ABSTRACT

We present a semi-analytical method to investigate the systematic effects and statistical uncertainties of the calculated angular power spectrum when incomplete spherical maps are used. The computed power spectrum suffers in particular a loss of angular frequency resolution, which can be written as $\delta \ell \sim \pi / \gamma_{\text{max}}$, where $\gamma_{\text{max}}$ is the effective maximum extent of the partial spherical maps. We propose a correction algorithm to reduce systematic effects on the estimated $C_\ell$, as obtained from the partial map projection on the spherical harmonic $Y^m_\ell$ basis. We have derived near optimal bands and weighting functions in $\ell$-space for power spectrum calculation using small maps, and a correction algorithm for partially masked spherical maps that contain information on the angular correlations on all scales.

1 INTRODUCTION

The measurement of the temperature and polarisation anisotropies of the Cosmic Microwave Background (CMB) radiation provides essential information for testing the cosmological models and determining their parameters. Most of the statistical information present in the CMB temperature or polarisation sky maps can be encoded in the angular power spectrum $C_\ell$. An overview of the physical mechanisms responsible for the CMB anisotropies and the effect of the cosmological parameters on the power spectrum shape can be found in (Zaldarriaga et al 1997) and (Hu & Dodelson 2002).

The following references give an overview of some recent CMB power spectrum measurements: The all sky WMAP (Wilkinson Microwave Anisotropy Probe) space mission (Nolta et al 2009), Larson et al (2010)); ACBAR (Reichardt et al 2009) which has made high resolution measurements using the Viper telescope at South Pole Station; the South Pole Telescope - SPT (Lueker et al 2009); the Cosmic Background Imager-CBI (Mason et al 2003) and the ACT telescope (Fowler et al 2010) in the Atacama desert; the polarisation measurement at Amundsen-Scott South Pole Station by the Degree Angular Scale Interferometer - DASI (Carlstrom et al 2003); as well as balloon borne experiments such as BOOMERANG (Jones et al (2006), Masi et al (2006)), Archeops (Benoit et al (2003), Tristram et al (2005)) and MAXIMA (Lee et al 2001). Table 1 summarizes typical sky coverage, the accessible $\ell$ range, and microwave frequency range for some of the above mentioned instruments.

Determining the CMB angular power spectrum is a complex process and the data analysis must take into account a number of effects, such as the non-stationary noise contribution, non-circular instrumental beams, the sky scanning strategy and foreground contamination. A review of the general methods for CMB data processing can be found, for example, in (Tristram & Ganga 2005).

The different systematic and statistical effects on CMB angular power spectrum estimates from partial sky maps have already been studied in length. In particular, several Montecarlo or analytical methods have been devised to evaluate or correct the impact of limited sky coverage on estimated angular power spectrum (Hivon et al (2002), Mitra et al (2009), Das et al (2009)).

In this paper we propose a different approach which is based on the analysis of the distortion of the angular correlation function. However, it should be noted that explicit computation of the angular correlation function is not needed. The use of the correlation function has also been studied by several authors, although with a different approach than the one developed here (Szapudi et al (2001a), Szapudi et al (2001b)). In section 2, we recall briefly the main relations between the angular correlation function $\xi(\gamma)$ and the angu-
lar power spectrum $C_{\ell}$, and express them as a set of linear algebraic equations. Using this formalism in section 3, we compute the distortion of the estimated $C_{\ell}$ in incomplete sky maps and we show how the angular correlation function can be corrected to minimize these distortions. We show in particular that power spectrum estimates on partial maps suffer a loss of resolution in $\ell$-space and we propose near optimal $\ell$-space window function (binning).

The algebraic approach presented in section 3 can not be used to compute the variance of the reconstructed angular power spectrum (see paragraph 3.1 and 3.4). We have thus used Montecarlo simulations to estimate $C_{\ell}$ uncertainties.

We present in section 4 the corresponding results for small maps ($\Omega \approx 4 \pi \times 10^{-2}$), representative of ground or balloon experiments such as OILMPO (Nati et al 2007), as well as the systematic shifts and possible correction for nearly complete maps ($\Omega \approx 4 \pi \times 0.9$) representative of space missions such as Planck (Planck Coll. 2006).

2 ANGULAR CORRELATION FUNCTION AND POWER SPECTRUM FROM THE FULL SPHERE

We recall here the basic relations for the angular power spectrum and correlation function. Detailed derivation of most of these formulae can be found in (Magneville & Pansart 2007) or (Wandelt et al 2001).

