Abstract

In this work we consider a minimal version of the scotogenic model capable of accounting for an electron electric dipole moment within experimental sensitivity reach in addition to providing a dark matter candidate and radiatively generating neutrino masses. The Standard Model is minimally extended by two sterile fermions and one inert scalar doublet, both having odd parity, while the Standard Model particles have an even parity, imposed by a $\mathbb{Z}_2$ symmetry. The neutrino Yukawa couplings provide additional sources of CP violation, and thus a possible impact on electric dipole moments of charged leptons. This model provides two possible dark matter candidates (one bosonic and one fermionic) and our results show that, independently of the ordering of the generated light neutrino spectrum, one can have sizeable electron electric dipole moment within ACME sensitivity reach in the case of fermionic dark matter candidate.

1 Introduction

Although the Standard Model (SM) provides a successful description of physics below the electroweak scale, it cannot accommodate the tiny neutrino masses suggested by neutrino oscillation experiments. One of the simplest options to generate non-zero neutrino masses at tree level is the seesaw mechanism, such as the Type-I [1–5], Type-II [6, 7], Type-III [8], inverse [9] and linear seesaw mechanisms [10,11].

On the other hand, exploring CP violation is important since it is one of the necessary ingredients at the origin of the baryon asymmetry of the Universe (BAU). Although CP violation in the SM has been confirmed in the quark sector, it is not large enough to reproduce the BAU as observed by the Planck Collaboration, $n_s/s = (8.59 \pm 0.11) \times 10^{-11}$ [12]. The possibility of CP violation in the lepton sector fueled the interest of generating the BAU via leptogenesis, as proposed in Ref. [13], where a lepton asymmetry arises from lepton number and CP violating out-of-equilibrium decays of (heavy) right-handed neutrinos. In addition, neutrinoless double beta decay ($0\nu\beta\beta$) is the observable associated with the existence of Majorana neutrinos and with CP violating phases; many other processes reflecting total lepton number violation by two units ($\Delta L = 2$), as in the case of the latter observable, are being actively searched for. For instance, at colliders, there are several possible signatures of lepton number violation [14–20]. As pointed out in several analyses, neutrino Majorana phases can also give rise to non-vanishing contributions to charged lepton electric dipole moments (EDMs) [21]; in particular, the computation of EDMs in the presence of right-handed neutrinos (like in the Type-I seesaw model) has been addressed in Ref. [22–24].

Recently, working in the framework of a “3 + $n_S$” (SM extended by a number $n_S$ of sterile fermions) model, a derivation of the 2-loop analytical expressions allowed to show that a non-vanishing contribution to the EDMs requires at least the addition of two non-degenerate sterile states to the SM field content [25]. A numerical evaluation of the contributions to the charged lepton EDMs in the case of the simple “3+2” toy model showed that, provided the masses of the two mostly sterile states are in the range from 100 GeV to 100 TeV, it is possible to have $|d_e|/e \geq 10^{-30}$ cm (although for the muon and tau EDMs the predictions remain several orders of magnitude below the corresponding future sensitivities) [25]. Interestingly, part of the regimes leading to sizable electron EDM within ACME next generation [26, 27] reach are also within detection reach of a future ILC. This is in contrast with the inverse seesaw realization, where minimal realizations have been found in Ref. [28], and for which it was shown in Ref. [29] that charged lepton EDMs can indeed be enhanced by large neutrino Yukawa couplings, naturally present in the inverse seesaw models. However, the maximum value of the predicted electron EDM is $|d_e^{\text{max}}|/e \sim 5 \times 10^{-31}$ cm, lying two orders of magnitude below the current experimental bound, $|d_e|/e \leq 8.7 \times 10^{-29}$ cm, and thus marginally short of the future sensitivity, $|d_e|/e \sim 10^{-30}$ cm [26,27].

The computation of charged lepton EDMs that has been done in the context of tree level seesaw mechanisms can straightforwardly be applied to the framework of radiative seesaw models, where small neutrino masses are generated at (one) loop level. Many models with radiative neutrino masses have been proposed so far. One interesting feature of the framework we consider in this study is that a dark matter candidate is also naturally included due to an imposed symmetry which forbids the Dirac neutrino mass term at tree level, and also stabilizes a lightest
new particle, rendering it a possible dark matter candidate. The scotogenic model which has been proposed by Ma [30] is the simplest model with radiative neutrino masses, and is well-studied as a benchmark model. In this model, the new Yukawa couplings between leptons and the new particles play an important role in generating neutrino masses at the one-loop level and in providing an interactive dark matter.

In this work, we explore the effect and the magnitude of CP violation in the scotogenic model by computing the electron EDM while taking into account all experimental and theoretical constraints such as lepton flavour violation, electroweak precision data, dark matter searches, vacuum stability and the perturbativity of the couplings.

The paper is organised as follows: in Section 2 we present the basic set up of the minimal scotogenic model we consider, the derivation of neutrino masses and the parametrization we adopt. In Section 3, we give the detailed computation of the electron EDM. We collect the relevant experimental and theoretical constraints that we impose in our analysis in Section 4. The numerical results are presented in Section 5, and our final remarks and discussion are collected in Section 6. In the Appendix, we give the general formulae of the loop functions for the charged lepton EDMs in the scotogenic model.

2 The Model

In the original version of the scotogenic model, which has been proposed in Ref. [30], the SM was extended by three singlet fermions $N_i$ ($i = 1, 2, 3$) and one inert scalar doublet $\eta$. In this work, we consider the same model but with only two massive neutral (sterile) fermions $N_i$ ($i = 1, 2$) with the aim of minimizing the degrees of freedom; in this case, only two non-zero (light) neutrino mass eigenvalues can be generated at one-loop level, the lightest neutrino remaining massless. A $Z_2$ symmetry is imposed such that the new particles have odd parity, while the SM particles have even parity. The Lagrangian involving the new particles is given by

$$
\mathcal{L} = (D_\mu \eta)^\dagger (D^\mu \eta) + \frac{1}{2} \overline{N_i} (i\partial^\mu - m_i) N_i - y_{i\alpha} \eta \overline{N_i} \gamma_\mu L_\alpha + \text{H.c.},
$$

where $L_\alpha$ ($\alpha = e, \mu, \tau$) are the SM left-handed lepton doublets and where $m_i$ ($i = 1, 2$) denotes the mass of the sterile fermions taking $m_1 < m_2$. With the additional inert scalar doublet $\eta$, the scalar potential $V$ becomes

$$
V = \mu_H^2 |H|^2 + \mu_\eta^2 |\eta|^2 + \frac{\lambda_1}{2} |H|^4 + \frac{\lambda_2}{2} |\eta|^4 + \lambda_3 |H|^2 |\eta|^2 + \lambda_4 |H|^4 + \lambda_5 \left[ (\eta^\dagger H)^2 + \text{H.c.} \right].
$$

