Background: Predictions of spectroscopic properties of low-lying states are critical for nuclear structure studies. Theoretical methods can be particularly involved for odd-mass nuclei because of the interplay between the unpaired nucleon and collective degrees of freedom. Only a few models have been developed for systems in which octupole collective degrees of freedom play a role.

Purpose: We aim to predict spectroscopic properties of odd-mass nuclei characterized by octupole shape deformation, employing a model that describes single-particle and collective degrees of freedom within the same microscopic framework.

Method: A microscopic core-quasiparticle coupling (CQC) model based on the covariant density functional theory is developed, which includes collective excitations of even-mass core nuclei and single-particle states of the odd nucleon, calculated using a quadrupole-octupole collective Hamiltonian combined with a constrained reflection-asymmetric relativistic Hartree-Bogoliubov model.

Results: Model predictions for low-energy excitation spectra and transition rates of odd-mass radium isotopes 223, 225, 227 Ra are shown to be in good agreement with available data.

Conclusions: A microscopic CQC model based on covariant density functional theory has been developed for odd-mass nuclei characterized by both quadrupole and octupole shape deformations. Theoretical results reproduce data in odd-mass Ra isotopes and provide useful predictions for future studies of octupole correlations in nuclei and related phenomena.

I. INTRODUCTION

Studies of reflection-asymmetric octupole shapes have been a recurrent theme of interest in nuclear structure physics over several decades. More recently, experimental evidence for stable octupole deformation in nuclei has been reported, e.g., in 224Ra [1], 144Ba [2], and 146Ba [3]. This type of shape deformation occurs predominantly in nuclei with neutron (proton) number N(Z) ≈ 34, 56, 88, and 134, characterized by the presence of low-lying negative-parity bands as well as pronounced electric octupole transitions [4, 5].

Octupole deformation in nuclei with an odd nucleon number has attracted specific interest in connection with observed parity-doublet structures and enhanced Schiff moments [4, 6–8]. In the last decade considerable effort has been devoted to studies of excited states in odd-mass nuclei characterized by static and dynamic octupole deformation [9–21]. New levels, transitions, and/or dipole moments have been measured for nuclei in different mass regions, e.g., neutron-rich nuclei around 144Ba [9–15], neutron-deficient nuclei approaching N, Z ≈ 56 [16, 17], heavy nuclei around 224Ra [18, 21]. Furthermore, it is expected that heavy odd-mass octupole-deformed nuclei, such as 225Ra, amplify atomic electric dipole moments (EDMs) and related nuclear Schiff moments that arise from time-reversal and parity-violating interactions in the nuclear medium [22–26]. Effects of symmetry violation are greatly enhanced in 225Ra by collective effects and a closely spaced parity-doublet structure resulting from octupole nuclear deformation [23, 25]. As a wealth of new data on odd-A systems become accessible, it is important to develop consistent and accurate models that can be employed in theoretical studies of their spectroscopic properties.

A variety of theoretical methods have been applied to studies of octupole nuclear shapes and the evolution of the corresponding negative-parity collective states: self-consistent mean-field approaches [22, 50], macroscopic+microscopic (MM) models [57, 59], algebraic (or interacting boson) models [60, 61], phenomenological collective models [62–67], and the reflection asymmetric shell model [68]. For the case of odd-A nuclei theoretical approaches include the particle-rotor model [69, 70], the cluster model [71], the reflection-asymmetric shell model [72], the interacting boson-fermion model [73, 74], etc. Microscopic calculations for odd-mass nuclei are generally more complex because, in addition to collective degrees of freedom, one has to explicitly consider single-particle degrees of freedom. To this end, nuclear energy density functionals (EDFs) generally present a good starting point since EDFs enable a complete and accurate description of ground-state properties, collective excitations, and decay properties over the entire chart of nuclides [75].
Recently several EDF-based approaches, e.g., the generator coordinate method (GCM) built on blocked one-quasiparticle states [83, 95], the interacting boson-fermion model (IBFM) [96], and the core-quasiparticle coupling (CQC) model [97] have been implemented for spectroscopic studies of odd-A quadrupole-deformed nuclei. Microscopic models for odd-A nuclei with octupole deformation are much less developed. Only very recently the IBFM was extended to include both quadrupole and octupole boson degrees of freedom and applied to a study of low-lying positive- and negative-parity spectra of odd-A $^{143-147}$Ba [39].

