Temperature dependence of the threshold magnetic field for
nucleation and domain wall propagation in an inhomogeneous
structure with grain boundary

Abstract

In order to study the dependence of the coercive force of sintered magnets on temperature, nucleation and domain wall propagation at the grain boundary are studied as rate-determining processes of the magnetization reversal phenomena in magnets consisting of bulk hard magnetic grains contacting via grain boundaries of a soft magnetic material. These systems have been studied analytically for a continuum model at zero temperature (A. Sakuma, et al. J. Mag. Mag. Mat. 84 52 (1990)). In the present study, the temperature dependence is studied by making use of the stochastic Landau-Lifshitz-Gilbert equation at finite temperatures. In particular, the threshold fields for nucleation and domain wall propagation are obtained as functions of ratios of magnetic interactions and anisotropies of the soft and hard magnets for various temperatures. It was found that the threshold field for domain wall propagation is robust against thermal fluctuations, while that for nucleation is fragile. The microscopic mechanisms of the observed temperature dependence are discussed.

I. INTRODUCTION

The mechanisms by which the coercive force manifests itself in permanent magnets have been studied extensively. It is known that a single crystal of magnetic material does not show the hysteresis phenomenon, i.e., the coercive force is absent, and thus the structure of ensembles of fine grains plays an important role for the coercive force. Magnetization reversal in an antiparallel field occurs as a nucleation event at some point in the system, and it propagates through the material, forming a domain. Nucleation may occur due to intrinsic or extrinsic sources. Thermal fluctuations of the bulk material constitute an intrinsic source of nucleation, while extrinsic sources are due to the inhomogeneous structure of the material, e.g., misalignment of the easy axis and impurities, etc. Regardless of the origin, the nucleated reverse magnetization propagates throughout the material if the bulk magnetic region is connected.

To prevent the propagation of the reversed domain and maintain the coercive field, we must consider the conditions under which the pinning of the domain wall is realized. To understand the nucleation phenomenon and also the properties of domain wall propagation at the grain boundary, one may study a system extending in one direction with a defect region, as depicted in Fig. 1. The magnetization reversal phenomena in this system have been studied at zero temperature, and in particular, Sakuma et al. studied the threshold fields as a function of the ratios of magnetic interactions and anisotropies of the soft and hard magnets at zero temperature analytically by solving a one-dimensional nonlinear equation, and presented the corresponding phase diagram. In the present paper, we study the threshold magnetic fields for nucleation and for domain wall propagation at finite temperatures by making use of simulations of the stochastic Landau-Lifshitz-Gilbert (LLG) equation for the system in Fig. 1. In the analytical studies, the case in which the soft magnet grain boundary has the exchange energy $A_2 < A_1$, and the anisotropy energy $K_2 < K_1$, was studied.

The case with strong anisotropy which was studied by Hirota et al. is also interesting. However, in the present paper we focus on the temperature dependence of the case which was considered in previous analytical studies at $T = 0$. The case with strong anisotropy will be studied separately in the near future. A strong anisotropy causes the formation of narrow domain walls, which is a phenomenon that also occurs effectively in the case we studied.
FIG. 1. Schematic picture of a system consisting of two bulk hard magnets and a boundary soft magnet. Regions I and III are characterized by $A_1$, $K_1$ and $M_1$, while region II is characterized by $A_2$, $K_2$ and $M_2$. Free boundary conditions are adopted for the lattice model.

We discuss the narrow domain wall phenomenon in more detail in the later sections of this paper.

It has been also pointed out that the magnetic reversal of this type of systems depends on the size of the boundary region due to the so-called spring exchange effect. It is also known that this dependence is weak for large width. With this in mind, we choose a fixed defect width larger than the domain wall width. We consider a material similar to Nd-Fe-B, in which the correlation length ($\xi \propto \sqrt{A/K}$) is long compared to the lattice spacing, in contrast to the case of Sm-Co. To take this fact into account, we choose the ratio $K_1/A_1 = 0.2$ in the hard magnet. This value is still large when compared with real materials, but we believe that it can represent a situation where there is a long correlation length. As for the soft magnets (grain boundary), there are various situations to be considered. For example, depending on the concentration ratio of Fe and Nd in the grain boundary region of a Nd-Fe-B magnet, the parameters $A$ and $K$ would change. Thus we investigate the general tendency of the threshold fields in a wide range of parameters. The case in which the grain boundary width is narrow compared with the correlation length is interesting as well, but lies beyond the scope of this work.

In soft magnets, the magnetic order weakens with rising temperature, and the threshold field for nucleation shows a rapid decrease with increasing temperature. However, the threshold field for the domain wall propagation is found to show a more complicated dependence due to a competition between the following mechanisms. On one hand, the reduction
of ordering in the hard magnetic regions due to the rise in temperature causes a reduction of the threshold.

On the other hand, in a lattice system, the discreteness of the system becomes important when the anisotropy becomes strong, where the so-called narrow domain wall appears instead of the Bloch type wall\textsuperscript{13} thus reducing the spring effect. When the spring effect disappears, the domain wall propagation is regarded as a nucleation at the surface of the hard magnet, and thus the threshold for the propagation of the domain wall has little dependence on the parameters of the soft magnet. Because of this effect, the threshold field of domain wall depinning shows a non-monotonic dependence on the parameters under consideration, which is qualitatively different from the analytical results\textsuperscript{3} even at $T = 0$, and generally the temperature dependence is milder than that of the threshold field of nucleation. As a result, the threshold field for domain wall propagation is robust against thermal fluctuations, while that for nucleation is fragile.

The paper is organized as follows: In Section II, we explain the model under consideration and the method we used to obtain our results. In Section III, we study the nucleation phenomenon at the boundary region and its propagation to the hard magnetic regions. In Section IV, the domain wall propagation phenomenon is studied. In Section V, we summarize and discuss our results. In Appendix A, the temperature dependence of the anisotropy energy in the bulk magnets is given. In Appendix B, we show how sharply the relaxation time changes with the magnetic field around the threshold values. In Appendix C, the narrow domain wall phenomenon is explained.

II. MODEL AND METHOD

We consider a continuous magnetic system modeled by the Hamiltonian

$$
\mathcal{H} = \int dr \left( \frac{A}{2} (\nabla m(r))^2 - K m_z(r)^2 - M H \cdot m(r) \right),
$$

where $m$ is the unit vector of the direction of the magnetization at position $r$, $A$ is the exchange energy and $K$ is the anisotropy energy. Here, it should be noted that the definition of exchange energy is different from that in the continuum model\textsuperscript{3} by a factor of 2. The last term is the Zeeman energy, $H$ is the magnetic field and $M$ is magnetization. The magnetic properties of the bulk hard magnet are specified by the exchange energy $A_1$ and anisotropy
$K_1$, and that of the grain boundary region with width $W$ by $A_2$ and $K_2$. The magnetizations in these regions are $M_1$ and $M_2$, respectively.

