ABSTRACT
Angular momentum transport in protostellar discs can take place either radially, through turbulence induced by the magnetorotational instability (MRI), or vertically, through the torque exerted by a large-scale magnetic field that threads the disc. Using semi-analytic and numerical results, we construct a model of steady-state discs that includes vertical transport by a centrifugally driven wind as well as MRI-induced turbulence. We present approximate criteria for the occurrence of either one of these mechanisms in an ambipolar diffusion-dominated disc. We derive “strong field” solutions in which the angular momentum transport is purely vertical and “weak field” solutions that are the stratified-disc analogues of the previously studied MRI channel modes; the latter are transformed into accretion solutions with predominantly radial angular-momentum transport when we implement a turbulent-stress prescription based on published results of numerical simulations. We also analyze “intermediate field strength” solutions in which both modes of transport operate at the same radial location; we conclude, however, that significant spatial overlap of these two mechanisms is unlikely to occur in practice. To further advance this study, we have developed a general scheme that incorporates also the Hall and Ohm conductivity regimes in discs with a realistic ionization structure.

Key words: accretion, accretion discs – ISM: jets and outflows – MHD – stars: formation.

1 INTRODUCTION
The mechanisms responsible for transporting angular momentum in protostellar discs are still not well understood. Perhaps the most generally relevant processes are:

(a) Radial transport through turbulence induced by the magnetorotational instability (MRI; e.g. Balbus & Hawley 1998). The MRI acts, essentially, by converting the free energy of differential rotation into turbulent motions that transfer angular momentum radially outward via the Maxwell stress of small-scale, disordered magnetic fields.

(b) Vertical transport by outflows driven centrifugally from the disc surfaces (e.g. Königl & Pudritz 2000). The transfer of angular momentum from the inflowing gas to the wind is mediated by a large-scale, ordered magnetic field that threads the disc (likely corresponding to interstellar field lines advected inward by the accretion flow but possibly generated locally by a disc dynamo).

Radial angular-momentum transport has been the hallmark of generic viscous disc models, for which the MRI process is thought to provide the most cogent physical basis. On the other hand, the ubiquity of bipolar outflows and jets in protostars and the apparent correlation between outflow and accretion signatures in these systems (e.g. Hartigan et al. 1995) have led to the suggestion that disc outflows might be a key ingredient of the accretion process on account of the high angular-momentum transport efficiency of centrifugally driven winds (e.g. Königl 1989). The possibility of a central role for vertical angular-momentum transport is supported by recent HST observations of protostellar jets, which have been interpreted in terms of magnetocentrifugal winds carrying a large fraction of the excess angular momentum of the accreted matter from the inner regions (r ≤ 1 AU) of the associated discs (see Ray et al. 2006 for a review). Although thermal pressure may contribute to the driving of the outflows (e.g. Pesenti et al. 2004), the stresses exerted by a large-scale magnetic field dominate the flow acceleration and collimation (Blandford & Payne 1982, hereafter BP82; see, however, Soker & Regev 2003 for an alternative view of the importance of thermal acceleration) and are the key to the efficient vertical angular-momentum transport indicated by the HST measurements.

Previous analytic and numerical investigations have considered the above two mechanisms under various simplifying assumptions. MRI studies have examined both the linear and nonlinear stages of the instability (e.g. Sano & Stone 2002a,b; Salmeron & Wardle 2003, 2005). The long-term global evolution of the instability in vertically stratified discs that are threaded by a single-polarity magnetic
field is still an open question (e.g. Miller & Stone 2000). The study of wind-driving discs has been complicated by the need to solve simultaneously for the inflow and outflow structures and by the non-local nature of the MHD solution. Progress has nevertheless been made semi-analytically by adopting a self-similarity formulation (e.g. Wardle & Königl 1993, hereafter WK93; Li 1995, 1996; Ferreira 1997) as well as numerically, with recent simulations reporting an evolution to a quasi-stationary state (e.g. Casse & Keppens 2002; Kuwabara et al. 2005). Since protostellar discs are weakly ionized over most of their extent, magnetic diffusivity effects have to be taken into account in modeling the accretion flow in both cases. In particular, both the MRI-driven turbulence and the centrifugal wind-launching mechanism require a minimum level of field–matter coupling to be effective (e.g. WK93; Sano & Inutsuka 2001). Therefore, the detailed ionization structure and conductivity properties of the disc need to be determined in order to incorporate either one of these processes into a realistic model.

