mass ($m_{4\ell}$) and the rapidity of the diboson system ($y_{4\ell}$), and the rapidity ($y_{Z_1}$) of the $Z$ boson whose invariant mass is closer to $m_Z$. We remind the reader that both the MiNNLO\textsubscript{PS} and the MiNLO’ predictions include hadronization and MPI effects, which however are expected to be very moderate for the inclusive observables considered in figure 3. We observe a very good agreement between the nNNLO+PS and the nNNLO predictions, both for the central values and for the scale-variation bands. The latter are at the few-percent level across the whole range shown in the plots, becoming larger (about ±5%) at high $m_{4\ell}$. Minor differences are visible in the tails of the distributions, in particular at large $m_{4\ell}$, where the nNNLO-accurate MiNNLO\textsubscript{PS} and fixed-order predictions however still overlap. Indeed, in the large invariant-mass region scale choices and terms beyond accuracy become increasingly important, as it was recently pointed out for $W^+W^-$ production in ref. [109] and extensively discussed for $t\bar{t}$ production [137, 138]. The MiNLO’ result is in all cases about 15-20% smaller than the nNNLO results, which provides mostly flat corrections to the distributions under consideration, increasing slightly only at large $m_{4\ell}$. We stress that the relatively flat QCD corrections are a feature of the chosen distributions (in the inclusive setup) that does not apply in general, as we shall see below. Although the MiNLO’ uncertainty is a factor of 5 larger than the MiNNLO\textsubscript{PS} and nNNLO ones, the MiNLO’ predictions do not overlap with the nNNLO-accurate results. This is not unexpected since a large part of the difference is caused by the loop-induced $gg$ contribution. Since the latter is missing in the MiNLO’ predictions, the MiNLO’ scale variation can not account for this new production process, which instead enters the nNNLO results. From the second ratio panel we can appreciate the effect of the loop-induced $gg$ contribution both at LO (comparing NNLO+PS to NNLO\textsubscript{q\bar{q}+PS}) and at NLO (comparing nNNLO+PS to NNLO\textsubscript{q\bar{q}+PS}). It is clear from the plots that due to the gluon flux the impact of the loop-induced $gg$ process is more prominent in certain phase-space regions. The LO (NLO) corrections, which inclusively
Figure 3: Comparison between selected distributions computed with \textsc{Matrix}, \textsc{MiNNLO}$_{\text{PS}}$ and \textsc{MiNLO}'. Upper panel: invariant mass of the $e^+e^-$ pair (left) and of the $ZZ$ pair (right); lower panel: rapidity of $Z_1$ (left) and of the $ZZ$ pair (right).

amount to $\sim 6$-$8\%$ ($\sim 10$-$15\%$) as pointed out before, contribute more significantly in the bulk region of the distributions, i.e. at the $Z$ resonance in $m_{e^+e^-}$ as well as for small $m_{4\ell}$ and central rapidities.

In figure 4 we show the same comparison for the transverse momentum of the $\mu^+\mu^-$ pair ($p_{T,\mu^+\mu^-}$) and the transverse momentum of the leading jet ($p_{T,j_1}$) above 30 GeV. The
first observable is already defined at LO, while the second one receives its first contribution only at NLO and its accuracy is thus effectively reduced by one perturbative order. The MiNNLO PS and the nNNLO results for $p_{T,\mu^+\mu^-}$ are in good agreement with each other in the whole range shown here. The MiNLO' result is more than 20% smaller at low values of the transverse momentum, while it agrees with the other two predictions at large values of $p_{T,\mu^+\mu^-}$. Hence, this distribution shows that in general QCD corrections are not uniformly distributed in phase space. By and large, the three predictions for the transverse momentum of the leading jet display a good agreement, especially in the tail of the distribution. The level of agreement between nNNLO and MiNNLO PS is expected as both predictions are effectively nNLO accurate at large $p_{T,j_1}$. The residual scale uncertainties are at the 5-10% level and they are larger than those in the other distributions, which is a direct consequence of the lower accuracy of the predictions for this distribution. Looking at the effect of loop-induced $gg$ contribution in the second ratio panel, we observe a rather peculiar behaviour with the nNNLO+PS corrections being negative with respect to NNLO+PS for $p_{T,j_1} \gtrsim 80$ GeV. However, this is completely in line with the results presented in figure 2 and it is a consequence of the fact that the NNLO+PS predictions include only a LO+PS calculation for the loop-induced $gg$ process, which is not expected to describe the high $p_{T,j_1}$ range as it is filled entirely by the parton shower, which has no accuracy in this region. This further underlines the need for including NLO corrections to the loop-induced $gg$ process. Indeed, after including the NLO corrections, the loop-induced $gg$ contribution reduces to 5% (and less) at high $p_{T,j_1}$ (comparing nNNLO to NNLO$_{gg+PS}$), which is more reasonable.