A phase diagram of the threshold magnetic fields for the nucleation and domain wall depinning in a one-dimensional continuum model were obtained analytically at zero temperature for the cases $A_1 > A_2$ and $K_1 \geq K_2$. The threshold field for nucleation $H_{NC}$ is defined to be the field above which a nucleation type solution does not exist, and that for domain wall depinning $H_{DWP}$ to be the field above which a domain-wall like solution does not exist.

We adopt the following variables to parameterize the model used in the previous work:\[3\]

the normalized external field

$$h = \frac{H}{H_{SW}}, \quad H_{SW} \equiv \frac{2K_1}{M_1},$$

in which $H_{SW}$ is the Stoner-Wohlfarth field of the bulk hard magnets, the ratio of exchange energies

$$F = \frac{A_2M_2}{A_1M_1},$$

and the ratio

$$E = \frac{A_2K_2}{A_1K_1}.$$  

Here, it should be noted that the domain wall energy is proportional to $\sqrt{AK}$.

For the nucleation process, the threshold of the normalized external field $h$ above which the nucleation occurs in the boundary region (II) for infinite width $W$ at $T = 0$ is given by

$$h_{NCII}(0) = \frac{E}{F}. \quad (5)$$

For finite width the threshold is slightly larger than this value.\[3\]

For the domain wall propagation, the threshold of the normalized external field $h$ above which the domain wall propagates from the boundary region (II) to the bulk regions (I and III) at $T = 0$ is given by

$$h_{DWP}(0) = \frac{1 - E}{(1 + \sqrt{F})^2}, \quad (6)$$

and this quantity is known as the depinning field. For $h < h_{DWP}(0)$, the domain wall is pinned at the border between the boundary and hard magnets, and does not propagate to the bulk region.
In the case \( h_{NC}(0) < h < h_{DWP}(0) \), the nucleated defect region is confined. For the magnetization reversal of the whole system the nucleated magnetization must propagate to the hard magnets (regions I and III). Thus, the threshold of the magnetization reversal in the case of nucleation, i.e., magnetization reversal from the initial configuration where all the regions are antiparallel to the applied field, is given by the largest of \( h_{NC}(0) \) and \( h_{DWP}(0) \). Thus, the threshold field for the nucleation to propagate to the hard magnets at \( T = 0 \) is given by

\[
h_{NC}(0) = \max \left[ \frac{E}{F}, \frac{1 - E}{(1 + \sqrt{F})^2} \right]. \tag{7}
\]

In the present paper, we study this problem in a microscopic spin system on a lattice with the shape of a long rod (Fig. 1), modeled by the Hamiltonian

\[
\mathcal{H} = - \sum_{(i,j)} A_{i,j} \mathbf{S}_i \cdot \mathbf{S}_j - \sum_{i=1}^{N} K_i S_{i,z}^2 - \sum_{i=1}^{N} H_i(t) S_{i,z}, \tag{8}
\]

where the nearest-neighbor interaction constants \( A_{i,j} \) are positive for all \( i, j \), \( \{K_i\}_{i=1}^{N} \) is a set of positive anisotropy constants, and \( H_i(t) = H_i(t) e_z \) is an external magnetic field pointing in the \( z \)-direction.

We consider a cubic lattice of length \( L_x = 60 \) with height \( L_z = 6 \) and depth \( L_y = 6 \). Each vertex of the lattice contains a spin, which we treat as a classical magnetic moment. We choose units such that \( g \mu_B = 1 \), where \( g \) is the g factor and \( \mu_B \) is the Bohr magneton. We denote the set of spins by \( \{\mathbf{S}_i\}_{i=1}^{N} \), where \( N \) is the total number of vertices in the lattice. We set the magnetization of the spins to be unity, i.e.,

\[
|\mathbf{S}_i| = M_1 = M_2 = 1. \tag{9}
\]

The time-evolution of this system is given by the Landau-Lifshitz-Gilbert equation \(^{11} \) for each \( i = 1, \ldots, N \).

\[
\frac{d}{dt} \mathbf{S}_i = -\frac{\gamma}{1 + \alpha_i^2} \mathbf{S}_i \times \mathbf{H}_{i}^{\text{eff}} - \frac{\alpha_i \gamma}{(1 + \alpha_i^2)} \mathbf{S}_i \times \left[ \mathbf{S}_i \times \mathbf{H}_{i}^{\text{eff}} \right]. \tag{10}
\]

The parameter \( \gamma = g \mu_B \) denotes the gyromagnetic constant and \( \alpha_i \) is the damping parameter. The effective field \( \mathbf{H}_{i}^{\text{eff}} \) on the \( i \)th spin is given by

\[
\mathbf{H}_{i}^{\text{eff}} \equiv \frac{\partial \mathcal{H}}{\partial \mathbf{S}_i} = 2 \sum_{j:\langle i,j \rangle} A_{i,j} \mathbf{S}_j + [2K_i S_{i,z} + H_i(t)] e_z. \tag{11}
\]
We include thermal effects by adding a white Gaussian noise field, denoted by \( \{ \xi_i(t) = (\xi_i^x, \xi_i^y, \xi_i^z) \}_{i=1}^N \), to \( H_i^{\text{eff}} \). Explicitly, the noise field satisfies the following properties:

\[
\langle \xi^j_i(t) \rangle = 0, \quad \langle \xi^j_i(t) \xi^l_k(s) \rangle = 2D_i \delta_{ik} \delta_{jl} \delta(t-s).
\] (12)

With the inclusion of the noise field, we treat the stochastic Landau-Lifshitz-Gilbert (SLLG) equation as a Langevin equation with the Stratonovich interpretation.

If the following relation\(^5,7\)

\[
\alpha_i S_i = \gamma D_i K_i B_T,
\] (13)

is satisfied, the system relaxes to the canonical equilibrium distribution \( P_{eq}(\{S_i\}_{i=1}^N) \propto \exp[-\beta H(\{S_i\}_{i=1}^N)] \). Even in the case of inhomogeneous magnetic systems \( (S_i \neq S_j) \), any choice within this condition realizes the canonical equilibrium state\(^7\). However, careful thought must be given to the choice of \( D_i \) and \( \alpha_i \), which depend on \( S_i \) and cause different relaxation processes. In this study, however, we treat homogeneous magnetic moments, i.e., \( S_i = 1 \), and we do not meet this problem.

We carried out simulations of the model by integrating Eq. (10) numerically using a middle point method\(^7\) which is equivalent to the Heun method\(^5\).