Angular momentum removal from real discs is likely to involve both the radial and vertical transport mechanisms discussed above. There have been a few attempts in the literature to construct quasi-steady disc models in which both of these mechanisms operate (e.g. Lovelace et al. 1994; Casse & Ferreira 2000; Ogilvie & Livio 2001), but these treatments invariably used a prescription for radial angular-momentum transport that did not explicitly account for its origin in MRI-induced turbulence. However, the fact that disc regions in which the entire excess angular momentum is carried away by a centrifugally driven wind are generally stable to the fastest growing mode of the MRI (WK93) indicates that a more refined approach is required. Broadly speaking, the MRI is suppressed in regions where the ratio $a \equiv v_A/c_0$ of the Alfvén speed corresponding to the vertical field component $B_z$ and the isothermal sound speed is comparatively large ($\gtrsim 1$); it may be expected to evolve into a fully developed turbulence when $a \ll 1$ (provided also that the gas is well coupled to the field). Since the value of $a$ increases with distance $z$ from the disc midplane, these considerations suggest that it could in principle be possible for both vertical and radial angular-momentum transport to take place at the same disc radius $r$, with the radial transport confined to a given range in $z$ and with the vertical transport dominating at greater heights.

The purpose of this paper is to construct semi-analytic models of protostellar discs that incorporate both centrifugally driven winds and MRI-induced turbulence and to identify the relevant parameter regimes where either one of these two mechanisms dominates the angular momentum transport. We pay particular attention to the possibility that both of these mechanisms operate at the same disc radius and consider how they might affect each other in that case. We describe our wind-driving disc model (formulated following WK93) and present an illustrative solution of a disc with a predominantly vertical angular momentum transport in Section 2. In Section 3 we outline our method of including MRI-induced turbulence (taking account of recent numerical simulations of the nonlinear evolution of the MRI) and illustrate it with a solution of a disc with a predominantly radial angular-momentum transport. We then consider the case of combined transport by wind and turbulence in Section 4 and summarize our results in Section 5.

2 VERTICAL TRANSPORT

We have devised a general scheme for modeling wind-driving protostellar discs using a tensor-conductivity formalism and a realistic vertical ionization structure. The conductivity tensor makes it possible to include in a systematic way the three relevant magnetic diffusion mechanisms (ambipolar, Hall and Ohmic). The solutions presented in this paper are, however, derived under the simplifying assumptions of pure ambipolar diffusivity and (except in Section 4) constant ion density. This enables us to apply the analytic results obtained for this case in WK93 to the formulation of a prescription for MRI-induced turbulent transport in a wind-driving disc model. A wider class of solutions of our general scheme will be presented in future publications.

Our wind solutions are based on the magnetocentrifugal mechanism for “cold” disc outflows proposed by BP82. In this scenario, matter at the disc surface is accelerated by magnetic stresses if the open magnetic field lines that thread the disc are inclined at a sufficiently large angle to the rotation axis (the “bead-on-a-wire” effect), potentially reaching super-Alfvénic speeds. Our modeling procedure is based on that of WK93 and we refer the reader to that study for further details. In brief, we solve the mass and momentum conservation equations for the neutral gas, and the induction equation for the evolution of the magnetic field, assuming a steady-state, geometrically thin and nearly Keplerian accretion disc and neglecting all radial derivatives except that of $v_r$. The disc is further assumed to be isothermal and weakly ionized. The latter condition implies that ionization and recombination processes, as well as the inertia and thermal pressure of the charged particles, have a negligible dynamical effect. In this limit, separate equations for the ionized species are not needed, and their effect on the neutrals can be conveyed by means of a conductivity tensor $\sigma(r,z)$ (assuming cylindrical polar coordinates; see Wardle 1999 and references therein). In addition, the field must satisfy $\nabla \cdot B = 0$ (which in the thin-disc approximation implies that $B_z$ can be assumed not to vary with height in the disc), whereas the current density $J$ must satisfy Ampère’s and Ohm’s laws.

