Intermetallic Fe₆Ge₅ formation and decay of a core–shell structure during the oxygen evolution reaction†

J. Niklas Hausmann, Roman A. Khalaniya, Chittaranjan Das, Ina Remy-Speckmann, Stefan Berendts, Andrei V. Shevelkov, Matthias Driess * and Prashanth W. Menezes * 

Herein, we report on intermetallic iron germanide (Fe₆Ge₅) as a novel oxygen evolution reaction (OER) precatalyst with a Tafel slope of 32 mV dec⁻¹ and an overpotential of 272 mV at 100 mA cm⁻² in alkaline media. Furthermore, we uncover the in situ formation of a core–shell like structure that slowly collapses under OER conditions.

The kinetically demanding oxygen evolution reaction (OER) is responsible for most of the efficiency loss in electrocatalytic water splitting.¹ To overcome this disadvantage, a vast amount of OER (pre)catalysts based on abundant Fe, Co, and Ni have been investigated.¹,² Various kinds of materials with these three metals have been investigated for their OER properties, including oxides, chalcogenides, pnictides, carbides, borides, borates, phosphates, borophosphates, and intermetallics.¹–⁵ Even though, at least at their surface, most of these compounds transform to layered (oxy)hydroxides under alkaline OER conditions, it has been shown that the nature of the non-OER active elements and the structure of the precatalyst influence the properties of the final catalyst.⁵–⁷ Such during OER formed catalysts have often shown high activities due to a remaining conductive core, an increased surface area, more exposed active sites caused by leaching of an element, and bulk instead of near-surface activity.⁵,⁶,⁸ In this regard, the exploration of novel precatalysts with exceptional structural characteristics could pave the way to superior OER catalysts. A promising and comparably unexplored class is intermetallics. In contrast to alloys, they contain conducting electrons together with a chance of self-supported corrosion during OER electrocatalysis.¹⁰ Herein, we report on the first iron-based OER catalyst containing germanium, intermetallic Fe₆Ge₅, and uncover its structural transformation during the OER.¹¹,¹²

Intermetallic Fe₆Ge₅ was synthesized using a high-temperature annealing method (details in the ESI†). It crystallises in its own structure derived from the B₈ type (Fig. 1a and Fig. S1, ESI†). The crystal structure consists of a dense packing of Fe and Ge atoms, it has been shown that the nature of the non-OER active elements and the structure of the precatalyst influence the properties of the final catalyst.⁵–⁷ Such during OER formed catalysts have often shown high activities due to a remaining conductive core, an increased surface area, more exposed active sites caused by leaching of an element, and bulk instead of near-surface activity.⁵,⁶,⁸ In this regard, the exploration of novel precatalysts with exceptional structural characteristics could pave the way to superior OER catalysts. A promising and comparably unexplored class is intermetallics. In contrast to alloys, they contain conducting electrons together with a chance of self-supported corrosion during OER electrocatalysis.¹⁰ Herein, we report on the first iron-based OER catalyst containing germanium, intermetallic Fe₆Ge₅, and uncover its structural transformation during the OER.¹¹,¹²

Intermetallic Fe₆Ge₅ was synthesized using a high-temperature annealing method (details in the ESI†). It crystallises in its own structure derived from the B₈ type (Fig. 1a and Fig. S1, ESI†). The crystal structure consists of a dense packing of Fe and Ge atoms and is built up by polyhedra of five different Fe atoms forming square pyramids, distorted octahedra and pentagonal prisms with Ge atoms.¹¹,¹²

Fig. 1 (a) Depiction of the Fe₆Ge₅ structure along [100] (Fe orange, Ge blue). (b) pXRD of the pristine Fe₆Ge₅ powder and image of the powder with a cm scale. The blue bars indicate the position and intensity of the reported reflections taken from the JCPDS database. (c) SEM/EDX mapping of a Fe₆Ge₅ particle.
The powder X-ray diffraction (pXRD) pattern reveals the formation of pure Fe$_6$Ge$_5$ (Fig. 1b). Scanning electron microscopy (SEM) images show irregularly shaped particles with a size of 0.5–10 μm (Fig. S2, ESI†). SEM energy dispersive X-ray (EDX) mapping uncovers a homogeneous distribution of Fe and Ge (Fig. 1c) and the corresponding EDX spectrum does not contain any impurity peaks (Fig. S3, ESI†) and confirms the Fe:Ge ratio of 6:5. After grinding, transmission electron microscopy (TEM) was conducted (Fig. S4, ESI†). The high-resolution image, the selected area diffraction pattern, and the EDX spectrum (Fig. S5, ESI†) confirm the presence of a pure, crystalline Fe$_6$Ge$_5$ phase. The Fe 2p X-ray photoelectron spectrum (XPS, Fig. S6a, ESI†) reveals the presence of Fe$^0$ consistent with the intermetallic nature of Fe$_6$Ge$_5$. Additionally, also a Fe$^{II}$ surface species is observed originating from surface passivation in air, which is typical for intermetallic species. In agreement with this observation, the Ge 3d XPS spectrum shows the presence of Ge$^0$ together with oxidised Ge$^{II}$ and Ge$^{III}$ species (Fig. S6b, ESI†).