In figure 5 we show an analogous comparison for the transverse-momentum spectrum.
of the electron ($p_{T,e^-}$) and of the leading lepton ($p_{T,\ell_1}$). For the $p_{T,e^-}$ distribution we observe excellent agreement over the whole range between the MiNNLOPS and the nNNLO results, which is fully expected since this distribution should be affected very mildly by resummation/shower effects. We have explicitly checked that a similar level of agreement is obtained when considering the same comparison at NNLO $q\bar{q}$ accuracy, as opposed to the GENEVA calculation in ref.[103], where differences between the GENEVA and fixed-order results are observed for $p_{T,e^-} > 40$ GeV. When comparing the MiNNLOPS and the MiNLO' predictions for the $p_{T,e^-}$ spectrum we observe that the effect of both the NNLO $q\bar{q}$ corrections and the loop-induced $gg$ contribution is particularly pronounced in the bulk region of the distribution, where the MiNLO' result is more than 20% smaller than the nNNLO result. On the other hand, the transverse momentum of the leading lepton is subject to shower effects, especially at low $p_{T,\ell_1}$, and indeed we observe a difference between the MATRIX results and the MiNNLOPS predictions below 40 GeV, which become increasingly larger the more steeply the distribution falls when $p_{T,\ell_1}$ approaches zero. Above this value, the shower effects are less pronounced and the two predictions are in good agreement. By comparing the nNNLO+PS predictions to the NNLO+PS and NNLO$q\bar{q}$+PS results we can see that the impact of the loop-induced $gg$ contribution is particularly relevant below 40 GeV, and it is also predominantly responsible for the relatively large shower effects that we observe. In fact, we have checked that for the NNLO$q\bar{q}$+PS result the relative impact of the shower is smaller than for the NLO+PS result in the $gg$ channel, which is expected considering the higher perturbative accuracy (and thereby logarithmic terms) already included at fixed order in the $q\bar{q}$ channel.

**Figure 5**: Same as figure 3, for the transverse momentum of the electron (left) and of the leading lepton (right).
Finally, in figure 6 we show predictions for the transverse momentum of the diboson pair ($p_{T,4\ell}$). In this case, we also show the NNLO+$N^3$LL result obtained with Matrix+RadISH [139], which interfaces Matrix [115] to the RadISH resummation formalism [140, 141], using $\mu_R = \mu_F = m_{4\ell}$ and $Q_{\text{res}} = m_{4\ell}/2$ for the resummation scale. Since Matrix+RadISH does not include the contribution stemming from the loop-induced $gg$ channel, we perform this comparison by considering only the $q\bar{q}$-initiated process, i.e. at the NNLO$_{q\bar{q}+\text{PS}}$ level. At small values of the $ZZ$ transverse momentum we observe an excellent agreement between the NNLO+$N^3$LL and the MiNNLO$_{PS}$ result, especially considering the lower accuracy of the parton shower in that region; MiNNLO$_{PS}$ is between 5% and 8% larger than the NNLO+$N^3$LL prediction below 10 GeV and has a larger uncertainty band reflecting its lower accuracy. On the other hand, the MiNLO$'$ result is $\mathcal{O}(10\%)$ smaller than the NNLO+$N^3$LL and the MiNNLO$_{PS}$ predictions and its uncertainty band does not overlap with either of the more accurate results below 40 GeV. Fixed-order calculations actually lead to unphysical results in the small-$p_{T,4\ell}$ region due to large logarithmic corrections, which need to be resummed to all orders. Indeed, the NNLO result diverges at low transverse momentum, and its prediction differs significantly from the ones including resummation effects. At larger values of $p_{T,4\ell}$ the NNLO result is instead in agreement with the NNLO+$N^3$LL, MiNLO$'$ and MiNNLO$_{PS}$ predictions, as one may expect since all of them have the same formal accuracy in the tail of the distribution.

In conclusion, we observe overall a very good agreement between MiNNLO$_{PS}$, fixed-order, and analytically resummed results across a variety of distributions, which provides a robust validation of our calculation. The MiNLO$'$ result, despite the considerably larger uncertainty bands, rarely overlaps with the (n)NNLO(+PS) predictions, thus highlighting the importance of higher-order corrections to this process. Moreover, certain observables require the resummation of large logarithmic contributions, which renders the matching to the parton shower mandatory.
3.3.2 Comparison against data

In this section we compare our MiNNLO$_{PS}$ predictions at nNNLO+PS to the CMS measurement presented in ref. [27] in the setup-fiducial defined in table 1. We have generated the events and estimated the theoretical uncertainties as described in section 3.1. We remind the reader that our predictions include MPI and hadronization effects, as well as QED corrections in the shower approximation.