The foregoing equations are integrated vertically from the midplane (indicated by a subscript 0) up to the position $z_c$ of the critical (sonic) point, and the values of the physical variables there are estimated. The solution is then integrated

---

1 Vertical angular momentum transport could alternatively take place through the process of magnetic braking, which involves the propagation of torsional Alfvén waves into the surrounding interstellar medium. This possibility is neglected in what follows, but see Krasnopolsky & Königl (2002).

2 The main ionization sources outside the innermost $\sim 0.1$ AU from the central object are nonthermal: interstellar cosmic rays, X-ray and UV radiation emitted by the magnetically active protostar and the decay of radioactive elements present in the disc. The gas near the disc surface is ionized primarily by X-rays in the vicinity of the star, and by UV photons (with a contribution also from the interstellar radiation field) in the outer disc (e.g. Semenov et al. 2004; Glassgold et al. 2005).
Angular momentum transport in protostellar discs

Angular momentum transport in protostellar discs is crucial for the evolution of protoplanetary discs. The flow of angular momentum is driven by the internal energy of the disc and the magnetic field. The magnetic field is generated by the dissipation of dissipation of the fluid's internal energy, which is due to the angular momentum transport. The magnetic field lines are (radially) bent and (azimuthally) sheared quasi-hydrostatic layer just above the midplane the magnetic energy comes to exceed the gas internal energy and the field line–drift speed is small compared to \(v_\phi\). The overall solution is determined by the following parameters:

(i) \(a_0 = v_\Omega, a_0/c_s\), the midplane ratio of the Alfvén speed (based on the uniform vertical field component) to the sound speed, which measures the magnetic field strength.

(ii) \(\eta\), the ratio of the Keplerian rotation time \(\Omega^{-1} = r/v_K\) to the neutral–ion momentum-exchange time (see WK93); this parameter measures the degree of coupling between the neutrals and the ionized gas component (and magnetic field) and does not vary with height if the ion density is constant.

(iii) \(\epsilon = -v_\phi/c_s\), the normalized inward radial speed at the midplane. In practice, the value of this parameter is determined in our solutions (for given values of the other parameters) by imposing the Alfvén critical-point constraint on the wind.

(iv) \(c_s/v_K = h_T/r\), the ratio of the tidal scale height to the radius – a measure of the geometric thinness of the disc.

(v) \(\epsilon_B = -\epsilon E_\phi/c_s B_z\), the normalized azimuthal component of the electric field \(E\). This parameter vanishes in a strictly steady-state solution but is nonzero if the magnetic field lines drift radially. Our formulation remains valid if the field–line drift speed is small compared to \(|v_r|\) (see WK93).

\[ (2\eta)^{-1/2} \lesssim a_0 \lesssim \sqrt{3} \lesssim \epsilon B \lesssim v_K/2c_s \]. (1)

The first inequality in equation (1) expresses the requirements that the fluid remain sub-Keplerian below the wind-launching region, the second gives the wind-launching condition \((B_{r,b} = 0.0 \lesssim 1)\), and the third gives the constraint that the base of the wind be located above a density scale height. The first two conditions imply a minimum value for the field–matter coupling parameter \(\eta\) (which a more detailed analysis sharpens to \(\eta > 1\)), whereas the last two imply that magnetic squeezing dominates the vertical confinement of the disc (\(h < h_T\)). The last inequality specifies that the rate of ambipolar diffusion heating at the midplane...
3 RADIAL TRANSPORT

Numerical simulations indicate that vigorous radial angular momentum transport is sustained by the MRI when the initial (subscript i) Elsasser number \( \Lambda_i \equiv \nu_{\perp}^2 / \eta \Omega_0 a_i \) is \( \geq 1 \) (e.g. Sano & Inutsuka 2001; Sano & Stone 2002a, b), where \( \nu_{\perp} \) is the (midplane) Alfvén speed based on the initial vertical field \( B_z,i \) and \( \eta \) is the Ohmic diffusivity.\(^{\text{a}}\) Now, for the vertical initial field geometry assumed here, the currents and fields are mutually orthogonal and ambipolar diffusion acts as a field-dependent Ohmic resistivity (e.g. Balbus & Terquem 2001). Under these conditions one can show that \( \Lambda_i = \eta \), so the minimum-coupling condition in this case is the same for vertical and for radial angular-momentum transport.