### A. Parameterization of the model

The width of the domain wall is given by

\[
\xi = \sqrt{\frac{A}{2K}}.
\] (14)

In our simulations, the width of region II is 20, and we choose \( \xi \) smaller than this width.

We investigate the case in which the bulk regions have the properties of a hard magnet, while region II has weaker magnetic properties. Therefore, we set the constants \( A_{i,j} = A_1 \), \( K_i = K_1 \) inside regions I and II, and \( A_{i,j} = A_2 < A_1 \), \( K_i = K_2 < K_1 \) in region II. The interaction constant \( A_{i,j} \) is taken such that, if both the \( i \)th and \( j \)th particles belong to region II, \( A_{i,j} = A_2 \), while if any of the two particles belongs to regions I or III, \( A_{i,j} = A_1 \).

It is known\(^14\) that the critical temperature of the classical Heisenberg model is about \( T_c \simeq 1.443A \) for \( K = 0 \). In the model with \( K = 0.2A \), the critical temperature increases slightly. The anisotropy is defined by the anisotropy energy as \( H_A = 2K/M \), or by the anisotropy constant given by \( D = K/M^2 \). Hereafter we use only the anisotropy energy \( K \).
to avoid confusion between the anisotropy constant at each region $D_i$ and the strength of the random field at site $i$, $D_i$.

To obtain a rough estimation of the temperature dependence of the ordering property, we study the temperature dependence of the square of the magnetization $\langle m^2_z(T, H = 0) \rangle$,

$$\langle m^2_z \rangle = \frac{\langle (\sum_i S_{i,z})^2 \rangle}{N^2},$$ \hspace{1cm} (15)

and also the temperature dependence of the anisotropy energy $K(T)$ of the bulk system for a system of $N = 20^3$ spins and $K = 0.2$. In Appendix A, we depict $\langle m^2_z(T, H = 0) \rangle$ for various values of $K$. There, we find that the critical temperature does not depend largely on $K/A$. There are several ways to estimate the temperature dependence of $K(T)$.

For example, the temperature dependence of the anisotropy field $H_A(T) = K(T)/M$ is defined to be the magnetic field at which the magnetization curve in the easy axis $m_z(H)$ and an extrapolated magnetization in the hard direction $m_x(H)$ meet. In the present paper, we define $K(T)$ from the zero field transverse susceptibility, which is explained in Appendix A, where the temperature dependence of the order parameter and the anisotropy $K(T)$ is given for various values of $K(0)$. There, we find that the temperature dependence of the anisotropy is more significant than that of the spontaneous magnetization $m_s(T)$. The Callen-Callen law,

$$K(T) \propto m_s(T)^3,$$

holds for a wide range of temperatures. Indeed, for the case $K(0) = 0.2$, this relation holds approximately for all temperatures.

To study the field thresholds for the system depicted in Fig.1, we apply a uniform external magnetic field $H_i(t) = H$ in the negative $z$ direction in the system with the following two initial conditions:

(1) In order to study the process of nucleation in region II, we start our simulations from the configuration in which all the spins point in the positive $z$ direction ($+++$), and

(2) In order to study the process of domain wall propagation, we start our simulations from the configuration in which the spins in region III point in the negative $z$ direction, while the rest of the spins point toward the positive $z$ direction ($+-+$).

In the present paper, we set the parameter for the noise amplitude $D_i = \alpha_i k_B T/\gamma$ with $\alpha_i = 0.1$ and $\gamma = g\mu_B = 1$. We take $A_1$ as the unit of energy and measure the temperature in this unit. To determine the threshold fields, we perform simulations for $5 \times 10^5$ updates.
with time steps of value $\Delta t = 0.01$. In the present notation the period of precession is of order $O(1)$, and $\Delta t = 0.01$ is small enough to simulate the situation.

If we simulate for a longer time the results may change, but we regard the observation time $t = 5 \times 10^3$ to be enough to grasp the dependence of the threshold on its parameters. Usually, an observation time of 1s corresponds to a simulation time of order $t \sim 10^{12}$, which is much longer than $t = 5 \times 10^3$. However, the change of relaxation time around the threshold is very sharp as is usual in critical phenomena. In Appendix B, we show examples of the field dependence of the relaxation time observed in long simulations. Thus, we expect that the estimation of the thresholds of the field do not depend largely on the observation time.

We classify the final configurations by specifying the signs of the magnetization in the three regions $(m_I, m_{II}, m_{III})$. For example, $(+++) \text{ denotes the configuration where no nucleation occurs, } (+-+) \text{ denotes the case where nucleation occurs but the reversed magnetization does not propagate, and } (-+-) \text{ denotes the case where nucleation occurs and the reversed magnetization propagates. There also exist the case of } (+-) \text{ when we start from } (+-+) \text{ to study the domain wall propagation phenomenon.}$

We define $h_{NCII}(T)$ as the boundary between the fields for which the final configurations are $(+++)$ and $(+-+)$, $h_{NC}(T)$ as the boundary between the fields for which the final configurations are $(+-+)$ and $(---)$ or between $(+++)$ and $(---)$, and $h_{DWP}(T)$ as the boundary between the fields for which the final configurations are $(+-+)$ and $(---)$.

We give examples of $(+-+)$ and $(---)$ in Fig. 2(a) and (b), respectively. There, we depict the time evolution of the spin configuration. To represent the configuration we draw spins at a line of the system $(x, y = 4, z = 4), x = 1, \ldots, 60$ at a set time in rows, and the vertical axis represents the time evolution.

III. TEMPERATURE DEPENDENCE OF NUCLEATION

Starting from the initial condition (1) with $(+++)$, we investigate the threshold fields for the nucleation in region II. We studied the time evolution of systems with $F = A_2/A_1 < 1$ and $E = FK_2/K_1 \leq 1$, for $t = 5 \times 10^3$ and various values of $h = H/2K_1$ to find the threshold fields.
FIG. 2. Time evolution of magnetization for $F = 0.7$, $E = 0.07$ and (a) $h = 0.2$, and (b) $h = 0.3$ at $T = 0$. Each row denotes a configuration of spins at the site $(x, 4, 4)$, $x = 1, \cdots 60$ at a time $t$. The vertical axis denotes the time. Spins of positive and negative $S_z$ are plotted by thin gray bar and bold blue bar, respectively. This notation is used in other plots of configurations in this paper.