For OER investigations of Fe$_6$Ge$_5$, we deposited 0.4 mg cm$^{-2}$ on fluorine doped tin oxide (FTO) glass plates using a binder-free method (electrophoretic deposition (EPD), see ESI† for details and Fig. S7 and S8 for SEM/EDX data of the thin film). The obtained system, Fe$_6$Ge$_5$/FTO, was analysed by linear scan voltammetry (LSV, Fig. 2a) together with the reference materials Fe, Fe(OH)$_3$, FeOOH, and Fe$_2$O$_3$ (same loading and deposition method). Fe$_6$Ge$_5$/FTO yielded a current density ($i$) of 10 mA cm$^{-2}$ at an overpotential ($\eta$) of 420 mV, whereas the second most active material, Fe/FTO, required over 70 mV more to reach the same $i$.

Motivated by this result, we deposited 1 mg cm$^{-2}$ of Fe$_6$Ge$_5$ on highly conducting, 3D porous nickel foam (NF, Fig. S9 and S10 for SEM/EDX data, ESI†). The Fe$_6$Ge$_5$/NF yielded 10 mA cm$^{-2}$ and 100 mA cm$^{-2}$ at $\eta$ values of 221 mV and 272 mV, respectively (Fig. 2b). The $\eta_{10/100}$ required for the best iron based reference material is again 60–70 mV larger confirming the trend observed on FTO. Furthermore, we loaded various Ni, Co, and NiFe based catalysts with the same mass loading by EPD on NF and performed LSVs. Again, Fe$_6$Ge$_5$ shows the best activity (Fig. S11a, see Table S1 for $\eta_{10}$ of state of the art catalysts, ESI†). The OER faradaic efficiency of Fe$_6$Ge$_5$ was determined to be 97% (Fig. S12, ESI†).

Inspired by the high activity of Fe$_6$Ge$_5$/NF, we performed further electrocatalytic investigations. Electrochemical impedance spectroscopy (EIS) at $\eta = 270$ mV of the iron-based materials revealed that Fe$_6$Ge$_5$ has the lowest charge-transfer resistance ($R_{ct}$, Fig. 2c) consistent with the activity trend from the LSVs. Steady state Tafel data (Fig. 2d) disclose a wide kinetically controlled region (from 0.1 to 100 mA cm$^{-2}$) with a slope of merely 32 mV dec$^{-1}$ indicating excellent OER kinetics and mass transport properties of the system (see Fig. S11b for Tafel slopes of the Fe reference materials, ESI†). A chronocoulometry (CA) measurement at $\eta = 280$ mV yields initially 100 mA cm$^{-2}$ (Fig. 2e). However, in the first 20 h, $i$ decreases by 25% to 75 mA cm$^{-2}$. Nevertheless, after this initial deactivation, $i$ remains stable. By cycling in a potential region without a faradaic process (Fig. S13, ESI†), we determined the double layer capacitance ($C_{dl}$) before and after the CA measurement (Fig. 2f). This comparison uncovers that the $C_{dl}$ increases by four times during the OER.

process. Such a strong change indicates that at least the surface of the material is transformed.

To understand the structural transformation of Fe\textsubscript{6}Ge\textsubscript{5}, we performed several analytical methods after 1 h at 10 mA cm\textsuperscript{-2} (Fig. S14, ESI†). The pXRD pattern (Fig. S15, ESI†) contains the characteristic reflections of the Fe\textsubscript{6}Ge\textsubscript{5} phase and no new, additional peaks indicating that the Fe\textsubscript{6}Ge\textsubscript{5} phase is still intact and that the newly formed phase is non-crystalline. SEM images show that the morphology of the particles did barely change (Fig. S16, ESI†). SEM/EDX mapping reveals a homogeneous distribution of Fe and Ge, however, the relative Ge content is 15% lower than in the pristine material (Fig. S16 and S17, ESI†).

TEM images show a porous material on the surface of the particles (Fig. 3a and b). And a SAED taken from such a surface region contains only two diffuse diffraction rings consistent with randomly distributed short-range ordered iron oxyhydroxide phases such as 2 line ferrihydrite and layered phases with edge sharing [MO\textsubscript{6}] octahedra (Fig. 3c).\textsuperscript{6,18} EDX data of the same area discloses a substantial incorporation of K and a Fe to O ratio of 1 to 2 while almost no Ge was left (Fig. 3c and Fig. S18 top, ESI†). A TEM SAED taken from the centre of the same particle contains reflections that can be assigned to a highly crystalline Fe\textsubscript{6}Ge\textsubscript{5} phase (Fig. 3d). Furthermore, EDX reveals an only 15% decreased Ge content and a slight inclusion of K and O (Fig. 3d and Fig. S18, ESI†, bottom).