In this work we extend the microscopic core-quasiparticle coupling model of Ref. [97] to include both quadrupole and octupole deformations in reflection-asymmetric odd-mass nuclear systems, based on the framework of covariant EDFs [80, 84]. The major development is the inclusion of octupole correlations in both the even-even core Hamiltonian [50–52, 98], with parameters determined by the axially reflection-asymmetric relativistic Hartree-Bogoliubov model calculations, and the core-quasiparticle coupling terms. Also, the inclusion of both neighboring even-even cores in the configuration space enables the model to take into account shape polarization effects, that is, differences in shapes and related observables which are critical for transitional nuclei [99]. The present study is focused on the low-lying positive- and negative-parity spectra of odd-A $^{223,225,227}$Ra, located in the vicinity of the even-even nucleus $^{224}$Ra with static octupole deformation. Furthermore, $^{225}$Ra is a favorable case to search for a permanent electric dipole moment.

In Sec. [I] the model and self-consistent microscopic calculation of the parameters of the Hamiltonian are described. Illustrative results for spectroscopic properties, such as low-lying excitation spectra, electric transitions, and wave functions are discussed in Sec. [II]. Section [IV] contains a summary of the principal results.

II. THEORETICAL FRAMEWORK

A. Core-quasiparticle coupling model with quadrupole and octupole interactions

In the core-quasiparticle coupling scheme, the configuration space of the odd-A nucleus is composed of both a particle coupled to the lighter even-even neighbor $A - 1$ and a hole coupled to the heavier even-even neighbor $A + 1$. For an odd-A nucleus in which low-energy excitation spectra are determined by octupole correlations, both the ground-state bands and the lowest negative-parity bands of the even-even cores are included in the configuration space. The ansatz for the wave function of the odd-mass system can therefore be written in the following form:

$$\langle \alpha JMj \pi \rangle^A = \sum_{\mu\Omega} \left\{ U_{\mu\Omega} [a_{\mu}^\dagger |\Omega\rangle]_{JMj,\pi}^A + V_{\mu\Omega} [a_{\mu} |\Omega\rangle]_{JMj,\pi}^{A+1} \right\},$$

(1)

where the total angular momentum is $J$, its projection is $M$, $\pi$ denotes the parity, and $\alpha$ denotes all additional quantum numbers that characterize the state. $\mu$ denotes the angular momentum $j$, its projection $m_j$, parity $\pi_j$, and additional quantum numbers $\nu$ of single-particle states, while $\Omega$ is the generic notation for the angular momentum $R$, its projection $M_R$, parity $\pi_R$, and additional quantum numbers $\nu$ of collective states of the even-even core. The coefficients $U_{\mu\Omega}$ and $V_{\mu\Omega}$ represent the probability amplitudes for the particle-like and hole-like states, respectively, that are formed by coupling the spherical single-particle state $|\mu\rangle^{A-1}$ to the collective state $|\Omega\rangle^{A-1}$ of the core $A - 1$, and the spherical single-hole state $|\nu\rangle^{A+1}$ to the corresponding collective state $|\Omega\rangle^{A+1}$ of the core $A + 1$.