A. $T = 0$

First, we study the phase diagram at $T = 0$. Figures 2(a) and (b) present instances of processes of nucleation and propagation from the nucleated reversed magnetization, respectively. For small values of $h$, nucleation does not occur (not shown), and as $h$ increases, nucleation begins to occur. In Fig. 2(a), for $h = 0.2$ we find nucleation at around $t = 2700$. There, the reversed magnetization remains inside the defect region. Thus, $h = 0.2$ is between $h_{NCII}(0)$ and $h_{NC}(0)$. For a larger field, the reversed magnetization propagates into the bulk hard magnetic region. We depict an example in which $h = 0.3$ in Fig. 2(b).

In Fig. 3 the phase diagrams for $T = 0$ for $F = 0.3$, 0.5, and 0.7 are shown. The dotted lines show the threshold fields for the nucleation, $h_{NCII}(0)$, and domain wall propagation, $h_{NC}(0)$, given by Eq. (5) and Eq. (6), respectively. The borders between the cases of final configurations $(+++, +++)$ and $(---+, - - - +)$ are plotted by blue upward triangles, and the borders between $(+-+, + - +)$ and $(-- --, - - - +)$ are plotted by red downward triangles. Here at $T = 0$, the error bars denote the step size of the external field, $\Delta h = 0.01$. The small deviation of the threshold of nucleation to the theoretical estimation is due to the fact that the width of
FIG. 3. Phase diagram ($T = 0$) of the final configuration starting from the initial condition (+++) for (a) $F = 0.3$, (b) 0.5 and (c) 0.7. The border between (+ + +) and (+ − +) is given by blue upward triangles. The upper limit of the error bar denotes the field above which (+ − +) appears and the lower limit denotes the field below which (+ + +) appears. Similarly, the border between (+ − +) and (−−−) is given by red downward triangles, and (−−−) appears above the upper limit of the error bars, while (+ − +) appears below the lower limit. The blue and red lines are guides for the eye. The dotted lines denote the analytical estimation for the threshold nucleation field, Eq. (5), and the threshold domain-wall propagation field, Eq. (6), for the continuum system.

region II is fixed to be $W = 20$. Namely, there is correlation from the hard magnet in the defect region due to its finite size, and this correlation stands in the way of the nucleation phenomenon. Consequently, the threshold in the simulation is larger than the analytical estimation, but the overall features are well reproduced.

It should be noted that at zero temperature, if we start from the completely aligned initial configuration, the initial state remains unchanged because it is an unstable stationary state. To avoid this situation, we introduced a small fluctuation to the angle of the magnetization $(\theta, \phi)$ with a Gaussian distribution of standard deviation $\sqrt{\langle (\theta - \theta_0)^2 \rangle} = 0.01$ with $\theta_0 = 0.03$[radian]. We confirmed that our results have little dependence on the choice of $\theta_0$.

B. $T > 0$

Now, we study the temperature dependence of the phase diagram. Nucleation occurs stochastically in region II, and the corresponding waiting time obeys a Poisson distribution.
In order to determine the threshold field, we made a histogram of the number of events. Namely, we performed simulations of 10 samples for each parameter, and counted the number of cases in which the system showed nucleation within the observation time \( t = 5 \times 10^3 \).

In Fig. 4 we show an example of the rate \( p(−−−, h) \) of samples in which the final configuration was \( (−−−) \), denoted by red open circles, and the rate \( p(++,+,h) \) of the number of samples in which the final configuration was \( (+++) \), denoted by blue open squares, for \( F = 0.7 \) and \( E = 0.14 \) at \( T = 0.1 \) when taking 10 samples. We also performed 100 samples, and show the rates by closed circles and closed squares. We find that a larger sample number does not change the estimation of the threshold point significantly, and thus we took the histograms with 10 samples in other cases.

We assign an error bar which extends from the point where there are ten (all) occurrences

![Number of final states/trials for (+−+) and (−−−)](image)

FIG. 4. The frequency \( p(++,+,h) \) of cases in which the final state \( (t = 5000) \) has the configuration \( (+++) \) is plotted by squares. The closed squares denote the frequency for each \( h \) obtained from 100 samples, while the open squares denote that obtained from 10 samples. The frequency \( p(−−−, h) \) of cases in which the final state \( (t = 5000) \) has the configuration \( (−−−) \) is plotted by circles. The solid circles denote the frequency for each \( h \) obtained from 100 samples, while the open circles denote that obtained from 10 samples. The frequency \( p(+−+, h) \) is given by \( 1 − p(++,+,h) − p(−−−, h) \). Here we find that the threshold field is well estimated by the sampling of 10 samples, and we define the threshold to be the field at which the dotted line crosses 0.5, and define the error bars to be the interval between the fields for \( p(m_1, m_2, m_3) = 1 \) and \( p(m_1, m_2, m_3) = 0 \).
to the point where there are zero occurrences of the configuration in question.

We identify the threshold as the point where the interpolated line of the histogram crosses \( p = 0.5 \). For example, the error bar of the threshold field \( h_{\text{NCII}}(0.1) \) between \( p(++,+,h) \) and \( p(+-+,h) \) is from 0.19 to 0.23, and the threshold point obtained from taking 100 samples lies at \( h = 0.203 \). Similarly, the error bar of \( h_{\text{NC}}(0.1) \) between \( p(++,+,h) \) and \( p(+-+,h) \) is from 0.23 to 0.26, with the 100-sample threshold estimation lying at \( h = 0.242 \).

In Fig. 5, we show the dependence of the threshold fields of nucleation at finite temperatures. We show diagrams for \( T = 0.1, 0.3 \) and 0.5 at \( F = 0.3, 0.5 \) and 0.7. We find that the nucleation field decreases significantly as the temperature rises.

When \( E \) is small, i.e., \( K_2 \) is small, \( h_{\text{NC}}(T) \) and \( h_{\text{NCII}}(T) \) decrease with temperature. This dependence is naturally understood as a consequence of thermal fluctuations. On the other hand, for large \( E \) (where \( K_2 \) is large) \( h_{\text{NC}}(T) \) and \( h_{\text{NCII}}(T) \) separate. In the case where \( F = 0.3 \), the reduction of the threshold \( h_{\text{NCII}}(T) \) is significant. As we show in Appendix A, the effective anisotropy decreases rapidly at finite temperatures, and for \( F = 0.3 \), i.e., \( A_2 = 0.3 \), the effective anisotropy falls substantially at \( T = 0.3 \). At \( T = 0.5 \), region II is in the paramagnetic state, where the concept of nucleation does not apply. However, regions I and III with \( A_1 = 1 \) are still robust against the external field, which keeps \( h_{\text{NC}}(T) \) at high values.