We consider a real signal $s(\Omega)$ on the sphere ($S^2$), measured for each direction $\Omega = (\theta, \phi)$. The function $s$ can be expanded on the spherical harmonic basis:

$$ s(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} a_{lm} Y_{lm}^*(\theta, \phi) $$

(1)

$$ a_{\ell m} = \int_{S^2} s(\Omega) Y_{\ell m}(\Omega^*) d\Omega $$

(2)

For an isotropic random signal, the angular power spectrum $C_{\ell}$ characterizes the statistical properties of the signal ($\langle \rangle$ denotes ensemble average).

$$ \langle a_{\ell m} a_{\ell' m'}^* \rangle = \delta_{\ell-\ell'} \delta_{m-m'} C_{\ell} $$

(3)

It is possible to compute an unbiased power spectrum estimator $\hat{C}_{\ell}$ from the spherical harmonic expansion coefficients with variance $\sigma_{\hat{C}_{\ell}}^2$ (cosmic variance):

$$ \hat{C}_{\ell} = \frac{1}{2\ell + 1} \sum_{m=-\ell}^{\ell} |a_{\ell m}|^2 $$

(4)

$$ \langle \hat{C}_{\ell} \rangle = C_{\ell} $$

$$ \sigma_{\hat{C}_{\ell}}^2 = \frac{2}{2\ell + 1} C_{\ell}^2 $$

(5)

For an isotropic signal, the angular correlation function $\xi(\gamma)$ can also be used to characterize the signal properties, where $\gamma$ is the separation angle ($\cos \gamma = \Omega \cdot \Omega'$):

$$ \xi(\gamma) = \frac{1}{4\pi} \sum_{l=0}^{\infty} (2l + 1) \hat{C}_l P_l(\cos \gamma) $$

(6)

$$ C_{\ell} = 2\pi \int_{-1}^{1} \xi(\gamma) P_l(\cos \gamma) d\cos \gamma $$

(7)

It should be noted that the above relation holds also for the computed angular correlation function ($\xi(\gamma)$) and power spectrum ($\hat{C}_{\ell}$) for a given sky realization.

$$ \xi(\gamma) = \frac{1}{4\pi} \sum_{l=0}^{\infty} (2l + 1) \hat{C}_l P_l(\cos \gamma) $$

(8)

$$ N(\gamma) = \frac{1}{\int_{S^2 \times S^2} \delta(\cos \gamma - \Omega \cdot \Omega') d\Omega d\Omega' = 8\pi^2} $$

(9)

The above relations, analogous to Fourier series, contain algebraic (sum) and analytic (integral) expressions, and involve the discrete variable $\ell \in \mathbb{N}$, as well as the continuous variable $\gamma \in [0, \pi]$. We can rewrite these expressions in a purely algebraic form, similar to the Discrete Fourier Transform (DFT). Indeed, if the $C_l$ spectrum is negligible for large $\ell > \ell_{\text{max}}$, and for any set of discrete values $\{\gamma_i\}$ of the $\gamma$ angle, the relations 6 and 8 can be written in matrix form:

$$ \{\xi(\gamma_i)\} = [\xi] = [K]\{\xi\} = [K]\{\xi\} $$

(9)

In the particular case where the number of $\gamma_i$ values is equal to the $\ell_{\text{max}} + 1$ non-zero $C_{\ell}$ values, the $[K]_{ij}$ matrix would be square. It can then be shown that the separation angles $\gamma_i$ at which the correlation function $\xi$ is computed ($\xi_i = \xi(\gamma_i)$), could be chosen such that the square matrix $[K]_{ij}$ of size $(\ell_{\text{max}} + 1) \times (\ell_{\text{max}} + 1)$ is non-singular (see appendix). The equation (9) may thus be inverted to get:

$$ [C] = [K]^{-1} \{\xi\} $$

(10)
Moreover, these $\gamma_i$ values are not very different from $\ell_{\text{max}} + 1$ equidistant $\gamma_i$ distributed from 0 to $\pi$, with the matrix elements close to $[|K|^2]_{\ell,i} \propto P_\ell(\cos \gamma_i)$.

3 ANGULAR POWER SPECTRUM FROM PARTIAL MAPS

3.1 Angular correlation function distortion

The above equation (10) can be used to analyse the impact of any linear distortion of $\xi$ on the calculated $C_\ell$. Any linear distortion of the angular correlation function (including truncation for $\gamma > \gamma_{\text{max}}$) can be represented by a matrix $[[D]]$ applied to $\xi$.

$$
\langle [\xi(\gamma)]^4 \rangle = \langle [D]^4 \rangle + \langle [\xi(\gamma)]^2 \rangle
$$

$$
\langle [C|^{\gamma} \rangle = \langle [K]^{-1} [D] [K] \rangle [C]\rangle
$$

$$
\langle [C|^{\gamma} \rangle = [[B]] \ast [C]\rangle
$$

$$
[[B]] = [[K]^{-1} [D] [K]]
$$

(11)

It should be stressed that in most cases, we can only compute the mean distortion caused by the measurement process, in particular due to the incomplete coverage. The above relations will not hold in general for a given realization or a single measurement. It will only be valid when an ensemble average is taken for the angular correlation function and power spectrum. This explains why it can not be used to estimate statistical uncertainties on the computed power spectrum.