The coupling $\lambda_5$ is generally complex, however the CP phase can be absorbed by a field redefinition of the doublet scalar $\eta$. Thus one can always consider $\lambda_5 > 0$, putting the new CP violating phases in the Yukawa coupling $y_{i\alpha}$ of Eq. (1). After the electroweak symmetry breaking, the neutral component of the inert scalar, $\eta^0 = (\eta_R + i\eta_I)/\sqrt{2}$, splits into the CP-even state $\eta_R$ and the CP-odd one $\eta_I$, whose masses are respectively given by

$$
m_R^2 = \mu_\eta^2 + (\lambda_3 + \lambda_4 + \lambda_5) \langle H \rangle^2,
$$

$$
m_I^2 = \mu_\eta^2 + (\lambda_3 + \lambda_4 - \lambda_5) \langle H \rangle^2,
$$

where
where $\langle H \rangle$ is the vacuum expectation value of the SM Higgs boson $H$. Notice that one can deduce from Eqs. (3), (4) that the latter squared mass difference is given by

$$m_R^2 - m_I^2 = 2\lambda_5 \langle H \rangle^2.$$  

As will be explained later, we focus on the case where the CP-even and CP-odd states are nearly degenerate ($m_R \approx m_I$) in order to have large enough Yukawa couplings $y_{i\alpha}$ to generate sizeable electron EDM. The mass of the charged scalar $\eta^+$ and the average of the squared mass of CP-even and CP-odd states are given by

$$m_{\eta^+}^2 = \mu_{\eta}^2 + \lambda_3 \langle H \rangle^2, \quad m_{\eta^0}^2 = (m_R^2 + m_I^2)/2.$$  

In this model, Majorana neutrino masses for left-handed neutrinos are induced at one-loop level as shown in Fig. 1 and the $(3 \times 3)$ neutrino mass matrix is computed as

$$(m_\nu)_{\alpha\beta} = \sum_{i=1}^{2} y_{i\alpha} y_{i\beta} m_i \left[ \frac{m_R^2 - m_i^2}{m_R^2 - m_i^2} \log \left( \frac{m_R^2}{m_i^2} \right) - \frac{m_I^2}{m_I^2 - m_i^2} \log \left( \frac{m_I^2}{m_i^2} \right) \right].$$  

In the particular case where the mass splitting between $m_R$ and $m_I$ is small (i.e. when the coupling $\lambda_5$ is small, see Eq. (5)), the Majorana neutrino mass matrix is simplified as

$$(m_\nu)_{\alpha\beta} \approx \sum_{i=1}^{2} y_{i\alpha} y_{i\beta} m_i \frac{\lambda_5 \langle H \rangle^2}{(4\pi)^2} \frac{1}{m_{\eta^0}^2 - m_i^2} \left[ 1 - \frac{m_i^2}{m_{\eta^0}^2 - m_i^2} \log \left( \frac{m_{\eta^0}^2}{m_i^2} \right) \right],$$  

that we can parametrize as follows

$$(m_\nu)_{\alpha\beta} \equiv (y^T \Lambda y)_{\alpha\beta},$$  

where the $(2 \times 3)$ matrix $y$ collects the Yukawa couplings $y_{1\alpha}$ (first line) and $y_{2\alpha}$ (second line) with $\alpha = e, \mu, \tau$, and where the matrix $\Lambda$ is given by

$$\Lambda = \begin{pmatrix} \Lambda_1 & 0 \\ 0 & \Lambda_2 \end{pmatrix}, \quad \text{with} \quad \Lambda_i = \frac{m_i}{(4\pi)^2} \frac{\lambda_5 \langle H \rangle^2}{m_{\eta^0}^2 - m_i^2} \left[ 1 - \frac{m_i^2}{m_{\eta^0}^2 - m_i^2} \log \left( \frac{m_{\eta^0}^2}{m_i^2} \right) \right].$$  

Interestingly, since the Majorana mass matrix is proportional to the coupling $\lambda_5$, the latter is directly linked to lepton number violation and thus, taking small $\lambda_5$ would be natural in the sense of t’Hooft [31] to induce small Majorana masses for the left-handed neutrinos.
The $3 \times 3$ neutrino mass matrix is diagonalized as $U_{\text{PMNS}}^T \hat{m}_\nu U_{\text{PMNS}} = \text{diag}(\hat{m}_1, \hat{m}_2, \hat{m}_3)$ with the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) matrix $U_{\text{PMNS}}$ where $\hat{m}_1 = 0$ ($\hat{m}_3 = 0$) in the case of normal (inverted) ordering of the light neutrino spectrum. In this case, the PMNS matrix is parameterized as usual by

$$U_{\text{PMNS}} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta_{23} & \sin \theta_{23} \\ 0 & -\sin \theta_{23} & \cos \theta_{23} \end{pmatrix} \begin{pmatrix} \cos \theta_{13} & 0 & e^{-i\delta_{\text{CP}}} \sin \theta_{13} \\ 0 & 1 & 0 \\ -e^{i\delta_{\text{CP}}} \sin \theta_{13} & 0 & \cos \theta_{13} \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta_{12} & \sin \theta_{12} \\ -\sin \theta_{12} & \cos \theta_{12} & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \kappa \sin \xi & \kappa \cos \xi \\ 0 & \kappa \sin \xi & \kappa \cos \xi \end{pmatrix}.$$  \hspace{1cm} (11) 