The Hamiltonian of the CQC model reads

$$H = H_{qp} + H_c = \left( \begin{array}{cc} (\epsilon^{A-1} - \epsilon_f) + \Gamma^{A-1} & \Delta^{A+1} \\ \Delta^{A+1} & -(\epsilon^{A+1} - \epsilon_f) - \Gamma^{A+1} \end{array} \right) + \left( \begin{array}{cc} E^{A-1} & 0 \\ 0 & E^{A+1} \end{array} \right).$$

(2)

The matrices $(\epsilon^{A+1} - \epsilon_f)$ and $(E^{A+1})$ are diagonal with respect to the basis states in the decomposition [1]:

$$\epsilon^{A+1} = \epsilon^{A-1} - \epsilon_f \delta_{\mu\nu} \delta_{\Omega\Omega'},$$

(3)

$$E^{A+1} = E^{A+1}_\Omega \delta_{\mu\nu} \delta_{\Omega\Omega'},$$

(4)

with the spherical single-particle energies $\epsilon^{A+1}_\mu$, Fermi surface $\epsilon_f$, and collective excitation energies $E^{A+1}_\Omega$. $\Gamma$ and $\Delta$ denote the mean field and pairing field that correspond to the long-range particle-hole and short-range particle-particle interactions, respectively. The quadrupole-quadrupole and octupole-octupole interactions determine the fields $\Gamma$, and a monopole pairing force is used for $\Delta$:

$$(\Gamma^{A\pm}) = -\chi_2 (-1)^j R^2 J^r \left\{ \begin{array}{ccc} j' & 2 & j \\
R^2 & J & R^2 \end{array} \right\} \left[ \langle \mu | \hat{Q}_2 | \mu' \rangle \langle \Omega | \hat{Q}_2 | \Omega' \rangle \right]^{A\pm}$$

$$- \chi_3 (-1)^j \left\{ \begin{array}{ccc} j & 3 & j' \\
R & J & R \end{array} \right\} \left[ \langle \mu | \hat{Q}_3 | \mu' \rangle \langle \Omega | \hat{Q}_3 | \Omega' \rangle \right]^{A\pm},$$

(5)

$$(\Delta^{A+1}) = (\Delta^{A-1}) = \langle \Omega, A - 1 | \hat{\Delta} | \Omega', A + 1 \rangle \delta_{\mu\nu} \delta_{\Omega\Omega'} \equiv (\Delta),$$

(6)

where $\langle \mu | \hat{Q}_\lambda | \mu' \rangle^{A\pm}$ and $\langle \Omega | \hat{Q}_\lambda | \Omega' \rangle^{A\pm}$ are the reduced quadrupole (\lambda = 2) and octupole (\lambda = 3) matrix elements of the spherical single-nucleon and core states, respectively. $\chi_2$ and $\chi_3$ are the corresponding coupling
strengths of the quadrupole and octupole fields. $\Delta_{\Omega}^{A\pm 1}$
denotes the average pairing fields in the collective states $|\Omega\rangle^{A\pm 1}$.
The Fermi surface $\varepsilon_f$ and coupling strengths $\chi_2$ and $\chi_3$ are free parameters that are adjusted to reproduce
the experimental ground-state spin and parity and/or the excitation energies of few lowest levels. Finally, the excitation energies $E_{\alpha J\pi}$ and eigenvectors $U_{\mu \Omega}$, $V_{\mu \Omega}$ are obtained as solutions of the eigenequation
following the method introduced in Ref. [109].

In its current version the CQC Hamiltonian Eq. (2) is formulated in the laboratory frame of reference. The deformation of single-nucleon orbitals is not static, rather it is induced dynamically by the quadrupole and octupole coupling terms in Eq. (5). In the Appendix of Ref. [101] an example for transforming the quadrupole coupling term to the principal-axis system of the core (intrinsic frame) is discussed (cf. Eq. (A2) in Ref. [101]). By combining the resulting deformed potential with the spherical quasiparticle Hamiltonian, one obtains the familiar form of the quasiparticle rotor model. Similarly, in the model used in the present work the quadrupole-quadrupole and octupole-octupole interactions between the core nucleus and the odd-nucleon in Eq. (5) will play the same role and induce the right deformation for the odd-nucleon orbitals.