Using the formalism described above, we have computed the effect of distorting or modifying the angular correlation function in some typical cases such as:

- Application of a sharp or a smooth cut $\xi(\gamma) \rightarrow \xi^c(\gamma) = \xi(\gamma) \ast \text{Cut}(\gamma)$ to the angular correlation function. In the case of a sharp cut, $\xi(\gamma)$ is set to zero for $\gamma > \gamma_{\text{max}}$ (step function cut).
- Undersampling $\xi$, by a factor $p > 1$, i.e. $\xi$, known only for $i = k \times p$
- Binning effect, where $\xi(\gamma)$ is replaced by the mean value of $\xi$ in a small interval around $\gamma_i$. The binning can represent the distortion of the $\xi$ when computed through the histogram of all pixel pair products $s(\hat{\Omega} \ast \hat{\Omega})$, binned as a function of their separation angle $\gamma$ ($\hat{\Omega} \cdot \hat{\Omega} = \cos(\gamma)$).

Figure 1 illustrates the effect of restricting the $\gamma$ range to $\gamma_{\text{max}} = 30^\circ$ (i.e. setting $\xi(\gamma) = 0$ for $\gamma > \gamma_{\text{max}}$, (left) and the undersampling (right). Restricting the range of angles for $\xi(\gamma)$, creates a correlation between different $\ell$ while undersampling produces an aliasing effect. Both of these effects are analogous to well known effects in standard Fourier analysis.

3.2 Partial maps : truncated $\xi^c(\gamma)$

When the angular correlation function is calculated from maps with a maximal extent $\gamma_{\text{max}}$, nothing can be known on the correlation function for $\gamma > \gamma_{\text{max}}$. In addition, the statistical errors on the estimated correlation function will be larger compared to the one computed on the corresponding full $(4\pi)$ map. It is well known that computing the angular power spectrum from a truncated $\xi^c(\gamma)$ using the integral equation (7) or the linear combination equation (10) produces spurious oscillations. However, these oscillations can be filtered out if the resulting power spectrum is binned.

$$
\langle \hat{C}_\ell \rangle = [[B]] \ast [C]\rangle
$$

$$
\hat{C}_\ell = \sum_{\ell} w_\ell(\ell) \hat{C}_\ell
$$

(12)

The filtered or weighted power spectrum $\hat{C}_\ell$ defined here is obtained by applying the weight function $w_\ell(\ell)$ to the power spectrum $C_\ell$. The weight function should be centered around $L$ and normalised such that $\sum_{\ell} w_\ell(\ell) = 1$. The $w_\ell(\ell)$ would be in general positive, with a maximum for $\ell = L$ and decreasing to zero $(w_\ell(\ell) \rightarrow 0)$ when $|\ell - L|$ increases. The expectation value of the filtered spectrum can then be expressed using the weight matrix $[[W]]_{L,L} = w_\ell(\ell)$:

$$
\langle \hat{C}_\ell \rangle = [[W]] \ast [[B]] \ast [C]\rangle
$$

(14)

$$
\langle \hat{C}_L \rangle = [[B_{\text{w}}]] \ast [C]\rangle
$$

(15)

We have computed the matrix $[[B_{\text{w}}]]$ relating true expectation values of $C_\ell$ to mean value of the weighted power spectrum $\langle \hat{C}_\ell \rangle$ from truncated angular auto-correlation function. The results shown here correspond to $\langle \xi(\gamma) \rangle$ truncated above $\gamma_{\text{max}} = 30^\circ$, for Gaussian or square (step-wise) weight functions. Figure 2 shows one of the rows of the $[[B_{\text{w}}]]$ matrix around $\ell \sim 500$ for different weight functions. For Gaussian weights width $\sigma \geq \frac{\pi}{\gamma_{\text{max}}}$ the effective $\ell$-space window or filter function becomes numerically very close to the corresponding Gaussian function. It can be seen also that applying top hat or square weights result in an effective window function significantly different from the corresponding square function. We have checked that this property and the value of optimal weight function width $\sigma \geq \frac{\pi}{\gamma_{\text{max}}}$ does not depend on the value of the central $L$, at least for large enough $L \geq \sigma_L$.

Our computation and simulations suggest that a Gaussian function with a width $\Delta \ell \sim \sigma_L = \frac{\pi}{\gamma_{\text{max}}}$ is a near optimal binning when the angular power spectrum is calculated from partial maps with maximum angular extent $\sim \gamma_{\text{max}}$. The word “optimal” should be understood in its common sense, and not the mathematical one, as the optimal solution depends on the chosen quantitative criteria. For example, different binning should be used if one seeks to increase the spectral resolution or if one is concerned by the statistical errors. As explained above, the suggested Gaussian binning has the following properties:

- The Gaussian weighted corrected angular spectra reduces the window function tails by an order of magnitude, compared to pseudo-$C_\ell$, while maintaining the $\ell$-space resolution as well as similar statistical uncertainties (see section 4). Using top hat (square) binning yields a window function with long tails and oscillations.
- The resulting true $\ell$-space window function is nearly identical to the weight or filter function applied to the computed $C_\ell$, with a simple analytical expression (Gaussian). This property is useful for presenting measured power spectra.