The PMNS matrix includes one Dirac phase $\delta_{\text{CP}}$ and one Majorana phase $\varphi_{\text{CP}}$. The $2 \times 3$ Yukawa matrix $y$ defined in Eq. (9) can be expressed adapting the Casas-Ibarra parametrization as \cite{32}

$$y = \sqrt{\Lambda}^{-1} C \sqrt{\hat{m}_\nu} U_{\text{PMNS}}^1,$$  \hspace{1cm} (12)

where $C$ is a $2 \times 3$ matrix satisfying $CC^T = I_{2 \times 2}$. Furthermore, this matrix $C$ can be parameterized as

$$C = \begin{pmatrix} 0 & \cos \xi & -\sin \xi \\ 0 & \kappa \sin \xi & \kappa \cos \xi \end{pmatrix}, \text{ for normal hierarchy },$$  \hspace{1cm} (13)

$$C = \begin{pmatrix} \cos \xi & -\sin \xi & 0 \\ \kappa \sin \xi & \kappa \cos \xi & 0 \end{pmatrix}, \text{ for inverted hierarchy },$$  \hspace{1cm} (14)

where $\kappa$ is the sign parameter $\kappa = \pm 1$ and $\xi$ is a complex angle. The non-zero $2 \times 2$ part of Eq. (13) and (14) corresponds to an element of the $O(2, \mathbb{C})$ group, whose determinant is given by the parameter $\kappa$. Consequently, the $2 \times 3$ Yukawa matrix $y$ can be defined in terms of 5 parameters experimentally determined by neutrino oscillation experiments (i.e. $\Delta \hat{m}_{ij}^2$ and the three mixing angles) and 7 free parameters that are: $\Lambda_1, \Lambda_2, \delta_{\text{CP}}, \varphi_{\text{CP}}$ and the matrix $C$ which includes three free real parameters. Hereafter we express $\sin \xi$ as $\sin \xi = |\sin \xi| e^{i\eta_{\text{CP}}}$.

Since the lightest $Z_2$ odd particle is stabilized, the model also includes a dark matter candidate which, depending on the mass hierarchy of the $Z_2$ odd particles, can be either the lightest singlet fermion $N_1$ or the neutral component of the inert scalar doublet $\eta$. The detailed phenomenology regarding neutrinos and dark matter for the scotogenic model has been explored in, for instance, Refs. \cite{33–37}.

A necessary requirement for the viability of the model considered here is that there is no vacuum expectation for the field $\eta$ ($\langle \eta \rangle = 0$) as otherwise the DM candidate is unstable. The relevant condition for this to hold is that the scalar masses are real (or their squares are positive such that the potential has a stable minimum). In order to ensure that a global minimum exists at finite vacuum expectation value (the potential being bounded from below), the following

---

\textsuperscript{1}We recall that due to the fact that in this minimal model where only two fermionic singlets (right-handed neutrinos) are considered, the diagonalisation of the neutrino mass matrix leads to a massless active neutrino and thus to only one Majorana CP violating phase, instead of two CP phases in the case of 3 sterile fermions.
theoretical conditions have to be satisfied [38],

\[ \lambda_1 > 0, \quad \lambda_2 > 0, \]

\[ \lambda_3 > -\sqrt{\lambda_1 \lambda_2}, \quad \lambda_3 + \lambda_4 - |\lambda_5| > -\sqrt{\lambda_1 \lambda_2}. \]  

(15)  

In addition, all the couplings in the model should be perturbative. Here we take a criterion of perturbativity such that all the couplings are smaller than \( \sqrt{4\pi} \). Since the scalar couplings \( \lambda_3, \lambda_4 \) and \( \lambda_5 \) are correlated with the mass eigenvalues \( m_{\eta^+}^2, m_R^2 \) and \( m_I^2 \), the perturbativity conditions are translated into the following constraints on the masses

\[ |\lambda_3| \leq \min \left[ \sqrt{4\pi}, \frac{m_{\eta^+}^2}{\langle H \rangle^2} \right], \quad \left| \frac{m_R^2 + m_I^2 - 2m_{\eta^+}^2}{2\langle H \rangle^2} \right| \leq \sqrt{4\pi}, \quad \left| \frac{m_R^2 - m_I^2}{2\langle H \rangle^2} \right| \leq \sqrt{4\pi}. \]  

(16)  

3 Electron Electric Dipole Moment

3.1 Experimental Status

The current experimental bounds for the charged lepton EDMs are

\[ |d_e|/e \leq 8.7 \times 10^{-29} \text{ cm}, \]  

(18)  

\[ |d_\mu|/e \leq 1.9 \times 10^{-19} \text{ cm}, \]  

(19)  

\[ |d_\tau|/e \leq 4.5 \times 10^{-17} \text{ cm}. \]  

(20)  

These have been measured by ACME Collaboration [26], Muon g–2 Collaboration [39] and Belle Collaboration [40], respectively. In particular, the upper bound for the electron EDM is much stronger than the bounds for the muon and tau EDMs. Moreover, the electron EDM is expected to reach \( |d_e|/e \sim 10^{-30} \text{ cm} \) with the next generation experiment of the ACME Collaboration [27]. We focus thus on the electron EDM hereafter, although the analytical formula we derive in this work is general for any charged lepton EDM.

3.2 Computation of Electron Electric Dipole Moment

Since EDMs are CP violating observables, relevant couplings for EDMs should be complex to give a non-zero contribution. Note that all the diagrams at one-loop level are proportional to the modulus of the neutrino Yukawa coupling \( y_{i\alpha} \). Thus the leading contribution to charged lepton EDMs comes at the two-loop level via the diagrams shown in Fig. 2. Unlike the case of minimal extensions of the SM via only sterile fermions, where the singlet fermions mix with the left-handed neutrinos as in, for instance, in Refs. [25, 29], there are no other two-loop level diagrams than those that are shown in Fig. 2 contributing to EDMs due to the exact \( Z_2 \) symmetry. The derivation of the charged lepton EDMs has been made using FeynCalc for the loop computations [41].