What determines which mode of angular momentum transport dominates when the coupling is sufficiently strong (\( \eta \gtrsim 1 \))? As already noted in Section 1, the MRI is suppressed for sufficiently high values of the field-strength parameter \( a \). A useful clue to the lower limit for MRI stability is provided by the first inequality in equation (1). As discussed in WK93, when this inequality is violated the surface layers of the disc become super-Keplerian, implying outward streaming motion that is unphysical in the context of a pure wind-driving disc model. However, as elaborated on below, an outward motion of part of the disc material is a characteristic of the two-channel MRI mode that underlies MRI-induced turbulence. Further support for this choice of an upper limit on \( a \) in the MRI-unstable region is provided by the fact that wind-driving disc solutions that satisfy the constraints expressed by equation (1) are stable to the fastest growing linear mode of the MRI, essentially because the minimum wavelength of this mode exceeds the magnetically reduced disc scale height (see WK93).\(^{\text{b}}\) The above limit on \( a \) was applied by WK93 at the midplane, since they considered discs in which the entire excess angular momentum of the accretion flow is transported by a wind. As we are now concerned with the possible existence of an alternative mode of transport, we propose to generalize this condition and apply it locally (i.e. using \( a(z) \propto \rho(z)^{-1/2} \) instead of its midplane value) to differentiate the MRI-unstable section of the disc (where \( 2\eta a^2 < 1 \)) from the region where only vertical angular momentum transport takes place (\( 2\eta a^2 > 1 \)).

By integrating the disc equations of the model described in Section 2 for the case in which \( a < (2\eta)^{-1/2} \) over the bulk of the disc we have verified that such systems do not develop winds. Since our current formulation does not allow for an alternative means of transporting angular momentum through the disc surfaces (such as magnetic braking, “failed” winds that do not cross the relevant critical surfaces, or nonsteady phenomena), the only remaining option is for the angular momentum to be transported magnetically between different heights and then to be carried away radially by bulk flow (with the gas that loses angular momentum moving in and the material that gains angular momentum moving out). Fig. 2 shows a solution of this type. The radial field component oscillates in the region where \( 2\eta a^2 \lesssim 1 \), with \( B_\phi \) exhibiting corresponding oscillations with an opposite sign. The regions where \( B_\phi \partial B_\phi / \partial z < 0 \) lose angular momentum to the field and have \( v_\phi < 0 \), with the converse behaviour characterizing regions where \( B_\phi \partial B_\phi / \partial z > 0 \). We associate this solution with a two-channel MRI mode for the case of a stratified, non-ideal MHD disc.\(^{\text{c}}\) As was first shown by Goodman & Xu (1994), such modes (which they considered in the unstratified, ideal-MHD case) are exact solutions in both the linear and the nonlinear regimes. Their analysis, however, revealed that these solutions are unstable to parasitic modes, and subsequent numerical simulations (carried out in both the ideal and non-ideal regimes) have verified that they rapidly evolve into a turbulent state (e.g. Hawley et al. 1995; Sano et al. 2004, hereafter S04).

To account for the turbulent angular momentum transport that we expect to develop in disc regions where \( \eta \gtrsim 1 \) and \( 2a^2 \eta \lesssim 1 \), we adopt the results of numerical simulations, which have found that the main contribution to the \( r \phi \) component of the stress tensor is provided by the turbulent Maxwell stress and that its spatial and temporal average \( \langle w_{r\phi} \rangle \) can be expressed in terms of the similarly averaged magnetic pressure by

\[
\langle w_{r\phi} \rangle \approx 0.5 \frac{\langle B_z^2 \rangle}{8\pi} \lesssim 0.5 \frac{\langle B_z^2 \rangle}{8\pi} \quad (2)
\]

(e.g. Hawley et al. 1995; S04). Using the characteristic ratios \( \langle B_\phi^2 \rangle / \langle B_z^2 \rangle \approx 24 \) and \( \langle B_z^2 \rangle / \langle B_\phi^2 \rangle \approx 3 \) for MRI turbulence reported in Table 4 of S04, we substitute \( \langle B_z^2 \rangle \approx 28 \) for \( \langle B_z^2 \rangle \) into equation (2) to get

\[
\langle w_{r\phi} \rangle \approx 14 Y \frac{B_{z,1}^2}{8\pi}, \quad (3)
\]

where \( Y \equiv \langle B_z^2 \rangle / B_{z,1}^2 = Y(\beta) \) is listed in Table 2 of S04.