When the power spectrum is estimated using incomplete spherical maps, a loss of resolution in angular frequen-
cies ($\Delta l \sim \pi/\gamma_{\text{max}}$) can also be understood using linear combinations of Legendre polynomial. We define new functions $Q_L$, through linear combinations of Legendre polynomials around a given $L$, with Gaussian weights:

\[
Q_L^\gamma = \frac{1}{2\pi} \sum_l \exp \left[ \frac{(l-L)^2}{2\sigma_l^2} \right] P_l \\
\Sigma w = \sum_l \exp \left[ \frac{(l-L)^2}{2\sigma_l^2} \right] \\
Q_L^\gamma (\cos \gamma) \approx P_l (\cos \gamma) \quad \gamma < \pi/\sigma_l \\
Q_L^\gamma (\cos \gamma) \approx 0 \quad \gamma > \pi/\sigma_l
\]

Note that these new functions $Q_L(\cos \gamma)$ behave like $P_L(\cos \gamma)$ at small angles ($\gamma \lesssim \gamma_{\text{max}} = \pi/\sigma_l$) and become negligible at large angles ($\gamma \gtrsim \gamma_{\text{max}} = \pi/\sigma_l$). This property is illustrated on the figures 3 and 4. It might be possible to use these $Q_L$ functions as a basis to decompose truncated angular correlation functions.

### 3.3 Partial maps : Decomposition on the $Y^m_l$ basis

As we mentioned in section 2, a signal defined as a function of direction can be decomposed in spherical harmonics (see equation (1)). Optimized algorithms for performing numerically this decomposition on pixelized spherical maps are commonly used in analyzing CMB data (Muciaccia et al 1997, Gorski et al 2005). The computed $a_{\ell m}$ coefficients are used to derive the angular power spectrum $C_\ell$ using equation (4). When an incomplete (or partial) sky map is expanded on the $Y^m_l$ basis, the resulting power spectrum suffers systematic effects and is often called a pseudo-$C_\ell$ spectrum. The pseudo–$C_\ell$ spectrum distortion has already been studied by several authors and can be found for example in (Hivon et al 2002, Magneville & Pansart 2007).

The partial map can be written as the result of applying a mask on the original signal. One can then show that the $\tilde{a}_{\ell m}$ coefficients computed on the masked map can be related to the true $a_{\ell m}$ through a linear relation, which can be written in matrix form:

\[
s^\gamma(\theta, \phi) = s(\theta, \phi) \times \text{mask}(\theta, \phi) \\
[\tilde{a}_{\ell m}] = [[A]] \times [a_{\ell m}]
\]

The above relation is completely general, independent of the statistical properties of the signal $s(\theta, \phi)$ and valid for each realization. The $[[A]]$ matrix coefficients depend on the mask spherical harmonic decomposition and Clebsch-Gordan coefficients. Then, using the isotropy of the signal, it is possible to compute the coupling matrix $[[B_{\ell \ell'}]]$ relating the pseudo–$C_\ell$ power spectrum to the true angular power spectrum. Although $[[A]]$ is a huge matrix, ($\sim 2 \times 10^6 \times \times 2 \times 10^6$ elements for $\ell_{\text{max}} = 1000$), only a small fraction of the elements contribute to the $[[B_{\ell \ell'}]]$ matrix.

\[
[[C_\ell^\gamma]] = [[B_{\ell \ell'}]] \times [C_\ell]
\]

The computations to obtain the $[[B_{\ell \ell'}]]$ coupling matrix using the above method are rather tedious, while it is possible to compute this matrix simply by applying the formalism presented in this paper.

One can construct an estimator $\xi'$ of the angular correlation function using equation (8) with the integrals limited to the partial map where the function $s(\Omega)$ is measured. A lengthy computation (Magneville & Pansart 2007) shows that this estimator is unbiased for separation angles $\gamma < \gamma_{\text{max}}$. However a fast computation of the angular corre-

Partial CMB maps: bias removal, optimal binning of $C_\ell$  

Figure 2. Weighted $\tilde{C}_\ell^i$ calculation truncated $\xi$ at $\gamma_{\text{max}} = 30^\circ$.  
Top: Row of the weighted CBT matrix ($[|\mathbf{B}_{\ell W}|]$) around $L \sim 500$ for Gaussian weights ($B_{\ell W G}$) with three different widths $\sigma_L = 4, 6, 8$. Bottom: Comparison of $B_{\ell W}$ matrix row for $L \sim 500$ with the corresponding Gaussian weights ($\sigma_L = 6$), in blue and top hat (square) weighted ($B_{\ell W SP}$, width = $6 \times \sqrt{12} = 20.8$) in red.

Figure 3. Legendre Polynomial and $Q_L = \sum P_L$ functions, plotted for $L = 100$ and $\sigma_L = 5, 10, 20$. We have plotted $|P_L|, |Q_L|$. Notice also that both axes have logarithmic scales.

Figure 4. Legendre Polynomial $|P_L|$ and and the $|Q_L|$ functions, plotted for $\sigma_L = 5$, and $\Theta = 20, 100, 200, 1500$. Notice that both axes have logarithmic scales.

The distortion function uses equation (6) or its linear form (9) and the full sphere function should be used. This corresponds to equation (8) with integrals on the full sphere $S^2 \times S^2$ putting $s(\Omega) = 0$ when $\Omega$ is not pointing to the “observed” partial map. This estimator (noted $\hat{\xi}^p$, which is of course highly biased, will be the one used hereafter.