Assuming that the masses of the new particles are much heavier than the charged lepton ones \( (m_{\alpha} \ll m_{\eta^0}, m_{\eta^+}, m_i) \), the EDM for a charged lepton \( \ell_\alpha \) can formally be expressed as

\[ d_\alpha = -\frac{e m_{\alpha}^2}{(4\pi)^2 m_{\eta^+}^2} \sum_{i,j=1}^{2} J_{ij\alpha\beta}^M \sqrt{x_i x_j} I_M(x_i, x_j) + J_{ij\alpha\beta}^D I_D(x_i, x_j), \]  

(21)
where \( x_i = m_i^2/m_\eta^2 \) (\( i = 1, 2 \)), \( I_M(x_i, x_j) \), \( I_D(x_i, x_j) \) are the loop functions computed from the two-loop diagrams of Fig. 2 and the CP phase factors \( J_{i,j\alpha\beta}^{M,D} \) are defined by

\[
J_{i,j\alpha\beta}^M \equiv \text{Im} \left( y_{i\alpha}^* y_{j\beta}^* y_{i\alpha} y_{j\beta} \right), \quad J_{i,j\alpha\beta}^D \equiv \text{Im} \left( y_{i\alpha}^* y_{j\beta} y_{i\alpha} y_{j\beta} \right). \tag{22}
\]

The first term in Eq. (21) corresponds to the contribution of diagrams (a1), (a2), (a3), (b1) and (b2), all involving Majorana fermion propagators, they hence pick up the Majorana mass of the singlet fermions in the propagators which can be regarded as lepton number violation; they thus contribute to the Majorana type loop function \( I_M(x_i, x_j) \). The second term in Eq. (21) stems from diagrams (c1) and (c2) with Dirac fermion propagators contributing to the Dirac type loop function \( I_D(x_i, x_j) \). The explicit expressions of the loop functions \( I_{M,D}(x_i, x_j) \) are given in the Appendix. Interestingly, one can see from the definition of Eq. (22) that the phase factors \( J_{i,j\alpha\beta}^M \) and \( J_{i,j\alpha\beta}^D \) are anti-symmetric under the exchange of \( i \) and \( j \). Thus, only the anti-symmetric part of the loop functions \( I_M(x_i, x_j) \) and \( I_D(x_i, x_j) \) contributes to the charged lepton EDMs. For this reason, the general formula of Eq. (21) can be further simplified in our case, where \( i, j = 1, 2 \), by taking into account the anti-symmetric character of both phase factors and loop functions as follows

\[
d_\alpha = - \frac{2e m_\alpha}{(4\pi)^4 m_\eta^2} \sum_\beta \left[ J_{12\alpha\beta}^M \sqrt{x_1 x_2} I_M(x_1, x_2) + J_{12\alpha\beta}^D I_D(x_1, x_2) \right]. \tag{23}
\]
Figure 3: Loop functions $I_M(x_i, x_j)$ and $I_D(x_i, x_j)$ as a function of $x_i$ where $x_j = m^2_j/m^2_{\eta^+}$ is fixed to 0.1, 1 and 10.

As for the expression for the electron EDM ($\alpha = e$), one obtains

$$d_e = -\frac{2e m_e}{(4\pi)^4 m^2_{\eta^+}} \left[ J^M \sqrt{x_1 x_2} I_M(x_1, x_2) + J^D I_D(x_1, x_2) \right],$$

with

$$J^M = J^M_{12e\mu} + J^M_{12e\tau} \quad \text{and} \quad J^D = J^D_{12e\mu} + J^D_{12e\tau}. \quad (25)$$

The behaviour of the loop functions $I_M(x_i, x_j)$ and $I_D(x_i, x_j)$ that have been numerically evaluated, are shown in Fig. 3 as a function of $x_i$ for several values of $x_j$. One can see that both loop functions are of the same order in most of the parameter space, and that the maximal values are $O(0.01)$ when there is a large hierarchy between the masses of the two sterile states, $x_i \ll x_j$ (i and j can be interchanged, as discussed above). Conversely, these loop functions are suppressed for larger new particle masses, $m_i$ and $m_{\eta^+}$. Furthermore, since the loop functions are anti-symmetric under the exchange of $i \leftrightarrow j$, they would also be suppressed if $m_i$ and $m_j$ are extremely degenerate as can be noticed from Fig. 3.

4 Constraints

Here we summarize the relevant experimental constraints on the minimal scotogenic model we consider.

4.1 Neutrino Masses and Mixings

We have checked that the considered framework with the parametrization of the neutrino Yukawa couplings given in Eq. (12) reproduce neutrino data (neutrino mixings and squared neutrino mass differences). We take the following range for the mixing angles and masses, which
corresponds to $3\sigma$ confidence level [42,43],

$$
0.270 \leq \sin^2 \theta_{12} \leq 0.344,
0.382 \leq \sin^2 \theta_{23} \leq 0.643,
0.0186 \leq \sin^2 \theta_{13} \leq 0.0250,
$$

$$
7.02 \leq \frac{\Delta m_{21}^2}{10^{-5} \text{ eV}^2} \leq 8.09,
2.317 \leq \frac{\Delta m_{31}^2}{10^{-3} \text{ eV}^2} \leq 2.607,
$$

in the case of normal hierarchy, and

$$
0.270 \leq \sin^2 \theta_{12} \leq 0.344,
0.389 \leq \sin^2 \theta_{23} \leq 0.644,
0.0188 \leq \sin^2 \theta_{13} \leq 0.0251,
$$

$$
7.02 \leq \frac{\Delta m_{21}^2}{10^{-5} \text{ eV}^2} \leq 8.09,
-2.590 \leq \frac{\Delta m_{32}^2}{10^{-3} \text{ eV}^2} \leq -2.307,
$$

in the case of inverted hierarchy.