\(^{\text{a}}\) \( \Lambda \) is often referred to in the MRI literature as \( \text{Re}_M \), the magnetic Reynolds number, but in general \( \text{Re}_M \neq \Lambda \).

\(^{\text{b}}\) Note, however, that the formal demonstration of this fact requires using only the third inequality in equation (1).

\(^{\text{c}}\) Similar field configurations were obtained by Ogilvie & Livio (2001), who also related them to the channel solution.
for a range of isothermal, uniform-$B_x, \beta$ models as a function of $\beta_z \equiv 2/a_0^2$, the initial plasma $\beta$ parameter. As the values of $\beta$ in our applications are smaller (by up to $\sim 1 - 2$ orders of magnitude at the midplane) than the ones listed in S04, we resort to extrapolation, which can be justified by the relatively weak dependence of $Y$ on $\beta$; we obtain $Y = 2, 7$ and 10 for $\beta = 10, 100$ and 500, respectively.

Radial angular-momentum transport is incorporated into the disc angular momentum conservation equation by adding (in the relevant disc region) the turbulent stress term, which we do by approximating $(1/r)\partial (r^2 \ll w_{r, \phi})/\partial r \approx \ll w_{r, \phi}$. This equation then reads

$$\frac{\rho v_K v_K}{2r} + \rho_0 \frac{d v_{\phi}}{dz} = -\frac{J_0 B_z}{c} - \ll w_{r, \phi},$$

where we used $\partial (r v_{\phi})/\partial r \approx v_K/2$ and $J_z \approx 0$. We assume that the small-scale (turbulent) magnetic field components only contribute to the radial angular-momentum transport. We interpret all the other magnetic-field (and velocity) terms that appear in the disc structure equations as corresponding to the mean values of the respective quantities. In a similar vein, we interpret the first term on the r.h.s. of equation (4) as representing the vertical angular-momentum transport induced by the mean field. This representation is akin to that of previous models that incorporated radial angular-momentum transport into discs threaded by an open magnetic field (see Section 1). The underlying assumptions of this approach – that the relationships obtained from local shear-box simulations remain applicable in a stratified disc, that $\ll B_x, B_z$ averaged out to zero and that $\ll (B_x^2 + B_z^2)$ does not have a significant $z$ dependence – will, however, need to be verified by means of global numerical simulations. According to the above formulation, vertical angular-momentum transport associated with a large-scale, ordered field occurs throughout the disc (with the angular momentum deposited into the mean field eventually transferred back to matter in the wind region above the disc), whereas radial transport effected by MRI-induced turbulence is confined to the layer where the conditions $1 \lesssim \eta \lesssim (2\alpha^2)^{-1}$ are satisfied.

Fig. 3 shows a weak-field disc solution, obtained by implementing the above prescription for the same values of $\eta$ and $a_0$ as in the channel solution presented in Fig. 2. In this case the angular momentum transport is purely radial throughout the disc. The azimuthal field component at the top of the disc does not generally vanish in weak field disc configurations of these type, implying a net vertical torque ($\propto B_y B_{\phi,b}$) on the disc. However, in the current formulation such a torque can only be included if the wind launching condition is satisfied. Since this is not the case here, we chose to eliminate all the magnetic terms from the derived solution for self consistency. The resulting error is, however, small since the mean-field contribution to the disc dynamics (in particular, to angular momentum transport and to vertical squeezing) is rather minor in this instance. The lack of strong magnetic squeezing is reflected in the more gradual decline of the density with height in this solution as compared with the pure wind-driving disc model presented in Fig. 4.