As $\xi^p$ and $\hat{\xi}^p$ are related by a multiplication by the correlation function $\xi_{\text{mask}}(\gamma)$ of the mask itself, we can notice that the average of the angular correlation function $\langle \xi^{p} \rangle$ computed on the masked sphere is related to the correlation function of the complete sphere by:

\[
\langle \xi^{p} (\gamma) \rangle = \xi(\gamma) \quad \text{(unbiased estimator)}
\]

\[
\langle \hat{\xi}^{p} (\gamma) \rangle = \xi_{\text{mask}}(\gamma) \times \xi(\gamma)
\]

Here, $\xi_{\text{mask}}(\gamma)$ can easily be computed using equation (6) and the optimized algorithms cited below, applied to the mask. The distortion matrix in relation (11) can then simply be written as a diagonal matrix $D_{\text{mask}}$ which can be used to compute the $[|\mathbf{B}_{\ell w^r}|]$.

\[
D_{\text{mask}}(i, i) = \xi_{\text{mask}}(\gamma_i)
\]

\[
[|\mathbf{B}_{\ell w^r}|] = [K]^{-1} \ast \left[ D_{\text{mask}} \right] \ast [K]
\]

Figure 5 illustrates the distortion of the angular correlation function estimated from $\tilde{a}_{\ell m}$ coefficients computed on the masked map. The undistorted angular correlation function corresponding to a WMAP-like $C_\ell$ power spectrum, the mean value of the distorted correlation function $\langle \xi \rangle$ and the mask correlation function $\xi_{\text{mask}}(\gamma)$ are plotted as a function of the $\gamma$ angle, for a partial $30^\circ \times 30^\circ$ map.

The analysis of the coupling matrix $[|\mathbf{B}_{\ell w^r}|]$ shows that the $\ell$-space resolution of pseudo-$C_\ell$ spectrum is compatible with the optimal resolution $\Delta \ell \sim \pi/\gamma_{\text{max}}$, but has long tails or correlation lengths. These long tails are responsible for the systematic shifts of pseudo-$C_\ell$ spectrum relative to the
3.4 Partial maps : Correcting pseudo–$C_\ell$ spectrum

In some sense, the correlation function $\tilde{\xi}(\gamma)$ obtained through the pseudo–$C_\ell$ computation applies a weighting function ($\xi^{\text{mask}}$) which is inversely proportional to the number of available measurement ($s(\theta, \phi)$) pairs i.e., to the statistical significance of the partial sphere correlation function. It is possible to obtain the unbiased correlation function by applying the inverse correction $1/\xi^{\text{mask}}$ to the correlation function of the masked sphere, up to a maximum angle $\gamma_{\text{max}}$ which should be less than the maximum extent of the partial map. As we increase $\gamma_{\text{max}}$, the statistical errors on the corrected angular correlation function, and the corrected angular power spectrum increase. There is thus a tradeoff between the $\ell$-space resolution and the statistical uncertainties of the recovered power spectrum $C_\ell$.

The statistical uncertainties (variance) associated with the recovered $\xi$ or $C_\ell$, depend on the true power spectrum and can not be computed using the formalism described here. It is however possible to compute the variance for specific partial map shapes, such as polar cap maps (see Magneville & Pansart (2007)). In this paper, we have computed theses uncertainties using Montecarlo simulation and the corresponding results are presented in the next section. In figure 6, the pseudo–$C_\ell$ window function is compared to the one obtained for the corrected $C_\ell$ for two values of $\gamma_{\text{max}}$ ($30^\circ$, $36^\circ$). On partial $30^\circ \times 30^\circ$, the maximum possible value for $\gamma_{\text{max}} \sim \sqrt{2} \times 30^\circ \sim 42^\circ$. Using a correction up to $\gamma_{\text{max}} = 36^\circ$, we obtain statistical errors comparable to those associated with the pseudo–$C_\ell$, while significantly decreas-

**Figure 6.** $30^\circ \times 30^\circ$ partial map : Comparison of $B_{\ell\ell}$ matrix row for $\ell = \ell_0 = 300$ (black) with Gaussian weighted $C_\ell^{p}$ (magenta) and $\gamma_{\text{max}} = 36^\circ$ (Top: linear Y-scale, bottom: logarithmic Y-scale).