1. Temperature dependence of the threshold field \( h_{\text{NCII}}(T) \)

In Fig. 6(a), we plot the temperature dependence of the threshold field \( h_{\text{NCII}}(T)/h_{\text{NCII}}(0) \) at \( E = F \) (i.e., \( K_2 = K_1 \)) for \( F = 0.3, 0.5 \) and 0.7. The threshold field monotonically decreases with rising temperature. We also find that \( h_{\text{NCII}}(T)/h_{\text{NCII}}(0) \) decreases monotonically when \( F \) decreases. That is, if \( A_2 \) decreases, nucleation in the region becomes easier and \( h_{\text{NCII}}(T)/h_{\text{NCII}}(0) \) decreases with \( F \), which is natural.

Because \( h_{\text{NCII}}(T)/h_{\text{NCII}}(0) \) is the temperature dependence of the threshold of the nucleation in region II, we may relate \( h_{\text{NCII}}(T)/h_{\text{NCII}}(0) \) to the temperature dependence of the bulk anisotropy energy \( K_2(T) \) estimated in Appendix A (Fig. 13(b)). That is, from the definition (2), the field \( h \) is proportional to \( 2K_2 \), and we may expect the following temperature dependence: \( h_{\text{NCII}}(T)/h_{\text{NCII}}(0) = K_2(T)/K_2(0) \).

In Fig. 13(b), we have data of \( K(T) \) for a system with \( A = 1 \) for various values of \( K(0) \)
FIG. 5. Dependences of the threshold fields between (+ + +) and (+ − +) (blue upward triangle) and between (+ − +) and (− − −) on $E$ for $T = 0.1$, 0.3 and 0.5 with $F = 0.3$, 0.5 and 0.7. The straight lines are guides for the eye, and the dotted lines correspond to the analytical estimation at $T = 0$.

$(K(0) = 0.0, 0.2, \ldots, 1.0)$. The value of exchange energy in region II is given by $A_2(= F)$. We can estimate the temperature dependence $K_2(T)$ of the system with $A_2$ by making use of the following scaling for the parameters in the Hamiltonian. Because in Fig. 13(b), the parameters are scaled by $A$, i.e., $T/A$ and $K/A$, we replace the parameters as

$$K_{\text{scaled}} = K_2 \times \left(\frac{A}{A_2}\right), \quad T_{\text{scaled}} = T \times \left(\frac{A}{A_2}\right).$$
FIG. 6. (a) Dependence on temperature of the threshold field between patterns (+−+) and (+++), (b) dependence on temperature of the threshold field for nucleation, i.e., between patterns (−−−) and (+−+), for $E = F = 0.3$ (red downward triangle), 0.5 (green square) and 0.7 (blue upward triangle). The lines between data points are guides for the eye.

The temperature dependence $K_2(T)$ is estimated as

$$K_2(T) = K_{A=1} \left( T \left( \frac{A}{A_2} \right), K_2 \left( \frac{A}{A_2} \right) \right) \times \left( \frac{A_2}{A} \right),$$

(17)

where $K_{A=1}(T, K)$ is the dependence given in Fig. 13(b).

If we adopt this transformation, the ratio $h_{NCII}(T)/h_{NCII}(0)$ is given by

$$\frac{h_{NCII}(T)}{h_{NCII}(0)} = K_{A=1} \left( T \left( \frac{A}{A_2} \right), K_2 \left( \frac{A}{A_2} \right) \right) \times \left( \frac{A_2}{A} \right) \times \frac{1}{K_2(0)}$$

(18)

The estimated value of $K_2(T)$ for the system of $F = 0.5$, $T = 0.3$, $E = F$ and $K_2 = 0.2$ is obtained by putting $A_2 = 0.5$, $K_2(0) = 0.2$:

$$\frac{h_{NCII}(0.5)}{h_{NCII}(0)} = K_{A=1} \left( 0.3 \left( \frac{1}{0.5} \right), 0.2 \left( \frac{1}{0.5} \right) \right) \times \left( \frac{0.5}{1} \right) \times \frac{1}{0.2} = K_{A=1}(0.6, 0.4) \times 2.25.$$

(19)

In Fig. 13(b) we find that $K_{A=1}(0.6, 0.4) \simeq 0.25$, and thus $h_{NCII}(0.5)/h_{NCII}(0) \simeq 0.6$. On the other hand, in Fig. 6(a), we find $h_{NCII}(0.5)/h_{NCII}(0) \simeq 0.5$. Thus, we find that the estimation of $h_{NCII}(T)$ (Fig. 6(a)) is lower than the estimation from the temperature dependence of the anisotropy energy $K_2(T)$ obtained from the data in Fig. 13(b). For other points, we find the same tendency, and we conclude that the thermal effects are stronger than the estimation from the temperature dependence of the anisotropy energy.
2. Temperature dependence of the threshold field $h_{NC}(T)$

In Figs. 6(b), the threshold field $h_{NC}(T)$ at $E = F$, i.e., $K_2 = K_1$, is shown. In contrast to $h_{NCII}(T)/h_{NCII}(0)$, the threshold field $h_{NC}(T)/h_{NC}(0)$ shows a non-monotonic dependence on $F$ at $T = 0.5$.

To understand the magnetic reversal processes of the case where $F = E = 0.3$ at $T = 0.5$, we depict time evolutions of the line configurations at various values of $h$ in Fig. 7. At this temperature, we find that the magnetization of region II with $A_2 = 0.3$ is always reversed, which should not be regarded as a nucleation process, but it should be regarded as a paramagnetic state with a field induced negative magnetization. Thus, the reversal of the hard magnets (regions I and III) occurs as a surface nucleation under a field consisting of the external field and the molecular field from region II:

$$h_{\text{surface}} = -H + A_1 \langle S_{i,z} \rangle_{\text{region II}}.$$  \hspace{1cm} (20)

Now let us consider the dependence of $h_{NC}(T)$ on $F$. Because $F = E$, we have $K_1 = K_2$ and $A_2 = F$. Therefore, the dependence on $F$ is the same as that on $A_2$. Increasing $A_2$ causes the increase of the threshold $h_{NCII}(T)$ in region II as we see in Fig. 6(b). As long as there is no nucleation in region II, the reversal of regions I and III does not take place. Thus, the increase of the threshold $h_{NCII}(T)$ with $A_2$ causes an increase of $h_{NC}(T)$. For $F = 0.5$ and 0.7, just after the nucleation takes place the whole system reverses. Thus $h_{NCII}(T) \simeq h_{NC}(T)$ and they decrease with $A_2$.

On the other hand, at $F = 0.3$, the magnetization in region II, $|\langle S_{i,z} \rangle_{\text{region II}}|$, is small.
Then, the magnitude of the second term \( A_1 \langle S_{i,z} \rangle \) regionII (< 0) is small, and thus the spring effect decreases with the temperature, which causes an increase of the threshold. Consequently, to reverse region I, a kind of surface nucleation at the surface of the hard magnets (regions I and III) must take place. On the other hand, the thermal fluctuation reduces the robustness of regions I and III. These mechanisms compete with each other, and \( h_{NC}(T) \) shows a weak dependence on temperature. Because of the above mentioned mechanisms, \( h_{NC}(T) \) has a non-monotonic dependence on \( F \).