### 4.2 Lepton Flavour Violating Processes

The lepton flavour violating (LFV) process $\ell_\alpha \to \ell_\beta \gamma$ imposes a very strong constraint on the model. The branching ratio of the process is computed as [36,44]

$$
\text{Br}(\ell_\alpha \to \ell_\beta \gamma) = \frac{3\alpha_{\text{em}}}{64\pi^2 G_F^2 m^4} \left| \sum_{i=1}^{2} y_{i\alpha} y_{i\beta}^* F_2 \left( \frac{m_i^2}{m_{\eta^+}^2} \right) \right|^2 \text{Br}(\ell_\alpha \to \ell_\beta \nu_\alpha \bar{\nu}_\beta),
$$

where $G_F$ is the Fermi constant, $\alpha_{\text{em}}$ is the electromagnetic fine structure constant and $F_2(x)$ is the loop function given in Ref. [36]. The current experimental upper bounds for these processes [45–47] are,

$$
\text{Br}(\mu \to e \gamma) \leq 4.2 \times 10^{-13},
$$

$$
\text{Br}(\tau \to \mu \gamma) \leq 4.4 \times 10^{-8},
$$

$$
\text{Br}(\tau \to e \gamma) \leq 3.3 \times 10^{-8},
$$

the bound from $\mu \to e \gamma$ being the most constraining one. One can see from Eq. (30) that if all the Yukawa couplings $y_{i\alpha}$ are assumed to be of the same order of magnitude, the constraint from $\text{Br}(\mu \to e \gamma)$ is translated into

$$
|y_{i\alpha}| \lesssim 6 \times 10^{-3} \left( \frac{\text{Max}[m_i, m_{\eta^+}]}{100 \text{ GeV}} \right).
$$

Therefore the predicted electron EDM can be roughly estimated by Eq. (21) taking into account this upper bound on the Yukawa couplings $y_{i\alpha}$. Unfortunately, the predicted electron EDM would be far below the future sensitivity of ACME ($d_e/e \sim 10^{-30} \text{ cm}$) due to the smallness of the Yukawa couplings. Thus a destructive interference between the contributions of the sterile fermion $N_1$ and $N_2$ mediated diagrams for the $\mu \to e \gamma$ process would be necessary to obtain an electron EDM within future sensitivity reach, while being consistent with bounds from LFV processes.
4.3 Electroweak Precision Data

The inert $SU(2)_L$ scalar doublet $\eta$ may impact on electroweak precision observables. In particular the oblique STU parameters [48] may receive new contributions due to the existence of the latter scalar doublet. Interestingly, when its CP-even and CP-odd neutral components are nearly degenerate in mass ($m_R \approx m_I$, meaning for small values of the coupling $\lambda_5$), the new contributions to the oblique parameters are computed as

$$\Delta S = \frac{1}{12\pi} \log \left( \frac{m^2_{\eta^0}}{m^2_{\eta^+}} \right), \quad \Delta T = \frac{2\sqrt{2}G_F}{(4\pi)^2 \alpha_{em}} F \left( m^2_{\eta^+}, m^2_{\eta^0} \right), \quad \Delta U = \frac{1}{12\pi} G \left( m^2_{\eta^+}, m^2_{\eta^0} \right),$$

where the loop functions $F(x, y)$ and $G(x, y)$ are given below:

$$F(x, y) = \frac{x + y}{2} - \frac{xy}{x - y} \log \left( \frac{x}{y} \right),$$

$$G(x, y) = -\frac{5x^2 - 22xy + 5y^2}{3(x - y)^2} + \frac{(x + y)(x^2 - 4xy + y^2)}{(x - y)^3} \log \left( \frac{x}{y} \right).$$

The experimental limits on the oblique parameters [49] are given by

$$\Delta S = 0.05 \pm 0.11, \quad \Delta T = 0.09 \pm 0.13, \quad \Delta U = 0.01 \pm 0.11,$$

with the correlation coefficients 0.90 between $\Delta S$ and $\Delta T$, $-0.59$ between $\Delta S$ and $\Delta U$, and $-0.83$ between $\Delta T$ and $\Delta U$ [50]. The constraint of the $T$-parameter is especially strong, and from Eqs. (35), (36) is translated into the following constraint on the mass splitting [48]

$$|m_{\eta^+} - m_{\eta^0}| \lesssim 140 \text{ GeV}.$$  

In fact, this constraint is not so important especially when the new scalar particle masses are heavier than a few hundred GeV since the latter mass splitting is proportional to the scalar coupling $\lambda_4$ as can be inferred from Eqs. (3)-(6), making the mass splitting bounded from above by perturbativity, see Eq. (17). This pertubativity requirement provides a stronger bound than Eq. (39) as discussed in Ref. [38]. In addition, if the inert scalar is identified as dark matter, the mass splitting is almost fixed within the bound of Eq. (39) for a given mass $m_{\eta^0}$ in order to reproduce the correct relic abundance of dark matter as we will see below.

There are also limits from LEP and LHC where the bounds for slepton searches can be translated into a bound for charged inert scalar $\eta^\pm$. The current ATLAS lower bound translated on $m_{\eta^+}$ gives $m_{\eta^+} \gtrsim 270 \text{ GeV}$ [51].

4.4 Dark Matter Searches

Depending on the mass hierarchy between the new particles (neutral fermions and inert scalar particles), this minimal scotogenic model provides two kinds of dark matter candidates, one bosonic candidate corresponding to the neutral component of $\eta$ and one fermionic candidate corresponding to the lightest Majorana fermion $N_1$. For both possible cases, we discuss in the following the constraints to reproduce the correct thermal dark matter relic abundance and from dark matter searches through direct and indirect detection for fermionic and inert scalar dark matter separately. In our numerical analysis, the relevant quantities such as cross sections and decay widths are computed with the public code micrOMEGAs [52].
4.4.1 Fermion Dark Matter

In the case of fermonic dark matter, the lightest neutral fermion $N_1$ being the potential candidate, the possible annihilation channel determining the dark matter relic abundance is $N_1 N_1 \rightarrow \ell_\alpha \ell_\beta, \nu_\alpha \nu_\beta$ via the Yukawa coupling $y_{i\alpha}$.

In order to obtain the observed relic abundance, the magnitude of the Yukawa coupling is roughly $y_{i\alpha} \gtrsim 0.1$ taking into account the fact that the dark matter mass should be heavier than the electroweak scale in order to be consistent with the LFV bounds and collider constraints. As discussed in Section 4.2, the Yukawa coupling is strongly constrained by bounds on LFV processes, however these LFV constraints can be evaded with co-annihilation effects for dark matter relic abundance and/or by destructive interference (between the $N_1$ and $N_2$ mediated diagrams) in the amplitude of the LFV processes, for example.