The comparison between MiNNLO$_{PS}$ predictions and experimental data is presented in figure 7. Altogether, we show predictions for six observables: the invariant mass and the transverse momentum of the diboson pair ($m_{4\ell}$ and $p_{T,4\ell}$), the sum of the four individual transverse-momentum distributions of each final-state lepton (which corresponds to the average of the lepton transverse-momentum distributions), the sum of the two distributions of the transverse momentum of the reconstructed $Z$ bosons (which analogously corresponds to the average of the $Z$ transverse-momentum distributions), and the separation between the two $Z$ bosons in the azimuthal angle ($\Delta \phi_{Z_1,Z_2}$) and in the $\eta$–$\phi$ plane ($\Delta R_{Z_1,Z_2}$). In all cases, except for $\Delta \phi_{Z_1,Z_2}$ that has a kinematical endpoint at $\Delta \phi = \pi$, the last bin shown in the figures also includes the contribution of the overflow.

By and large, we observe a quite remarkable agreement between our predictions and the experimental data. The invariant mass is well described at low $m_{4\ell}$, but there is a tendency of the data to undershoot the prediction at large $m_{4\ell}$, with the last bin being almost two standard deviations away. In this region EW corrections are known to be important and they are only partly included here through the QED shower. Below, we discuss how the inclusion of the NLO EW corrections at fixed order improves the agreement with data in this region. The transverse-momentum distribution of the $ZZ$ pair is also well described, except for a two-sigma deviation in the last bin, with a remarkable agreement for $p_{T,4\ell}$ values below $\sim 100$ GeV, where the all-order corrections provided by the shower are particularly important. The two averaged distributions of $p_{T,4\ell}$ and $p_{T,2Z}$ also compare very well to MiNNLO$_{PS}$, with deviations in the tail of the distributions only. In the last bins the experimental data are about two standard deviations away from the theoretical predictions, which can again be related to the missing EW corrections, as discussed below. The $\Delta \phi_{Z_1,Z_2}$ and the $\Delta R_{Z_1,Z_2}$ distributions are also very well described by MiNNLO$_{PS}$, with the data fluctuating (within one sigma, except for one bin with a two-sigma deviation) around the central theoretical prediction across the whole plotted range.

The comparison at the level of integrated cross section in section 3.2 showed that the inclusion of NLO EW effects has a small, but non-negligible impact in the fiducial setup. Since in our comparison with data we include QED effects via parton-shower matching, one may wonder whether the proper inclusion of NLO EW effects in a Monte Carlo context, see e.g. ref. [42, 142], would further improve the agreement with the data, especially in the tails of distributions where EW logarithms are important. A possible way to assess the impact of the EW corrections beyond the parton shower approximation is to apply to the MiNNLO$_{PS}$ predictions a differential $K$-factor correction for the NLO EW corrections that is computed at fixed order accuracy.

We have done this exercise turning off the QED shower in the MiNNLO$_{PS}$ predictions.
Figure 7: Comparison between the MiNNLOPS predictions and the CMS data of ref. [27] based on a 137 fb$^{-1}$ 13 TeV analysis for various observables. The MiNNLOPS predictions include hadronization and MPI effects, as well as QED effects as provided by the PYTHIA8 parton shower. See text for more details.
to avoid double counting. The central rescaled prediction is shown in the lower ratio panels in figure 7. We adopt as our default a factor \(K_{\text{NLOEW}}^{(x)}\), defined using the multiplicative scheme \(\text{nNNLO} \times \text{NLO}_{\text{EW}}\) [48], which includes an estimate of mixed higher-order corrections, divided by the nNNLO result. Note that for distributions starting at NLO QCD we do not perform this additional comparison, since one would need to compute the EW corrections to the \(ZZ+1\)-jet process. We find that the inclusion of NLO EW corrections within this approximation improves the agreement with the experimental data for the tails of the \(m_{4\ell}\) and the averaged \(p_T,Z\) distributions, where the effects of Sudakov logarithms are expected to be visible. For the averaged \(p_T,\ell\) distribution their impact is a bit milder, also because the distribution extends to lower values, and there is no significant improvement compared to data. We leave a consistent inclusion of NLO EW effects in our MiNNLOPS predictions with a complete and consistent matching to QCD and QED showers to future work.