IV. TEMPERATURE DEPENDENCE OF DOMAIN WALL PROPAGATION

Next, we use the initial condition (2) where a domain wall exists in the system and we study whether the domain wall can propagate to region I. In the present situation, the magnetization of region III is already reversed, and thus the threshold of the domain wall propagation \( h_{DWP}(T) \) should be smaller than \( h_{NC}(T) \). Indeed, once nucleation occurs in region II, \( h_{DWP}(T) \) should be the same as \( h_{NC}(T) \). However, in Fig. 5 \( h_{NC}(T) \) was raised by \( h_{NCH}(T) \), where the dependence of the domain wall depinning was masked by \( h_{NCH}(T) \). The parameter dependence of the domain wall propagation itself is important, and thus in this section we study \( h_{DWP}(T) \) as a function of the parameters \( F \), \( E \) and \( T \).

A. \( T = 0 \)

First, we compare the results at \( T = 0 \) with those obtained analytically. The dependence of \( h_{DWP}(0) \) on \( E \) is shown in Fig. 8. For relatively large values of \( F \), e.g., \( F = 0.5 \) and 0.7, we find good agreements with the analytical result which shows that \( h_{DWP}(0) \) decreases with \( E \). However, for the small value \( F = 0.3 \), it is found that \( h_{DWP}(0) \) increases with \( E \).

If \( F \) is small, that is, if the interaction in region II \( (A_2) \) is small, the correlation length of the magnetization is short. If \( E \) becomes large, that is, if \( K_2/A_2 \) becomes large, the domain wall width becomes short. Thus, we understand that the effect of the reversed magnetization on region III is well shielded in region II, and thus a larger external field is necessary to reverse region I by a surface nucleation process. This effect did not appear in the analytical estimation, where a continuous change of spins is assumed and the configuration is of the Bloch type. In the case for large values of \( K/A \), the usual Bloch wall does not appear, and
FIG. 8. Dependence of $h_{\text{DWP}}(T)$ at $T = 0$ for $F = 0.3, 0.5$ and $0.7$, compared with those obtained analytically. The error bars denote the threshold between the final state $(- - -)$ and $(+ - -)$, and their length is given by the step size on $h$, i.e., $\Delta h = 0.01$. The solid lines are guides for the eye, and the dotted lines denote the analytical estimation.

the so-called narrow domain wall\[13\] appears with a discontinuous change, which is explained in Appendix C.

B. $T > 0$

Next, we study the temperature dependence of $h_{\text{DWP}}(T)$, which is shown in Fig. 9. As the temperature rises, $h_{\text{DWP}}(T)$ is reduced. But, the dependence is much weaker than in the case of $h_{\text{NC}}(T)$ except for the case $F = 0.3$ where $h_{\text{DWP}}(T)$ shows a similar dependence to that of $h_{\text{NC}}(T)$. For $F = 0.3$, $h_{\text{DWP}}(T)$ increases with $E$ at low temperatures. The time evolutions of domain wall propagation for $E = 0.27$ at $h = 0.40$ and $0.60$ are shown in Fig. 10. For $h = 0.4$, the domain wall is pinned at the border between regions I and II. When the field is increased up to $h = 0.6$ the domain wall penetrates into region I. As we discussed above, we may again understand this phenomenon as a kind of surface nucleation of hard magnets.

In the case of a narrow domain wall, the effect of the reversal of regions II and III is masked. In order to see this situation, we plot the magnetization profiles $\langle m(x) \rangle$ in Fig. 11. These are obtained by averaging in the steady state of the $(+ - -)$ type after the domain wall is pinned at the border of regions I and II.
FIG. 9. Domain wall propagation field for $F = 0.3$, 0.5 and 0.7, and $T = 0.1$, 0.3 and 0.5. The lines joining the data points are guides for the eye. The dotted lines represent the fields given by Eqs. (5) and (6), and the dashed lines represent the eyeguides for the total nucleation field depicted in Fig. 5.

For $F = 0.3$ and $E = 0.27$ (Fig. 11(a)), we find a sharp change of the spin direction. In this case, as we discussed above, $A_2 = 0.3$ and $K_2 = K_1 \times 0.9 = 0.2 \times 0.9 = 0.18$, and the width of the Bloch domain wall in the defect region, $\xi = \sqrt{0.3/(2 \times 0.18)} \approx 0.745$, is less than unity, so the continuous approximation is not adequate. For comparison, the magnetic profile at $T = 0.1$ for $F = 0.7$ and $E = 0.63$ with $h = 0.1$ shows a smooth profile. In this case, the increase of $h_{DWP}(T)$ does not take place as we see in Fig. 9.
FIG. 10. Time evolution of the magnetization reversal process for $F = 0.3$, $E = 0.27$ and (a) $h = 0.4$, and (b) $h = 0.6$ at $T = 0.1$. Each row denotes a configuration of spins at the site $(x, 4, 4)$, $x = 1, 60$ at a time $t$. The vertical axis denotes time.

FIG. 11. Magnetization profiles $\langle m(x) \rangle$ for (a) $F = 0.3$, $E = 0.27$ and $h = 0.45$ at $T = 0.1$, and (b) $F = 0.7$, $E = 0.63$ and $h = 0.10$ at $T = 0.1$. The lines are guides for the eye.

In Fig. 12, we show the domain wall motion at $T = 0.1$ for $h = 0.05$, $F = 0.3$ and $E = 0.27$. There, we observe a narrow domain wall, and it is temporally trapped at the right border and also at some intermediate points in region II. However, it finally moves to the left border and remains trapped there until the end of the observation time (not shown).

Indeed, as we discussed in previous sections, if $T > 1.4A_2$ then the defect region is paramagnetic. In this case the magnetic reversal of the hard magnets can be regarded as that of isolated magnets approximately. In all cases, the domain wall propagation can be regarded as a surface nucleation with the relation (20).
FIG. 12. Time evolution of the magnetization reversal process for $F = 0.3$, $E = 0.27$ and $h = 0.05$ at $T = 0.1$. Every row denotes a configuration of spins at the site $(x, 4, 4), x = 1,60$ at a time $t$. The vertical axis denotes the time.