Since the fermionic dark matter candidate $N_1$ interacts only with leptons through the Yukawa coupling $y_{i\alpha}$ and does not interact with quarks and gluons at tree level, there is no substantial constraint from direct detection of dark matter. For indirect detection, a possible signal would be the internal bremsstrahlung processes $N_1 N_1 \rightarrow \ell_\alpha \ell_\beta \gamma$ because the annihilation cross section for $N_1 N_1 \rightarrow \ell_\alpha \ell_\beta$ determining the thermal relic abundance is proportional to the small dark matter relative velocity $v^2$ which is estimated to be of the order of $v \sim 10^{-3}$ in the Galactic center [54–56]. Notice that the current experimental bound for this channel is not very strong and thus does not provide a constraint on the model.

4.4.2 Scalar Dark Matter

Contrary to the fermionic dark matter case, the inert scalar candidate for dark matter has additional interactions other than the Yukawa coupling $y_{i\alpha}$ such as gauge and scalar interactions, and the relic abundance can be controlled by the corresponding additional couplings. In the following, we identify $\eta_I$ as the dark matter candidate with a positive scalar coupling $\lambda_5$. The inert scalar dark matter in the scotogenic model is basically similar to the inert doublet dark matter [38], the only difference being the existence of the additional Yukawa coupling $y_{i\alpha}$. For the case of the original inert doublet dark matter, there are two allowed regions of dark matter mass: $50 \text{ GeV} \lesssim m_\eta \lesssim 70 \text{ GeV}$ and $535 \text{ GeV} \lesssim m_\eta \lesssim 20 \text{ TeV}$ which can reproduce the correct relic abundance and satisfy the relevant constraints [57]. The upper limit of the dark matter mass is derived from the perturbativity requirement, see Section 2. For the minimal scotogenic model, the dark matter mass would be similarly restricted in these two regions. Since an extreme fine-tuning between the Yukawa couplings would be required for the light mass region $50 \text{ GeV} \lesssim m_\eta \lesssim 70 \text{ GeV}$ to be consistent with all the constraints and in order to obtain a large enough electron EDM, we focus in our numerical analysis on the heavy mass region $535 \text{ GeV} \lesssim m_\chi \lesssim 20 \text{ TeV}$.

For direct detection, the elastic scattering with nuclei occurs at tree level via the diagram mediated by the SM Higgs boson if the scalar couplings $\lambda_3$, $\lambda_4$ and $\lambda_5$ are sufficiently large. The gauge interactions also contribute to this process at one-loop level, however the order of

\footnotetext[2]{The co-annihilation channels are also relevant if another fermionic singlet $N_2$, or if the inert scalar particles $\eta_R, \eta_I, \eta^+$, are nearly degenerate in mass with $N_1$, see for instance [53].}

\footnotetext[3]{Notice that if $N_1$ and $N_2$ are nearly degenerate and if the Yukawa coupling is complex as in our case, inelastic scattering process with nucleons can be induced at loop level [35].}
magnitude of the latter contribution would be subdominant, \( \mathcal{O}(10^{-50}) \) cm\(^2\) \[58\]. The current bound for the spin-independent cross section with a proton is given by the XENON1T \[59\] and the PandaX-II Collaborations \[60\]. The experimental bound for the spin-independent cross section gives a strong constraint on the scalar couplings, in particular when the dark matter mass is less than a few TeV.

For indirect detection, the continuum gamma-rays are generated from the annihilation modes \( \eta \eta \rightarrow WW, ZZ, hh \) and subsequent decays of the final state particles, providing a constraint on the model. In particular, if the dark matter mass is much heavier than the masses of the SM gauge and Higgs bosons, the annihilation cross sections for these channels are enhanced by non-perturbative Sommerfeld effect, and in this case, the constraint becomes stronger. We include in our analysis the Sommerfeld effect, and impose the experimental bound obtained from the H.E.S.S. Collaboration \[61\].\(^4\) The detailed discussion for the Sommerfeld effect and the experimental bounds can be found in Ref. \[57\] and references therein.

5 Numerical Analysis

In this section, we investigate viable parameter space in the case of fermionic dark matter and scalar dark matter below, considering in each case both normal and inverted ordering of the light neutrino spectrum. The results are displayed and discussed separately for the cases of fermionic and scalar dark matter since the corresponding phenomenological constraints for dark matter are different.

5.1 Fermionic dark matter

As motivated above, we consider in this case where the lightest fermionic singlet is the dark matter candidate, the following intervals in our numerical computations:

\[
100 \text{ GeV} \leq m_1 \leq 100 \text{ TeV}, \quad 1 \leq \frac{m_2}{m_1}, \frac{m_{\eta^0}}{m_1}, \frac{m_{\eta^+}}{m_1} \leq 10, \quad 0 \leq \delta_{\text{CP}}, \varphi_{\text{CP}}, \eta_{\text{CP}} < 2\pi, \quad 0 \leq |\sin \xi| \leq 1, \quad |\lambda_3|, |\lambda_4| \leq \sqrt{4\pi}. \tag{41}
\]

The intervals for the different masses in Eq. (40) cover most of the parameter space. Notice that the ratio between the mass of the singlet fermion \( N_1 \) and the inert scalar doublet cannot be very large, this is due to the fact that the annihilation cross section for \( N_1 N_1 \rightarrow \ell_\alpha \bar{\ell}_\beta, \nu_\alpha \nu_\beta \), determining the relic abundance, is mediated by the inert scalar doublet, and is suppressed if the scalars are too heavy.

The numerical results are shown in Figs. 4 and 5 for normal and inverted hierarchy of the light neutrino mass spectrum, respectively, where the electron EDM, the scalar couplings \( \lambda_5, \lambda_3 \) and \( \lambda_4 \) the mass ratios between the new particles \( (m_2/m_1, m_{\eta^0}/m_1 \) and \( m_{\eta^+}/m_1) \), the phase factors \( |J^M|, |J^D| \) and the CP phase \( \eta_{\text{CP}} (= \text{Arg}(\xi)) \) are displayed as a function of the dark matter mass \( m_1 \).

From the left-top panels in Figs. 4 and 5, one can see that the electron EDM can be larger than the future prospect of the next generation experiment of the ACME collaboration \[27\] (dashed horizontal black line) when the dark matter mass is lighter than 4 TeV. The predicted\(^4\) The bound for the annihilation cross section may be updated with the latest H.E.S.S. measurement \[62\].
electron EDM can be even slightly larger in the case of inverted hierarchy as can be seen in the first left panel of Fig. 5.