The electromagnetic multipole operator consists of single-nucleon and collective parts:

$$\hat{M}_{\lambda \nu} = \hat{M}_{\lambda \nu}^{s.p.} + \hat{M}_{\lambda \nu}^c.$$ 

The corresponding reduced transition matrix element between states $|\alpha_i J_i \pi_i\rangle$ and $|\alpha_f J_f \pi_f\rangle$ reads

$$\langle \alpha_f J_f \pi_f | \hat{M}_{\lambda} | \alpha_i J_i \pi_i \rangle = \sqrt{(2J_f + 1)(2J_i + 1)} \sum_{\Omega, \mu, \Omega_i} (-1)^{j_f + j_i + R + \lambda} \begin{bmatrix} J_f & \lambda & J_i & \mu \\ i & j & J_f & \mu \end{bmatrix} \left[ M_{\mu \Omega}^{s.p.} + M_{\mu \Omega}^c \right]$$

with

$$M_{\mu \Omega}^{s.p.} = U_{\mu \Omega}^{f} U_{\mu \Omega}^{i} \langle \mu_f | \hat{M}_{\lambda}^{s.p.} | \mu_i \rangle |\Omega_f\rangle^{A-1},$$

$$M_{\mu \Omega}^c = V_{\mu \Omega}^{f} V_{\mu \Omega}^{i} \langle \mu_f | \hat{M}_{\lambda}^c | \mu_i \rangle |\Omega_f\rangle^{A-1},$$

The explicit expressions for the reduced matrix elements of the electric dipole, quadrupole, and octupole operators are given in Sec. [113].

B. Microscopic inputs based on covariant EDFs

The full dynamics of the CQC Hamiltonian Eq. (2) is determined by the energies $\varepsilon_{\mu}^{A\pm 1}$ and $E_{\Omega}^{A\pm 1}$, quadrupole matrix elements $\langle \mu | \hat{Q}_2 | \mu' \rangle^{A\pm 1}$ and $\langle \Omega | \hat{Q}_2 | \Omega' \rangle^{A\pm 1}$, octupole matrix elements $\langle \mu | \hat{Q}_3 | \mu' \rangle^{A\pm 1}$ and $\langle \Omega | \hat{Q}_3 | \Omega' \rangle^{A\pm 1}$, and pairing gaps $\Delta_{\Omega}^{A\pm 1}$. In the following the superscript $A \pm 1$ will be omitted for convenience. In this particular study we will calculate the input for the CQC model using an axially reflection-asymmetric implementation of the relativistic Hartree-Bogoliubov (RHB) model [20], combined with the quadrupole-octupole collective Hamiltonian [52]. The RHB model provides a unified description of particle-hole ($ph$) and particle-particle ($pp$) correlations on a mean-field level by combining two average potentials: the self-consistent mean field that encloses long range $ph$ correlations and a pairing field $\Delta$ which sums up $pp$ correlations. In the present analysis, the mean-field potential is determined by the relativistic density functional PC-PK1 [102] in the $ph$ channel, and a separable pairing force [103] is used in the $pp$ channel. PC-PK1 denotes a parametrization for the covariant nuclear energy density functional with nonlinear point-coupling interactions, that was adjusted in a fit to ground-state properties of 60 selected spherical nuclei, including binding energies, charge radii, and empirical pairing gaps [102].
In the first step of the construction of the CQC Hamiltonian [2], a constrained RHB calculation for spherical configurations of the even-mass cores is carried out to determine the single-nucleon states |µ⟩ and corresponding energies εµ, and the quadrupole (λ = 2) and octupole (λ = 3) matrix elements

\[
\langle \mu | Q_\lambda | \mu' \rangle = \langle n_{\mu} | r^\lambda Y_\lambda | n'_{\mu'} \rangle = (-1)^{j + j' + 1 + \lambda} \frac{(2\lambda + 1)(2j + 1)}{4\pi} C_{j' j \lambda 0}^{2} \langle n_{\mu} | r^\lambda | n'_{\mu'} \rangle,
\]

where \( C_{j' j \lambda 0}^{2} \) are the corresponding Clebsch-Gordan coefficients.