V. SUMMARY AND DISCUSSION

The temperature dependences of the threshold fields for nucleation ($h_{\text{NCII}}(T)$ and $h_{\text{NC}}(T)$) and domain-wall pinning ($h_{\text{DWP}}(T)$) were studied in the system depicted in Fig. 1, where region II has a weaker exchange interaction $F = A_2/A_1 < 1$ and a weaker anisotropy $K_2/K_1 = E/F < 1$ (or $K_2 < K_1$) and it is sandwiched between the hard magnets.

We found that the threshold fields of nucleation phenomena ($h_{\text{NCII}}(T)$ and $h_{\text{NC}}(T)$) strongly depend on temperature. The threshold $h_{\text{NCII}}(T)$ decreases monotonically with the temperature and also with $A_2$ (Fig.6(a)). This is due to the reduction of magnetic order in the soft magnet region II. We estimated the reduction of anisotropy energy of region II ($K_2(T)$) by making use of the bulk information given in Appendix A, and we found that the reduction of the threshold is faster than that estimated from $K_2(T)$. As for the threshold of deconfinement of the nucleated magnetization $h_{\text{NC}}(T)$, we found a similar dependence for relatively large $F$ (i.e., $F = 0.5$ and 0.7). But, for $F = 0.3$ the spring effect from region II is suppressed and a saturation behavior was found (Fig.6(b)). There, the process can be regarded as a surface nucleation phenomenon at the hard magnet region.

The domain-wall pinning shown in Fig. 9 has a similar mechanism to that for the deconfinement of the nucleated negative magnetization $h > h_{\text{NC}}(T)$. That is, the threshold $h_{\text{DWP}}(T)$ is the same as $h_{\text{NC}}(T)$ if the nucleation already takes place. But, the process of $h_{\text{NC}}(T)$ must occur after nucleation occurs in region II, i.e., $h_{\text{NC}}(T) > h_{\text{NCII}}(T)$, and the
intrinsic dependence of the depinning process is not observed when \( h_{\text{NCII}}(T) \) is large at large \( E \). Thus, we studied the threshold of depinning \( h_{\text{DWP}}(T) \) starting from the initial configuration (+ + −). The comparison of \( h_{\text{NCII}}(T) \) and \( h_{\text{DWP}}(T) \) was given in Fig. 9. As observed in the analytical estimation at \( T = 0 \), the general tendency is that a small \( F \) (interaction \( J_2 \)) makes the threshold of the domain wall propagation large, while a large \( F \) causes the threshold of the nucleation in the soft magnet to become large. As new phenomena due to the temperature and the discreteness of the atomic structure, we found the following properties. The depinning threshold generally increases with decreasing of \( F \) (i.e., with \( A_2 \)) as given in the analytical estimation at \( T = 0 \). For small values of \( K_2 \) the threshold becomes smaller than that estimated for the continuous model at \( T = 0 \) (the dotted line), which is a natural temperature effect. However, for small \( F \), the threshold increases with \( E \) (i.e., \( K_2 \)) which we have attributed to the narrow domain wall effect. Moreover, for small \( F \), the threshold is robust against changes in temperature. We have concluded that this robustness is due to the mechanism of surface nucleation phenomena at the surface of the hard magnet because the spring effect is reduced largely in those cases.

Thus for the domain wall pinning at high temperatures, the surface nucleation of the hard magnets would be important, and it is expected that the suppression of nucleation at the surface would help the increase of the coercive force at high temperature. In the present paper, we studied only the cases of soft magnet in the grain boundary, that is, in the parameter region \( A_1 > A_2, K_1 \geq K_2 \). But, in real situations other cases, such as \( A_1 \leq A_2 \) and/or \( K_1 < K_2 \), also exist. In such cases, surface coating may assist the coercive force. We leave this case for future study.

Appendix A: Temperature dependence of the effective anisotropy

The magnetic reversal of a single domain has been discussed in the relation of effective anisotropy. At $T = 0$, the coercive force is given by the Stoner-Wohlfarth mechanism, i.e.,

$$H_c = 2K/M,$$

(A1)

where $K$ is the anisotropy energy and $M$ is the magnetization of the spin. At finite temperatures, one may characterize the properties of the system by introducing a temperature-dependent effective anisotropy $K(T)$. The effective anisotropy has been studied extensively through various methods. Here, we estimate $K(T)$ from the temperature dependence of the transverse magnetic susceptibility

$$
\chi_{xx} = \left( \frac{\partial m_x}{\partial H_x} \right)_{H_{xx}=0}.
$$

(A2)

At $T = 0$, all the spins are aligned and the angle of the magnetization is given by minimizing the energy $E = K \sin^2 \theta - H_x M \sin \theta$. Thus, the transverse magnetization is given by

$$m_x = M \sin \theta_{\text{min}} = \frac{H_x M^2}{2K}, \quad \rightarrow \quad \chi_{xx} = \frac{M^2}{2K}.
$$

(A3)

At $T > 0$, the susceptibility at $H_{xx}$ is given by the fluctuations of $M_x$,

$$
\chi_{xx} = \frac{\langle M_x^2 \rangle - \langle M_x \rangle^2}{TN} = \frac{\langle M_x^2 \rangle}{TN}, \quad M_x = \sum_{i=1}^{N} M \sin \theta_i.
$$

(A4)

Here, one may define an effective anisotropy $K(T)$ by analogy with (A3) using the values at finite temperatures, i.e., $K(T)$ and $m(T)^2$ as

$$
K(T) \equiv \frac{m(T)^2}{2\chi_{xx}} = \frac{T N m(T)^2}{2\langle M_x^2 \rangle},
$$

(A5)

where

$$
m(T) \equiv \sqrt{\langle M_x^2 \rangle + \langle M_y^2 \rangle + \langle M_z^2 \rangle}.
$$

(A6)

We show the temperature dependence of $\left( \sum_{i=1}^{N} S_i \right)^2 / N^2$, which represents the square of the spontaneous magnetization ($\simeq m_s(T)^2$) approximately, and the above defined $K(T)$ for various values of $K/A$ in Fig. 13(a) and (b), respectively.
FIG. 13. Temperature dependences of (a) $\langle \left( \sum_{i=1}^{N} S_i \right)^2 \rangle / N^2 \approx m_s(T)^2$ for various values of $K$ ($K/A = 0.0, 0.2, 0.4, 0.6, 0.8$ and $1.0$), which are plotted by closed circle, upward triangle, square, downward triangle, diamond, and open circle, respectively. (b) Big symbols denote temperature dependences of $K(T)$ for various values of $K$. The small symbols denote $K(0)m(T)^{3/2}$ which agree with $K(T)$ at high temperatures. The dotted curves are drawn as guides for the eye.

As we see in Fig. 13, the Callen-Callen law holds well for $K = 0.2$. But, trivially it does not hold for $K = 0$ and it also does not hold for large $K$.