The scalar couplings $|\lambda_3|$ and $|\lambda_4|$, and $\lambda_5$ as a function of the dark matter mass $m_1$ are displayed on the right-top and left-middle panels of Figs. 4 and 5. The orange coloured points for $|\lambda_3|$ and $\lambda_5$, and the red coloured points for $|\lambda_4|$ denote electron EDM larger than the future prospect $|d_e|/e \geq 10^{-30}$ cm. One can find that the typical magnitude of the coupling $\lambda_5$ is $10^{-11} \lesssim \lambda_5 \lesssim 10^{-8}$ to satisfy all the constraints. In order to have the electron EDM within
future sensitivity reach of ACME, the coupling $\lambda_5$ should be in the range $\lambda_5 \lesssim 3 \times 10^{-10}$ in the case of normal ordering for the light neutrino spectrum. In the case of the inverted ordering, the coupling $\lambda_5$ can be a few factor larger than that in the case of normal hierarchy, and is bounded from below by the perturbativity condition on the Yukawa coupling since the coupling $\lambda_5$ behaves like $\lambda_5 \propto y^{-2}$ as one can see from Eq. (10) and (12). On the other hand, it is bounded from above because of the condition from the dark matter relic abundance. This can be understood since $\Omega_{\text{DM}} h^2 \propto |y|^{-4} \propto \lambda_5^2$. 

Figure 5: Numerical results for fermion dark matter in the case of inverted hierarchy for the light neutrino spectrum. Each point complies with all the constraints discussed in Section 4.
From the right-middle plots of Figs. 4 and 5, one can see that the charged inert scalar mass is close to $2 \lesssim m_\eta^+/m_1 \lesssim 4$ for most of the parameter points. This is because the branching ratios of the LFV processes given by Eq. (30) are drastically reduced when the mass of the charged inert scalar $m_\eta^+$ is in this range due to destructive interference between the $N_1$ and $N_2$ mediated diagrams. Because of this, the strong constraint of the LFV processes can be evaded.

On the left-bottom panels of Figs. 4 and 5, we display the phase factors $|J^M|$ and $|J^D|$ as a function of the dark matter mass. One can find that the phase factors $|J^M|$ and $|J^D|$ are always of the same order in both cases of normal and inverted hierarchies of the light neutrino mass spectrum. Although the explicit form of the phase factors $J^M$ and $J^D$ is not shown here due to complexity (the definition being given in Eq. (22) and (25)), we found that the phase factor behaves as $J^M, J^D \propto \sin \theta_{13}$ in the case of normal hierarchy of the light neutrino spectrum. On the other hand, $J^M$ and $J^D$ can be maximal $J^M, J^D \sim (\sqrt{A^\pi})^4 \sim 100$ in the inverted hierarchy case because there is no $\sin \theta_{13}$ factor of supression. Notice that we have numerically checked that if one assumes $\eta_{CP} = 0$, the phase factor $|J^D|$ is suppressed with about two orders of magnitude compared to $|J^M|$, in the inverted hierarchy case.

The right-bottom panels in Fig. 4 and 5 show Arg($\xi$) = $\eta_{CP}$ as a function of $m_1$ where the orange points denote the allowed parameter points with $|d_e|/e \geq 10^{-30}$ cm. One can see a small dependence on $\eta_{CP}$ of the maximum dark matter mass $m_1$ allowed by all the constraints in the plots while the predicted electron EDM is below the future sensitivity for a large dark matter mass.

5.2 The Case of Inert Scalar Dark Matter

In the case in which the neutral component of the inert scalar doublet $\eta$ is the dark matter candidate, one expects a larger viable parameter space than in the case of fermionic dark matter (see section above). This is due to the fact that the inert scalar dark matter can annihilate into $\eta^0\eta^0 \rightarrow WW, ZZ, jj, hh$, other than $\eta^0\eta^0 \rightarrow \ell_\alpha \ell_\beta, \nu_\alpha \nu_\beta$ via the Yukawa coupling $y_{\ell\alpha}$, which are relevant to reproduce the observed relic abundance of dark matter.

We thus explore a larger range for the new particles mass ratios and consider the following intervals in our numerical computations:

$$100 \text{ GeV} \leq m_{\eta^0} \leq 100 \text{ TeV}, \quad 1 \leq \frac{m_1}{m_{\eta^0}}, \frac{m_2}{m_{\eta^0}}, \frac{m_{\eta^+}}{m_{\eta^0}} \leq 1000, \quad (42)$$

$$0 \leq \delta_{CP}, \varphi_{CP}, \eta_{CP} < 2\pi, \quad 0 \leq |\sin \xi| \leq 1, \quad |\lambda_3|, |\lambda_4| \leq \sqrt{4\pi}. \quad (43)$$

The numerical results for the bosonic dark matter case are shown in Figs. 6 and 7 for normal and inverted hierarchy of the light neutrino mass spectrum, respectively, where the electron EDM, the scalar couplings $|\lambda_3|, |\lambda_4|$ and $|\lambda_5|$, the mass ratios between the new particles $(m_i/m_{\eta^0}$ and $m_{\eta^+}/m_{\eta^0})$, the phase factors $|J^M|, |J^D|$, and Arg($\xi$) = $\eta_{CP}$ are plotted as a function of the dark matter mass $m_{\eta^0}$.

From the left-top panels in Figs. 6 and 7 one can see that unlike the case of fermionic dark matter, the predicted electron EDM cannot reach the future sensitivity $|d_e|/e = 10^{-30}$ cm of the next generation of ACME collaboration. One can see that the phase factors $|J^M|$ and $|J^D|$ displayed on the left-bottom panels of Figs. 6 and 7 as a function of the dark matter mass, are almost of the same order as the corresponding ones in the case of fermion dark matter, and the
dark matter mass region is also similar. Therefore the difference between the predicted electron EDM between these cases (bosonic and fermionic dark matter) can only be due to the behaviour of the loop functions $I_M$ and $I_D$ (presented in Fig. 3).