In the next step a constrained, axially reflection-asymmetric RHB calculation for the entire energy surface as function of the quadrupole deformation β2 and octupole deformation β3 is performed to compute the microscopic input, i.e., the moments of inertia \( I \), collective masses \( B_{22}, B_{23}, B_{33} \), and the potential \( V_{\text{coll}} \) for the quadrupole-octupole collective Hamiltonian (QOCH) of the even-mass core [52]:

\[
\hat{H}_{\text{coll}} = - \frac{\hbar^2}{2\sqrt{wL}} \left[ \frac{\partial}{\partial \beta_2} \sqrt{I \frac{w}{B_{33}}} \frac{\partial}{\partial \beta_2} - \frac{\partial}{\partial \beta_3} \sqrt{I \frac{w}{B_{23}}} \frac{\partial}{\partial \beta_3} \right] + \frac{j^2}{2I} + V_{\text{coll}}(\beta_2, \beta_3).
\]

\( J_\perp \) denotes the component of angular momentum perpendicular to the symmetric axis in the body-fixed frame of the core. The Coriolis interaction is contained in the rotational term of QOCH because of \( J_\perp = J - j \), where \( J \) and \( j \) are the total angular momentum of the odd-A nucleus and angular momentum of the single nucleon, respectively. In addition to the rotational term, we also include the vibrational term and the collective potential in Eq. (15), and this enables a description of more complex excitation modes, e.g., phonon excitations and shape coexistence. The additional quantity that appears in the vibrational kinetic energy, \( w = B_{22}B_{33} - B_{23}^2 \), determines the volume element in the collective space,

\[
\int d\tau_{\text{coll}} = \int \sqrt{wL} d\beta_2 d\beta_3 d\Theta,
\]

where \( \Theta \) are the Euler angles.

The eigenvalue problem of the collective Hamiltonian [15] is solved using an expansion of eigenfunctions in terms of a complete set of basis functions that depend on the collective coordinates \( \beta_2, \beta_3 \), and \( \Theta \) [52]. The collective wave functions are thus obtained as

\[
\Psi_\Omega(\beta_2, \beta_3, \Theta) = \psi_{n_\Omega R_{\pi R}}(\beta_2, \beta_3) |RM_R0\rangle.
\]

The corresponding reduced matrix elements and average pairing gaps are calculated using the expressions

\[
\langle \Omega | Q_\lambda | \Omega' \rangle = \sqrt{2R + 1} C_{R_0}^{00} \times \int d\beta_2 d\beta_3 \sqrt{wL} \psi_{n_\Omega R_{\pi R}}(\beta_2, \beta_3) \psi_{n_\Omega R_{\pi R}}(\beta_2, \beta_3),
\]

where \( q_\lambda(\beta_2, \beta_3) \) and \( \Delta(\beta_2, \beta_3) \) are the mass quadrupole (λ = 2) and octupole (λ = 3) moments and pairing gaps, respectively, computed from the RHB intrinsic state at each point on the deformation surface (β2, β3).

In the case of electric dipole transitions the reduced matrix elements for the single-nucleon states are calculated from:

\[
\langle \mu | \hat{D}_1 | \mu' \rangle = e_\tau (-1)^{j + j'} \frac{3(2j' + 1)}{4\pi} C_{j' j 0}^{2}(n_{\mu} | r | n'_{\mu'}),
\]

with \( e_\tau = \frac{N}{A} e \) for the odd proton and \( e_\tau = -\frac{Z}{A} e \) for the odd neutron. For the even-even core:

\[
\langle \Omega | \hat{D}_1 | \Omega' \rangle = \sqrt{2R + 1} C_{R_0}^{010} \times \int d\beta_2 d\beta_3 \sqrt{wL} \psi_{n_\Omega R_{\pi R}}(\beta_2, \beta_3) \psi_{n_\Omega R_{\pi R}}^\ast(\beta_2, \beta_3),
\]

where \( D_1(\beta_2, \beta_3) \) is the electric dipole moment calculated from the RHB intrinsic state using the dipole operator

\[
\hat{D}_1 = \sqrt{\frac{3}{4\pi}} e \left( \frac{N}{A} z_p - \frac{Z}{A} z_n \right).
\]