So far, we have considered the case $H = 0$. Now we consider the anisotropy for the case $|H| > 0$. At $T = 0$, the energy barrier between the metastable antiparallel state ($\theta = 0$) and the stable state ($\theta = \pi$) can be regarded as a quantity to measure the anisotropy. This quantity is obtained by studying the energy as a function of $\theta$:

$$E(\theta) = K \sin^2 \theta - H \cos \theta. \quad \text{(A7)}$$

The energy of the metastable state for a negative field $H(< 0)$ at $\theta = 0$ is

$$E(0) = -H = |H| \quad \text{(A8)}$$

and it has a maximum at some angle $\theta_{\text{max}}$, so the energy barrier is defined as

$$\Delta E \equiv E(\theta_{\text{max}}) - |H|. \quad \text{(A9)}$$

At $T > 0$, we can estimate the free energy barrier in a mean-field approximation from the Hamiltonian (8). Denoting the number of nearest neighbors by $z$ and choosing $m_y = 0$
without loss of generality, the free energy is given by

\[ F(T, H, m_x, m_z) = \frac{z N A}{2} (m_x^2 + m_z^2) - k_B T N \ln Z(T, H, m_x, m_z) \]  \hspace{1cm} (A10)

with

\[ Z(T, H, m_x, m_z) = \int_0^\pi \sin \theta d\theta \int_0^{2\pi} d\phi \]
\[ \exp \left( \beta A z (m_z \cos \theta + m_x \sin \theta \cos \phi) + \beta K \cos^2 \theta + \beta H \cos \theta \right). \]  \hspace{1cm} (A11)

In Fig. 14(a), we plot the angular dependence of the free energy gap for \( D = 0.2 \): \( \Delta f(\theta) = (F(T, H = -0.1, m_x, m_z) - F(T, H = -0.1, 0, -1))/N \). Here the angle \( \theta \) is defined by \( \theta = \tan^{-1}(m_z/m_x) \). This difference can be regarded as a kind of anisotropy. We find that the gap disappears at around \( T = 1.6 \).

In Fig. 14(b), we plot the temperature dependences of the spontaneous magnetization for \( H = 0 \), and the free energy gap: \( \Delta f = (F(T, H, m_x, m_z) - F(T, H, 0, -1))/N \). At finite magnetic field, the potential barrier due to the anisotropy is reduced significantly from that at \( H = 0 \).
Appendix B: Threshold field dependence on observation time

FIG. 15. Dependence of the average time $t_{NC}$ of domain wall depinning after nucleation on the reduced field $h = H/2K_1$. $F = 0.3$, $T = 0.1$, $K_1 = 0.2$, and $E = 0.06$. After $t = 5000$, $t_{NC}$ increases very rapidly, and thus we estimate $t_{NC}$ from data obtained by simulations with $t_{\text{max}} = 5000$.

At finite temperatures, if we perform simulations of systems with a finite size for long times, the system should reach equilibrium. That is, the life time of metastable states is finite. However, when we study the coercive force, the life time of metastable states is important. For the estimation of the threshold fields of nucleation or domain wall depinning, we look for the parameter at which the relaxation time increases rapidly. In realistic time scales, such as 1 second, the corresponding simulation time extremely large. However, it is fortunate that the relaxation time near the threshold increases very rapidly. In Fig. 15 we show an example of the relaxation time for the case $F = 0.3$, $T = 0.1$, $K_1 = 0.2$, $E = 0.06$ which is found in the top left panel of Fig. 5. Simulations begin with the configuration $(+ + +)$, nucleation occurs in region II at a very small field ($h \approx 0.15$), and then the transition from $(+ - +)$ to $(- - -)$ takes place at around $h \approx 0.37$.

In the figure, we depict the average relaxation time $t_{NC}$ obtained over 10 samples by performing long simulations which stopped when the relaxation from $(+ - +)$ to $(- - -)$ occurred. We find a rapid increase of $t_{NC}$ at around $h = 0.37$, and thus in the present work, we decided to adopt $t_{\text{max}} = 5000$ to estimate $h_{NC}(T)$. If we adopt a longer $t_{\text{max}}$, then the threshold decreases slightly, but because of the rapid change we expect that the estimation
here gives approximate information for the threshold fields. This observation is also valid for the case in which the initial configuration is $(+ + -)$ and we study the threshold field for domain wall propagation.

**Appendix C: Bloch domain wall and Narrow domain wall**

In the continuous limit the system is modeled by a one dimensional model

$$E = \int dx \left[ \frac{A}{2} \left( \frac{d\theta}{dx} \right)^2 + K \sin^2 \theta \right],$$

where we put $M = 1$. The solution of domain wall type (Bloch wall) is given by

$$\theta(x) = 2 \tan^{-1} \left( e^{x/\xi} \right), \quad \xi = \sqrt{\frac{A}{2K}}. \quad (C2)$$

On the other hand, for the case of strong anisotropy, the discreteness of the lattice is relevant, and the model should be treated as a discrete lattice:

$$E = -A \sum_i \cos(\theta_i - \theta_{i+1}) + K \sum_i \sin^2 \theta_i. \quad (C3)$$

The minimum energy state is given by

$$\frac{K}{A} \sin 2\theta_i + \sin(\theta_i - \theta_{i-1}) + \sin(\theta_i - \theta_{i+1}) = 0, \quad \text{for all } i. \quad (C4)$$

We assume a solution of domain wall type and set $\theta_{-\infty} = 0$ and $\theta_\infty = \pi$. For the strong anisotropy case, we have $\theta_i \approx 0$ for $i < 0$, and we linearize the above relation.

$$\frac{K}{A} 2\theta_i + (\theta_i - \theta_{i-1}) + (\theta_i - \theta_{i+1}) = \left( 2 \frac{K}{A} + 2 \right) \theta_i - \theta_{i+1} - \theta_{i-1} = 0. \quad (C5)$$

This has the solution for $n < 0$

$$\theta_n = \theta_0 \lambda^{\lfloor n \rfloor}, \quad \text{with} \quad \lambda = \rho - \sqrt{\rho^2 - 1}, \quad \text{(C6)}$$

where $\rho = D/J + 1$. Assuming that the center of the configuration is located at the middle of $i = 0$ and 1, we set $\theta_1 = \pi - \theta_0$. The value of $\theta_0$ is determined by the relation (C4) at $i = 0$

$$\left( 1 - \frac{K}{A} \right) \sin 2\theta_0 = \sin((1 - \lambda)\theta_0). \quad (C7)$$
For $K > \frac{2}{3}A$, this relation only has the solution $\theta_0 = 0$, while $K < \frac{2}{3}A$ it has nonzero solution.