- **(i)** Compute the pseudo–$C_\ell$ angular power spectrum on the masked sphere $\tilde{C}_\ell^{p}$ through fast spherical harmonic decomposition, as well as the pseudo–$C_\ell$ of the the mask itself.
- **(ii)** Compute the corresponding discrete angular correlation function and the mask correlation function

$$
\frac{\hat{\xi}(\gamma_i)}{\xi^{\text{mask}}(\gamma_i)} = \left[ \mathbf{K} \right] \ast \frac{\tilde{C}_\ell^{p}}{C_\ell^{\text{mask}}} \tag{21}
$$

- **(iii)** Define the truncation angle $\gamma_{\text{max}}$ compatible with the maximum map extent and desired $\ell$ resolution. Compute the corrected-truncated angular correlation function using the diagonal correction matrix $D_{\text{cor}}$.

$$
\hat{\xi}(\gamma_i) = \left[ \mathbf{D_{\text{cor}}} \right] \ast \frac{\hat{\xi}(\gamma_i)}{\xi^{\text{mask}}(\gamma_i)} \tag{22}
$$

$D_{\text{cor}}(i, i) = 1/\xi^{\text{mask}}(\gamma_i)$ \quad $\gamma_i < \gamma_{\text{max}}$

$D_{\text{cor}}(i, i) = 0 \quad \text{if } i \neq j \text{ or } \gamma_i > \gamma_{\text{max}}$

The correction matrix is equal to the inverse of the mask

© 2010 RAS, MNRAS 000, 1–11
distortion (see equation (20)) if angular correlation information is present up to $\gamma_{\text{max}} = \pi$. It is useful to apply a step smoothing function to avoid the discontinuity of $\xi'$ for $\gamma = \gamma_{\text{max}}$, such as a sigmoid:

$$f(\gamma) = 1/[1 + \exp((\gamma - \gamma_{\text{max}})/\delta)]$$

with $\delta \sim 0.01\gamma_{\text{max}}$.

This step smoothing function enhances the behavior of the computed power spectrum, decreasing residual oscillations.

(iv) Compute the corrected angular spectrum and apply the Gaussian filter function in $\ell$-space with $\sigma_\ell = \pi/\gamma_{\text{max}}$.

$$\begin{align*}
\hat{C}_\ell' &= ([K^{-1}] \ast [\xi'(\gamma_i)]) \\
\hat{C}_\ell &= ([W_G] \ast \hat{C}_\ell') \\
W_G(\ell, \ell') &= \frac{\exp((\ell-\ell')^2/2\sigma^2)}{\sum_\ell \exp((\ell-\ell')^2/2\sigma^2)}
\end{align*}$$

The coupling matrix $B_\ell$ is independent of the true power spectrum and can be computed using the following relation:

$$\begin{align*}
\{\hat{C}_\ell'\} &= \{B_\ell\} \ast \{C_\ell\} \\
\{B_\ell\} &= \{[W_G] \ast ([K^{-1}] \ast [D_{\text{cor}}] \ast [K])
\end{align*}$$

4 SIMULATION RESULTS ON SMALL MAPS AND MASKED MAPS

There is a tradeoff between the achievable resolution and the uncertainties of the estimated power spectrum. In order to evaluate these uncertainties, we have performed Monte-Carlo simulations to generate partial and full sky spherical maps and compute the power spectrum using spherical harmonic decomposition and the corrected/truncated angular auto correlation function. The method to correct systematic effects proposed in this work is independent of the true power spectrum. The computation of the coupling matrix and correction matrix is rather fast with a CPU time comparable to few Monte-Carlo realisations using fast spherical harmonics map analysis ($\sim$ minute). Reasonable estimates of errors for a given input power spectrum can be obtained using few hundred realisations. Although it is possible to compute the systematic effects due to the limited sky coverage using Monte-Carlo, this would require much larger computation time compared to the uncertainty estimates. The estimate of the $\{B_{\ell M}\}$ coupling matrix elements with sufficient precision would need a large number of Monte-Carlo realisations, due to the cosmic variance. In addition, this computation process would have to be repeated for several input power spectra.

The simulations have been performed with different partial map geometries and input (true) $C_\ell$ power spectra to check the validity of the conclusions. However, for the sake of clarity, we present here the results only for two map geometries and two input spectra. We have used WMAP-like true $C_\ell$ power spectrum, labeled $\ell_{\text{wm}}$ map and a second shape, labeled $\ell_{\text{te}}$, which have sharp features on top of a smooth spectrum $C(\ell) = C_{\ell M}/[\ell \times (\ell + 1)] + \text{peaks}$ in order to illustrate the $\ell$-space resolution effect. The results presented here have been obtained for the following two map geometries:

(i) Partial square map, $30^\circ \times 30^\circ$, covering the angular range $75^\circ \leq \theta \leq 105^\circ$ and $\phi_0 \leq \phi \leq \phi_0 + 30^\circ$. This map covers $\sim 0.27$ sr $= 0.0222 \times 4\pi$ sr. This small map corresponds to the case of ground or balloon CMB instruments.

(ii) A nearly complete spherical map, but with an equatorial band removed (set to zero). This case shows the distortion of the $C(\ell)$ power spectrum obtained from all sky space experiments such as WMAP or Planck, where some part of the sky with strong non-CMB microwave signals has to be masked. The removed equatorial band illustrates the effect of Galactic cut applied to CMB maps. We have performed simulations on $4\pi$ spherical maps with a $\Delta \theta = \pm 10^\circ$ equatorial band cut ($s(\theta, \phi) = 0$ for $80^\circ < \theta < 100^\circ$, $\forall \phi$). Such a map covers $82.5\%$ of the whole sky ($0.825 \times 4\pi$ sr) and provides correlation information for the whole angular range ($0 \leq \gamma \leq \pi$).