4 COMBINED TRANSPORT

We now consider the case of a disc with moderate coupling ($\eta \sim 1$) and field strength ($a_0 < (2\eta)^{-1/2}$ but $a \sim 1$ at the surface), so both radial angular-momentum transport by a turbulent magnetic field (between the midplane and the height $z_1$ where $2\eta a_0^2 \approx 1$) and vertical transport by a large-scale field (between $z = 0$ and the top of the disc at $z_3$) take place at the same radial location. Solutions of this type occupy a limited region of parameter space, corresponding to a large enough $a_0$ for a wind to be launched from the disc surfaces and a sufficiently small $\eta_0$ to render $2\eta_0 a_0^2 < 1$ (but $\eta_0 \gtrsim 1$ so as not to suppress the growth of MRI-unstable modes). We have found that if $\eta$ is assumed to be both $> 1$ and constant with height (as was done in the previous Sections), the vertical extent $\Delta z_{MRI}$ over which radial transport operates is very narrow. The value of $\Delta z_{MRI}$ is limited by the fact that $a_0$ has a lower limit below which the wind-driving surface layers of the disc become sub-Keplerian (corresponding to an effective violation of the first inequality in equation (1) in these regions). To circumvent this limitation, we have allowed $\eta$ to fall slightly below 1 (with the expectation that it is still large enough to sustain MRI turbulence; see Sano & Stone 2002a,b) and to decrease with height. The adopted profile is motivated by the inferred behaviour of $\eta(z)$ in the ambipolar diffusion-dominated upper layers of realistic protostellar discs at $r \sim 1 - 10$ AU, where the ion density is most strongly affected by the decrease of the neutral gas density with height (see footnote 9). Fig. 4 shows illustrative solutions obtained under these assumptions. The solid lines depict the structure of the disc when only vertical angular-momentum transport is included (cf. Fig. 1). The dashed lines indicate how the above solution is modified when radial transport is incorporated using the prescription discussed in Section 3 and keeping the value of $a_0$ fixed. Key properties of the two solutions are compared in Table 1 assuming that $c_s$ and $\rho_0$ also remain unchanged. The mass accretion rate per disc circumference is evaluated from $M_{in}/2\pi r_0 = -2\int_0^{r_0} \rho v_\phi dz$; the listed value ($M_{in}$) is this quantity normalized by $(\rho_0 c_s H_0)$. The vertical and radial torques (per unit area) on the disc are normalized by $r_0 B_0^2/4\pi$ and are given by $T_z = \kappa \lambda$ and $T_r = (4\pi \ll w_{r, \phi} \gg /B_0^2) (\Delta z_{MRI}/r_0)$, respectively (with
Δz_{MRI} = z_i for the given setup), whereas the azimuthal field component at the disc surface is obtained from \( |B_{φ,b}/B_z| = \kappa(λ−1) \). The heights \( z_i, z_{b}, \) and \( z_s \) are listed in units of the scale height \( h \), which is determined for each solution as the value of \( z \) where the density drops to \( ρ_0/\sqrt{c_s} \).

The addition of radial angular-momentum transport results in this case in an increased inflow speed (measured by \( ε \)) and a higher mass inflow rate (\( \mathcal{M}_{in} \)). The higher \( |v_r| \) corresponds to a stronger radial neutral-ion drag (since the ions and field remain pinned at the midplane under the assumption that \( ε_φ = 0 \); see footnote \[6\]), and therefore (by the ion radial force-balance condition; see WK93) to a stronger bending of the magnetic field lines away from the vertical (reflected in the higher value of \( B_{φ,b} \)). This, in turn, increases the level of magnetic squeezing (reflected in the lower value of \( h \)), resulting in a stronger density stratification. Although the thickness of the disc remains virtually unchanged (at \( z_b = 1.25 h_T \)) and the height of the sonic point actually goes down in the combined solution (from 2.90 \( h_T \) to 2.82 \( h_T \)), the increased stratification (measured by \( z_b/h \) and \( z_s/h \), respectively) means that the density at the top of the disc is a lower fraction of the midplane density than in the pure wind solution, leading to a lower wind outflow rate (measured by \( \kappa \)) and a correspondingly lower vertical torque (measured by \( T_z \)).