III. RESULTS AND DISCUSSION

As an illustrative application of the microscopic CQC model, we consider the case of a single neutron coupled to an axially symmetric octupole-deformed even core: the spectroscopy of 223,225,227Ra, for which extensive data are available. Furthermore, we note that 225Ra is the nucleus of choice in the search for a permanent electric dipole moment. The corresponding even-core nuclei 222–228Ra present good examples of axially symmetric octupole-deformed systems, as shown by the deformation energy surfaces in Fig. 1. All four core nuclei 222–228Ra exhibit a global minimum with \( \beta_3 > 0.1 \) and octupole deformation energy \( \Delta E_{\text{oct}} > 0.4 \text{ MeV} \). As the neutron number increases, both the octupole deformation and \( \Delta E_{\text{oct}} \) increase from 222Ra to 226Ra, and then start to decrease from 228Ra. The isotope 226Ra exhibits the deepest octupole minimum with \( \Delta E_{\text{oct}} \approx 0.94 \text{ MeV} \). Similar deformation energy surfaces of Ra isotopes have also been
basis are included. For the collective states of the core nuclei, we include the following states: $0^+_1$, $2^+_1$, $1^+_2$, $3^+_1$, $1^+_2$, $3^+_2$, $1^+_1$, $3^+_2$, and $1^+_2$ in the positive-parity ground-state band and $1^+_1$, $3^+_1$, $1^+_2$, $3^+_2$, in the lowest negative-parity band.

Before discussing the full spectrum, in Fig. 3 we show the evolution of quasiparticle energies [eigenenergies of $H_{qp}$ in Eq. (3)] relevant for the bandheads of the low-energy spectra of $^{229}$Ra: $J^\pi = 1/2^\pm, 3/2^\pm$, and $5/2^\pm$, as functions of the octupole coupling strength $\chi_3$. One clearly observes the parity doublet structure of the bandheads. In particular, we note the pronounced dependence of the $J^\pi = 1/2^\pm$ states on the strength of the octupole interaction.

On this and the following pages we group, by isotope, the figures with the excitation spectra and the tables with the dominant configurations. Figure 4 displays the low-lying excitation spectrum of the odd-mass nucleus $^{223}$Ra calculated with the CQC model, in comparison with available experimental data [104]. The levels are grouped into different bands according to the dominant decay pattern. Here six low-lying bands with bandheads $J^\pi = 3/2^\pm, 5/2^\pm$, and $3/2^\pm$ are shown, and they are displayed as three parity doublets. The ground-state band and its partner are well reproduced by the CQC model, especially the very small energy difference $\approx 50$ keV between the two bandheads. In Table I we also list the probabilities of dominant configurations in the wave functions of selected states in the ground-state band and band 2 of $^{223}$Ra. The parity doublet is dominated by the strongly mixed configurations of $3d_{5/2}$ and $2g_{9/2}$ for the low-spin states, and gradually the $1i_{11/2}$ configuration becomes dominant for high-spin states. Note that both the ground-state band and band 2 are predominantly built by coupling the single neutron to the corresponding positive-parity and negative-parity bands in the core nuclei, respectively. There is no mixing between opposite-parity bands of the cores in the yrast states, and this points to weaker octupole correlations compared to $^{225}$Ra and $^{227}$Ra below. For the second parity doublet, i.e., bands 3 and 4, in Fig. 4 the overall structure is reproduced but the theoretical bandheads are $\approx 130$ keV lower than the corresponding experimental levels. We can also obtain the $J^\pi = 1/2^\pm$ parity doublet and compare it with the experimental spectrum. However, the theoretical results exhibit opposite staggering, possibly due to a weaker Coriolis coupling, and this could be solved by adding a magnetic dipole particle-core interaction term [106].