(iii) A more realistic case where we have applied the 5-year WMAP CMB temperature analysis (KQ85) mask (Gold et al 2008) to simulated CMB maps. The mask and corresponding normalised correlation function is shown in figure 7. The unmasked area corresponds to $\sim 0.82 \times 4\pi$ sr, nearly equal to the area of maps with a $10^\circ$ equatorial band removed. It has a complex and patchy shape.

Figure 7. WMAP KQ85 CMB temperature analysis mask (top) and the corresponding normalised correlation function $\xi_{\text{mask}}(\gamma)$ (bottom).

Given the overall shape of the $C_\ell$ spectra studied here, we have represented $\ell \times (\ell + 1) C_{\ell M}$ for the power spectrum, and $\ell \times (\ell + 1) \sigma_{\ell M}$ for the associated statistical uncertainties on all figures that follow in this section. The systematic shifts of the recovered power spectrum can be quantified using difference between the recovered and true power spectrum, normalised to the cosmic variance $\sigma_{\ell M}$:

$$\delta(\ell) = \frac{(\hat{C}_\ell - C_\ell)}{\sigma_{\ell M}(\ell)}$$
Figure 8. 30° × 30° partial maps: Comparison of computed power spectrum and true $l_{\text{map}}$ power spectrum (top) and the associated statistical errors (bottom). True power spectrum in black, pseudo−$C_\ell$ in red, $C_\ell$ computed from corrected angular correlation function truncated at $\gamma_{\text{max}} = 30^\circ$ (light blue), and corrected $C(\ell)t$ binned with Gaussian weights (blue).

4.1 Small 30° × 30° maps

The figures 8 and 9 show the recovered power spectrum on small 30° × 30° maps for a true WMAP-like power spectrum. The systematic shifts of the pseudo−$C_\ell$ power spectrum are clearly visible, in particular on figure 9 (top). The false oscillations on the raw power spectrum recovered from truncated $\xi$ is also shown on the figure 8 (top).

It can also be seen that by choosing $\gamma_{\text{max}} = 36^\circ$, it is possible to avoid nearly all the systematic shifts of the power spectrum, while keeping the level of statistical fluctuations comparable to the pseudo−$C_\ell$, and without losing the $\ell$-space resolution (see figure 9 and 10). However, it should also be noted that the corrected $C_\ell$ suffers a systematic overestimation at low $\ell \lesssim (2 - 3 \times \sigma_\ell = 2 - 3\pi/\gamma_{\text{max}})$, as expected from the coupling matrix $B_\ell$.

The systematic shift $\delta(\ell)$ decreases by a factor 10-30, changing from $\delta \sim 0.25 - 0.75$ in the case of pseudo−$C_\ell$ to less than 0.05 for Gaussian weighted $C_\ell$ computed from corrected $\xi(\gamma)$ correctly up to $\gamma_{\text{max}} = 36^\circ$ (figure 9).

4.2 Maps with ±10° Galactic cut

The figure 11 shows the bias introduced on the recovered power spectrum, specially at low multipoles $\ell \lesssim 30$ using uncorrected $C_\ell^p$ from map projection on the $Y_\ell^m$ basis. In this case, the angular correlation function can be estimated at all angular scales, but the $\xi(\gamma)$ obtained from the pseudo−$C_\ell$ is distorted. By correcting the $\tilde{\xi}(\gamma)$, it is possible to recover the unbiased power spectrum $C_\ell^p$, as shown on figure 11 (top). The systematic shift $\delta(\ell)$ changes from $\delta \sim 0.25$ in the case of pseudo−$C_\ell$ to less than 0.05 for Gaussian weighted $C_\ell$ computed from corrected $\xi(\gamma)$. However, the statistical fluctuations are larger, compared to the cosmic variance, reachable if the complete 4\pi map is available, or to the pseudo−$C_\ell$ variance on the cut map. Figure 12 shows the effect of the equatorial cut on a sharp feature present in the simulated power spectrum. Figure 13 shows the effect of the equatorial cut on the sharp feature present in the simulated power spectrum around $\ell = 50$. The power spectrum computed from corrected angular autocorrelation also corrects this distortion.

Although more sophisticated methods can be used to recover the spectrum at low multipoles from cut maps, the correction algorithm proposed here can be used to easily correct the pseudo−$C_\ell$ spectrum.

4.3 Maps with WMAP KQ85 mask

The effect of the WMAP KQ85 foreground suppression mask on the recovered power spectrum is shown in figure 13. This mask cuts an equatorial area on the map which is significantly less extended than in the case of the simple ±10° cut discussed above, but it removes also a large number of smaller patches of the sky scattered over the map. As a result, it can be seen that the systematic effects at low multipoles on the recovered pseudo−$C_\ell$ are smaller compared...
Partial CMB maps: bias removal, optimal binning of $C_\ell$

5 CONCLUSIONS

We have established a simple method to evaluate and correct systematic effects associated with power spectrum computed using the pseudo–$C_\ell$ on partial maps. The coupling matrix $B_{\ell\ell'}$ can indeed be computed using matrix algebra and the sky mask spherical harmonic decomposition. We have also described an algorithm to correct the systematic shifts of the calculated power spectrum, as well as a near optimal $\ell$-space window or filter function. It should be noted that it is possible to improve the $\ell$ resolution, compared to the natural resolution $\Delta \ell \sim \sigma_\ell \sim \pi/\gamma_{\max}$, at the expense of higher statistical fluctuations. For all sky CMB experiments such as WMAP or Planck, non-CMB dominated parts of the sky (galaxy . . . ) are usually excluded from the angular power spectrum estimation. We show that our method can be used to correct the power spectrum distortions at low $\ell$ in such cases, when the angular power is computed using fast spherical harmonic decomposition on almost complete maps.