4 Conclusions

In this work, we have advanced the state-of-the-art for Monte Carlo simulations of \(Z\)-boson pair production at the LHC. For the \(q\bar{q}\)-initiated process we have matched NNLO QCD predictions to parton showers using the MiNNLOPS method. We have included the loop-induced \(gg\)-initiated process, which contributes at \(\mathcal{O}(\alpha_s^3)\), in the POWHEG-BOX-RES framework at NLO QCD accuracy matched to parton showers. When combined, the ensuing nNNLO+PS results constitute the most accurate theoretical predictions for this process to date. We remind the reader that the benefits of the MiNNLOPS approach reside in (1) the possibility to include NNLO corrections on-the-fly, without the need of any a-posteriori reweighting, (2) the absence of any merging scale or unphysical boundaries to partition the phase space into different regions according to the number of resolved emissions, and (3) the fact that the logarithmic accuracy of the parton shower is preserved by the matching (when using a \(p_T\)-ordered shower). We stress that this last feature is in general far from trivial.

We have performed an extensive comparison of our MiNNLOPS predictions against (n)NNLO fixed-order results and the analytic resummation in the transverse momentum of the four-lepton system. We found excellent agreement with fixed-order predictions in phase-space regions where shower effects are expected to be small. As expected, for distributions that have a singularity at fixed order the MiNNLOPS predictions feature the appropriate Sudakov damping close to the singularity and yield physical results. In particular, the comparison to the NNLO+N^3LL \(p_{T,4\ell}\) spectrum showed quite a remarkable agreement. Moreover, we have shown that MiNNLOPS corrections are at the level of 15-20% with respect to MiNLO', and that the matching to the parton shower is crucial for observables sensitive to soft-gluon effects. It is interesting to notice that we do not observe the mild tension in the \(p_T,e^-\) distribution observed in ref. [103] when comparing NNLO_{q\bar{q}}+PS to fixed-order predictions, which motivates a more comprehensive comparison between GENEVA and MiNNLOPS predictions in the future.

We have compared our nNNLO+PS predictions against 13 TeV CMS data of ref. [27] and found excellent agreement both at the level of production rates and shapes of kine-
matical distributions, with nNNLO+PS predictions and CMS data agreeing on almost all bins within one sigma. In the few bins where the differences are at the two-sigma level we have shown that the inclusion of NLO EW corrections removes those differences in most instances. Our final results have missing higher-order uncertainties that are of the order of 2% both for inclusive and fiducial cross sections. These uncertainties are of similar size as the current precision of experimental results, which will further decrease in the future. It is then clear that theoretical predictions with an accuracy comparable to that of the results presented in this paper are mandatory to fully exploit ZZ cross section measurements at the LHC. This is particularly the case when using ZZ production data for off-shell Higgs cross section measurements in the $H \rightarrow 4\ell$ channel to put bounds on the Higgs width, or when constraining the coefficients of effective-field-theory operators or anomalous triple-gauge couplings. It is interesting to note that, even though the loop-induced $gg$ contribution is only about 10% of the total cross section, its uncertainty dominates our final predictions. It is unlikely that a three-loop calculation for this process will become available in the near future. Still, the theoretical precision can be further improved if one imposes fiducial cuts that suppress the loop-induced gluon fusion contribution. For instance, when requiring a large invariant mass of the lepton system or when considering high-$p_T$ leptons, as done in BSM searches, the gluon-fusion contribution becomes less important since the gluon PDFs decrease strongly at large $x$ values. On the other hand, electroweak effects become more important in these regions. The approximate combination considered here, which already increases the agreement with the experimental data in the high-energy tails, needs to be improved by combining highest-order QCD and QED corrections consistently in parton-shower simulations in the future.

Since the evaluation of the two-loop contributions is numerically highly demanding, we made full use of the reweighting facility of POWHEG and introduced the possibility to evaluate the two-loop contributions only at the very end of the event generation, considerably speeding up the calculation. The code used for our simulations will be soon made publicly available within POWHEG-BOX-RES. We are confident that this will be valuable for upcoming experimental measurements of ZZ production at the LHC, which require an accurate and fully exclusive simulation of hadron-level events, including all-order, non-perturbative, and QED effects.

Acknowledgments

We are grateful to Stefano Forte, Pier Francesco Monni, Paolo Nason and Emanuele Re for various fruitful discussions. We thank the authors of ref. [54] for providing the $gg4l$ code and especially Jonas Lindert for very helpful communication. We have used the Max Planck Computing and Data Facility (MPCDF) in Garching and the cloud-computing facilities of the group of Massimiliano Grazzini at the University of Zurich to carry out the simulations related to this work. LB and LR are supported by the Swiss National Science Foundation (SNF) under contract 200020_188464.