In Fig. 5 and Table I we display the excitation spectrum and the dominant configurations in the wave functions of states in $^{225}$Ra, respectively. In general, the low-lying excitations and parity doublet structure are reproduced by the CQC model, except the staggering behavior of the ground-state $K = 1/2$ band. The ground state $J^\pi = 1/2^+$ and its parity partner $J^\pi = 1/2^-$ in band 2 are particularly interesting because they are associated with the enhancement of the Schiff moment [23][25]. Here we obtain a good description for both the excitation en-

---

1 DD-PC1 denotes a parametrization for the covariant nuclear energy density functional with density-dependent point-coupling interactions. It was adjusted in a fit to the experimental masses of a set of 64 deformed nuclei in the mass regions $A \approx 150 - 180$ and $A \approx 230 - 250$ [105].
energy and electric transition rates, as shown in Table IV.
In Table II the pronounced mixing between positive- and negative-parity single-particle states and collective states of the cores reflects a strong octupole coupling between the odd neutron and the even-even cores.

Figure 2 and Table III contain the results for $^{227}$Ra. The structure of bands is similar to that found in $^{223,225}$Ra. Bands 1, 2 and bands 3, 4 form two parity-doublet sequences. The low-lying band 5 is also reproduced but the partner band of opposite parity has not been determined in experiment. Band 6 is the corresponding theoretical prediction. The ground-state band and its partner band in $^{227}$Ra are characterized by pronounced octupole correlations that are reflected in the mixing of positive- and negative-parity core states. One also notices that the lowest band structure of $^{227}$Ra is mainly built on the configurations with a neutron hole coupled to the heavier core $^{229}$Ra.

Tables IV and V collect the results for intraband and interband electric quadrupole $E2$ transition rates and interband electric dipole $E1$ and octupole $E3$ transition rates.

The overall agreement between theoretical predictions and experiment values is satisfactory, especially considering that the present calculation includes the full configuration space and, therefore, does not contain adjustable parameters in the form of effective charges. More specifically, most of the intraband \(E2\) transition rates are reproduced very well, while the calculated interband \(B(E2)\) values appear to be somewhat smaller than the experimental values. The theoretical \(B(E1)\) values are generally large when compared to the data, but they are of the same order of magnitude. Some of these values are large, which is consistent with the pronounced octupole correlations predicted in these nuclei. Octupole correlations can be quantified by the calculated \(E3\) transition rates in Table V where rather large \(B(E3)\) values are predicted and they increase with angular momentum. In the Supplemental Material \([107]\) we also include model predictions for the intraband and interband \(B(E2)\), and interband \(B(E1)\), and \(B(E3)\) values of \(^{223,225,227}\text{Ra}\) in Tables S1, S2, and S3, respectively.  

### IV. SUMMARY

In summary, we have extended our microscopic CQC model to odd-mass nuclei characterized by both quadrupole and octupole shape deformations. The dynamics of the CQC Hamiltonian is determined by micro-
especially the parity doublets, intraband and interband results reproduce the available data on band structure, spectra for the odd-A nuclei have been put to the test in a study of low-lying excitation energies of few lowest states. The model has been used to study the parity doublets, pronounced octupole correlations in the low-energy structure predicted for 223–227Ra. The theoretical results reproduce the available data on band structure, especially the parity doublets, intraband and interband B(E2), and interband B(E1). The near degeneracy of the parity doublets, pronounced E1 transitions, and large predicted B(E3) values indicate the importance of pronounced octupole correlations in the low-energy structure of 223,225,227Ra.