The correction method described here can easily be extended to the CMB-polarisation power spectrum. A similar approach for polarised maps has been developed in (Chon et al 2004). It should also be possible to use this method to improve the angular power spectrum calculation by taking into account individual pixel measurement errors. For observations with negligible correlated noise, a weighting function mask inversely proportional to the individual pixel measurement uncertainties can be applied to the map before decomposition on the $Y_{\ell m}$ basis, and subsequently corrected for.
APPENDIX

We will show that one can invert equation (9) for a certain choice of the separation angles $\gamma_i$. We assume that the power at large angle $\ell$ is negligible. We can then consider that $C_\ell = 0$ for all multipoles with $\ell > \ell_{\text{max}}$. The sum in equation (6) becomes finite, so for $n_\ell$ given discrete values of $\gamma_i$, the matrix elements in equation (9) are:

$$[[K]]_{\ell i} = \frac{2\ell + 1}{4\pi} P_\ell(\cos(\gamma_i))$$  \hspace{1cm} (25)

with $1 \leq i \leq n_\ell$ and $0 \leq \ell \leq \ell_{\text{max}}$.

If the matrix $[[K]]$ is invertible, one may write $[C_i] = [[K]]^{-1} \ast [\xi_i]$ and the $C_\ell$ spectrum can be recovered from the values of the angular correlation function computed at angular separations $\gamma_i$.

In the following we will show that the separation angles $\gamma_i$ can be chosen such that the square matrix is non-singular.

$P_\ell(x = \cos(\gamma))$ is a polynomial of degree $\ell$ in the interval $[-1, +1]$. Using equation (6) we see that $\xi(\gamma)$ is a polynomial of degree at most $\ell_{\text{max}}$. The integrand $\xi \times P_\ell$ of equation (7) is a polynomial of degree at most $\ell_{\text{max}} + \ell$, so for the highest multipole $C_{\ell_{\text{max}}}$ the integrand has a degree of at most $2\ell_{\text{max}}$.

We know that, using Gauss-Legendre quadrature of order $n_\ell$, integrals of polynomials of degree up to $2n_\ell + 1$ can be exactly expressed as a $n_\ell$-th weighted sum of the polynomials computed at special values of $x$ (see Abramowitz et al. (1972)).

For all $\ell \leq \ell_{\text{max}}$ and for $L \geq \ell_{\text{max}} + 1$, the integral in equation (7) can be expressed as the algebraic sum:

$$C_\ell = 2\pi \sum_{i=1}^{L} \xi(\gamma_i) P_\ell(\cos(\gamma_i)) \times w_i$$  \hspace{1cm} (26)

where $x_i = \cos(\gamma_i)$ are the $L$ roots of $P_L(x)$ and $w_i$ the weights. For $L \geq \ell_{\text{max}} + 1$, this can be written in a matrix form:

$$[C_\ell] = [[K']] \ast [\xi_i]  \hspace{1cm} 0 \leq \ell \leq \ell_{\text{max}}$$

$$K'_{\ell i} = 2\pi P_\ell(\cos(\gamma_i)) \times w_i  \hspace{1cm} 1 \leq i \leq L$$

Clearly, if we take $L = \ell_{\text{max}} + 1$, the number of abscissas values is $n_\ell = \ell_{\text{max}} + 1$ and the matrix $[[K']]$ is square. In that case $[[K']] = [[K]]^{-1}$ and equation (7) can be written

$$[C_\ell] = [[K]]^{-1} \ast [\xi_i]  \hspace{1cm} (1 \leq i \leq \ell_{\text{max}} + 1, 0 \leq \ell \leq \ell_{\text{max}})$$  \hspace{1cm} (27)

Remark: Numerically, the angular correlation function could also be computed at $\ell_{\text{max}} + 1$ regularly spaced values $\gamma_i$ between 0 and $\pi$. This is possible because the $\gamma_i$ corresponding to the Legendre polynomial roots $x_i = \cos(\gamma_i)$.
satisfy the relation
\[ \frac{2i - 1}{2\pi + 1} \leq \frac{\gamma_i}{\pi} \leq \frac{2i + 1}{2\pi + 1} \] for \( P_i(\cos(\gamma)) \) \hspace{1cm} (28)

and are nearly regularly spaced.

Thus the angular distance between a Legendre polynomial root and the nearest regularly spaced abscissa is always lower than the resolution associated with the highest multipole (\( \sim \pi/\ell_{\text{max}} \)).