The scalar couplings $|\lambda_3|$, $|\lambda_4|$ and $\lambda_5$ are displayed on the right-top and left-middle panels of Figs. 6 and 7. For dark matter mass lighter than $m_{\eta^0} \lesssim 1$ TeV, the annihilation cross sections for the channels into the gauge bosons are large enough in order to obtain the observed relic abundance, and the scalar couplings $|\lambda_3|$ and $|\lambda_4|$ have to be subdominant. For $m_{\eta^0} \gtrsim 1$ TeV,
Figure 7: Numerical results for scalar dark matter in the case of inverted hierarchy for the light neutrino mass spectrum. Each point complies with all the constraints discussed in Section 4.

the scalar couplings $|\lambda_3|$ and $|\lambda_4|$ starts to be $O(1)$, and reach the perturbativity bound $\sqrt{4\pi}$ at around $m_{\eta^0} \sim 5$ TeV. The scalar coupling $\lambda_5 (\propto y^{-2})$ can be larger compared to the case of fermionic dark matter since the inert scalar dark matter has the additional gauge and scalar interactions to reproduce the correct relic abundance. As can be seen, the parameter space of $\lambda_5$ drastically changes around $m_{\eta^0} \sim 6$ TeV. This implies that the correct relic abundance cannot be obtained without the Yukawa coupling $y_{i\alpha}$ for $m_{\eta^0} \gtrsim 6$ TeV. While only the region of $10^{-11} \leq \lambda_5 \leq 10^{-8}$ is shown in the plots, we have checked that the scalar coupling $\lambda_5$ can be
larger. However in this case, the predicted electron EDM is still too small due to the smallness of the Yukawa coupling.

From the right-middle plots of Figs. 6 and 7, one can find that the fermion masses can be much larger than the dark matter mass while the charged inert scalar should be almost degenerate with the dark matter mass (green points). The region of $m_i/m_{\eta^0} \lesssim 2$ is excluded by the several LFV constraints.

The right-bottom plots show $\eta_{CP}$ dependence of dark matter mass allowed by all the constraints, and these plots are similar to the ones obtained in the case of fermionic dark matter. In all the plots in Fig. 6 and 7, the dark matter mass region $6 \text{ TeV} \lesssim m_{\eta^0} \lesssim 9 \text{ TeV}$ is strongly constrained by gamma-ray observations for dark matter indirect detection due to the peak of the Sommerfeld enhancement for the annihilation cross sections.

6 Conclusions and Discussions

We have computed the charged lepton EDMs in the (minimal) scotogenic model whose leading contribution is induced at two-loop level. The numerical computation has been conducted taking into account all the various relevant experimental and theoretical constraints on the parameter space of the model. We have found that the predicted electron EDM could reach the future sensitivity $|d_e|/e = 10^{-30}$ cm of the next generation of the ACME, consistently complying with all the constraints, only when the lightest singlet fermion is identified as a dark matter candidate. Notice that the predicted electron EDM is actually larger than what was obtained in several seesaw models, as the case of the inverse seesaw where neutrino masses are generated at tree level [29]. In the case of normal hierarchy of the light neutrino mass spectrum, the CP phase factors $|J^M|$ and $|J^D|$ complying with all the constraints are one order of magnitude smaller than the case of inverted hierarchy. However the magnitude of the predicted electron EDM is eventually almost of the same order for both cases.

The electron EDM which has been calculated in this paper may be correlated with another observables related to CP violation such as the BAU. In the scotogenic model, the generation of BAU via resonant leptogenesis has been discussed in [63,64]. Correlating the BAU, the radiative neutrino mass generation and a fermonic dark matter scenario, while having an electron EDM within ACME reach is certainly very interesting and we leave this possibility for a future project.

Appendix A: Loop Functions

Here we give the loop functions which appear in the formula of charged lepton EDMs at two-loop level in Eq. (21). The contribution from the pair of the diagrams (a1) and (a2), and the contribution from the diagram (a3) are given by

\[ I_{M_{1+2}}(x_i, x_j) = \int_0^1 \prod_{a=1}^4 ds_a \delta \left( \sum_{a=1}^4 s_a - 1 \right) \int_0^1 \prod_{b=1}^4 dt_b \delta \left( \sum_{b=1}^4 t_b - 1 \right) \frac{s_1 s_4 (1 - t_3 - t_4)^2 - t_1 t_2 (1 - s_2 - s_3)^2}{2 [(s_2 + s_3)(1 - s_2 - s_3)(t_1 x_i + t_2) + (t_3 + t_4)(s_1 x_j + s_4)]^2}, \]  

(44)

\[ I_{M_3}(x_i, x_j) = \int_0^1 \prod_{a=1}^3 ds_a \delta \left( \sum_{a=1}^3 s_a - 1 \right) \int_0^1 \prod_{b=1}^4 dt_b \delta \left( \sum_{b=1}^4 t_b - 1 \right) \frac{s_1 s_2 (1 - t_4)(-t_1 + s_2 t_1 - s_3 t_4)}{[s_2(1 - s_2)(t_1 x_i + t_2 + t_3) + t_4(s_1 x_j + s_3)]^2}. \]  

(45)

For the diagrams (b1) and (b2), each diagram gives non-zero contribution, however one can find that these can exactly be the same expressions with opposite sign in the limit \( x_\alpha, x_\beta \to 0 \). Thus the contributions from (b1) and (b2) cancel with each other, and the whole Majorana type loop function is given by \( I_M(x_i, x_j) = I_{M_{1+2}}(x_i, x_j) + I_{M_3}(x_i, x_j) \).

The diagrams (c1) and (c2) providing the Dirac type contribution include a divergence for each diagram. However the divergence cancels out and the whole loop function is finite as given by

\[ I^D(x_i, x_j) = \int_0^1 \prod_{a=1}^3 ds_a \delta \left( \sum_{a=1}^3 s_a - 1 \right) \int_0^1 \prod_{b=1}^4 dt_b \delta \left( \sum_{b=1}^4 t_b - 1 \right) \frac{t_1(t_2 - t_3)}{2 [t_1 + t_2 x_i + t_3 x_j]} \\
+ \int_0^1 \prod_{a=1}^3 ds_a \delta \left( \sum_{a=1}^3 s_a - 1 \right) \int_0^1 \prod_{b=1}^4 dt_b \delta \left( \sum_{b=1}^4 t_b - 1 \right) \frac{s_1(1 + 4s_1)}{2} \frac{t_1(t_2 - t_3)}{[s_1(t_1 + t_2 x_i + t_3 x_j) + t_4]^2}. \]