The results shown in Fig. 4 illustrate the possibility that the incorporation of MRI-induced turbulence could increase the overall angular momentum transport in the disc, but reduce the amount of angular momentum carried away by the wind. It may be worth noting in this connection that the enhanced squeezing of the disc brought about by the addition of radial transport also reduces the width of the turbulent layer in comparison with the value of \( z_i \) that would have been estimated from the pure wind solution (in which \( a \) increases less rapidly with \( z \)). These considerations suggest that the joint operation of the two angular-momentum transport mechanisms might be self-limiting, in which case it would be unlikely to introduce a dynamical instability. This conclusion could be tested through an explicit stability analysis (e.g. Königl 2004 and references therein) or by means of numerical simulations.

5 CONCLUSION

We have constructed a semi-analytic scheme for modeling magnetized protostellar accretion discs. The model takes into account both vertical angular-momentum transport associated with a large-scale magnetic field that threads the disc and drives a centrifugal wind from its surfaces and radial angular-momentum transport through MRI-induced turbulence. A novel feature of this model is an explicit prescription that identifies the vertical extent of the disc region that is susceptible to sustainable MRI turbulence at any given radius and incorporates a turbulent-stress term (based on published results of numerical simulations and related to the local magnitude of the large-scale field) into the angular-momentum conservation relation for this region. Our general scheme employs a tensor-conductivity formalism and incorporates a realistic vertical ionization structure for the disc. However, in this paper we specialize to the ambipolar diffusion-dominated regime and assume that the ion density is nearly constant with height. This allows us to compare our results with the pure vertical-transport solutions obtained for this case by WK93 and to use the algebraic relations de-

Table 1. Comparison of the two solutions shown in Fig. 4.

Angular momentum transport in protostellar discs

We have concentrated on the case where the neutral-ion coupling parameter \( \eta \) is \( \gtrsim 1 \), which allows both the wind-driving and MRI-turbulence mechanisms to operate efficiently. Vertical transport through a wind is expected to dominate when the field-strength parameter \( a \) (the ratio of the local Alfvén and sound speeds) is sufficiently high (\( \lesssim 1 \)), whereas radial MRI-induced transport should prevail for \( a \ll 1 \). We constructed a low-\( a \) disc solution exhibiting oscillatory field and velocity profiles and suggested that it evidently represents the steady-state analogue in a diffusive (and stratified) disc of the nonlinear MRI channel mode originally identified by Goodman & Xu (1994). Although the question of the stability of stratified channel solutions in the non-ideal MHD regime has not yet been explicitly addressed, the current evidence (from linear analyses and numerical simulations) suggests that they may well be unstable. On the assumption that, in fact, such flows rapidly become turbulent, we incorporated a turbulent-stress prescription (based on the results of numerical simulations) into the angular momentum conservation equation for this region. We showed that, when implemented, this prescription stabilizes such flows and suggested that vertical angular-momentum transport mediated by large-scale fields could take place (e.g., in the form of magnetic braking) even if the conditions for wind launching are not fulfilled.

8 It is, however, worth pointing out again in this connection that vertical angular-momentum transport mediated by large-scale fields could take place (e.g., in the form of magnetic braking) even if the conditions for wind launching are not fulfilled.

\( \eta \) is evidently the steady-state analogue in a diffusing oscillatory field and velocity profiles and suggested that it evidently represents the steady-state analogue in a diffusive (and stratified) disc of the nonlinear MRI channel mode originally identified by Goodman & Xu (1994). Although the question of the stability of stratified channel solutions in the non-ideal MHD regime has not yet been explicitly addressed, the current evidence (from linear analyses and numerical simulations) suggests that they may well be unstable. On the assumption that, in fact, such flows rapidly become turbulent, we incorporated a turbulent-stress prescription (based on the results of numerical simulations) into the angular momentum conservation equation for this region. We showed that, when implemented, this prescription stabilizes such flows and suggested that vertical angular-momentum transport mediated by large-scale fields could take place (e.g., in the form of magnetic braking) even if the conditions for wind launching are not fulfilled.