XPS reveals more information about the in situ formed surface structure. In the deconvoluted 2p Fe spectrum, a small, residual amount of Fe\textsuperscript{0} is present while the major oxidation states are Fe\textsuperscript{II} and Fe\textsuperscript{III} (Fig. 3e).\textsuperscript{15} Also, in the 3d Ge spectrum, a minor amount of residual Ge\textsuperscript{0} can be found but Ge\textsuperscript{III} and Ge\textsuperscript{IV} are the dominant species (Fig. 3f).\textsuperscript{17} The deconvoluted O 1s spectrum contains three peaks (Fig. 3g). Two peaks are consistent with reported iron oxyhydroxide phases and can be assigned to iron oxide (529.6 eV) and iron hydroxide (531.1 eV), respectively.\textsuperscript{18–20} The hydroxide peak also overlaps with the Ge\textsubscript{2}O\textsubscript{3} and the peak at 532.5 eV is in accordance with Ge\textsuperscript{IV}O\textsubscript{2}.\textsuperscript{17}

To this point, the Fe\textsubscript{6}Ge\textsubscript{5} characterisation uncovers a highly active OER catalyst consisting of a conductive Fe\textsubscript{6}Ge\textsubscript{5} core and an in situ formed amorphous shell. The stoichiometry of the newly formed shell is K\textsubscript{x}FeO\textsubscript{2}H\textsubscript{y}. Structurally, the shell shows diffraction and XPS data consistent with randomly distributed short-range ordered layered oxyhydroxide structures or 2 line ferricydrate.\textsuperscript{6,18} Such structures are typical for under OER conditions formed phases from an Fe containing precursor.\textsuperscript{7,8,16,21} The arguments for the superior activity of the Fe\textsubscript{6}Ge\textsubscript{5} system compared to that of the Fe/Ni/Co-based reference materials are: (i) a high porosity which probably enables the electrolyte to penetrate the shell and leads to more active iron sites to participate in the OER process and a higher surface area, (ii) more edge iron sites and defects due to the disordered amorphous structure, and (iii) the presence of a conductive Fe\textsubscript{6}Ge\textsubscript{5} core facilitating electron transport to the active sites.\textsuperscript{5,7,22}

However, when such core–shell like structures are formed, it is important to investigate whether they remain or slowly the entire particle transforms.\textsuperscript{16,23} The long-term CA measurement
(Fig. 2c) shows that, after the first hour, a continuous deactivation takes place within the next 20 h. The reason for that may be a further transformation of the structure. To investigate this, we performed SEM/EDX and XPS investigations after the 25 h CA measurement (Fig. S19–S21, ESI†). We find a barely altered morphology, but the Ge content decreased by 60%. The XPS data are to a large extent consistent with the one after 1 h OER, but barely show signals for FeO and GeO above the noise level. Thus, the conducting Fe₆Ge₅ core is constantly shrinking. In such a system, the OER reaction could take place either at the core–shell interface or at the near surface area of the particle (particle–electrolyte interface). In the first scenario, the mass transport limitation will increase with a shrinking core due to a larger iron oxohydroxide shell that the electrolyte/oxide must penetrate until it reaches the reaction zone. In the second scenario, the limitation will arise from a longer distance that the electrons must travel through the poorly conducting iron oxohydroxide until they reach the reaction zone. It is likely that a mixture of both scenarios transpires and leads to the deactivation of the Fe₆Ge₅ system.

The question that follows is: what are the criteria that make a core–shell structure stable? For the transformation of the core, it must be in contact with the electrolyte and electrically wired to the anode. The first condition is not given if the formed iron oxohydroxide is not penetrable by the electrolyte resulting in a stable core–shell structure. The electrolyte penetrability of the shell will be determined by its porosity which will be *inter alia* a function of the leaching species. From a rational point of view, large leaching species should preferably lead to porosity. The volume of germanium calculated from its van der Waals radius is large (39 Å³) compared to other leaching elements in well-known OER precatalysts such as carbon (21 Å³), phosphorus (24 Å³), sulphur (24 Å³), or selenium (29 Å³). Note here that in solutions the nature of these leaching species is highly oxidised as can be seen in their Pourbaix diagrams (e.g. for germanium GeO₂− should be present). Nevertheless, the void that they leave in the structure depends on the size of the original precatalyst species and not the oxidised one in solutions. Thus, the larger volume of germanium could be the reason why the *in situ* formed shell is electrolyte penetrable and does not protect the inner core. The fact that the transformation takes a comparably large amount of time under a rather high current density is caused by the large particle size of the utilized Fe₆Ge₅.

In conclusion, our work does not only present a detailed electrocatalytic analysis of a new, intermetallic compound but also evidences that core–shell structures can be metastable on a pathway to full precatalyst transformation.
