Short-length routes in low-cost networks via Poisson line patterns

David J. Aldous* and Wilfrid S. Kendall

Abstract

In designing a network to link \( n \) points in a square of area \( n \), one might be guided by the following two desiderata. First, the total network length should not be much greater than the length of the shortest network connecting all points. Second, the average route length (taken over source-destination pairs) should not be much greater than the average straight-line distance. How small can we make these two excesses? Speaking loosely, for a non-degenerate configuration the total network length must be at least of order \( n \) and the average straight-line distance must be at least of order \( n^{1/2} \), so it seems implausible that a single network might exist in which the excess over the first minimum is \( o(n) \) and the excess over the second minimum is \( o(n^{1/2}) \). But in fact one can do better: for an arbitrary configuration one can construct a network where the first excess is \( o(n) \) and the second excess is almost as small as \( O(\log n) \). The construction is conceptually simple and uses stochastic methods: over the minimum-length connected network (Steiner tree) superimpose a sparse stationary and isotropic Poisson line process. Together with a few additional (required for technical reasons), the mean values of the excess for the resulting random network satisfy the above asymptotics; hence a standard application of the probabilistic method guarantees the existence of deterministic networks as required (speaking constructively, such networks can be constructed using simple rejection sampling). The key ingredient is a new result about the Poisson line process. Consider two points at distance \( r \) apart, and delete from the line process all lines which separate these two points. The resulting pattern of lines partitions the plane into cells; the cell containing the two points has mean boundary length \( \approx 2r + \text{constant} \times \log r \). Turning to lower bounds, consider a sequence of networks in \([0, \sqrt{n}]^2\) satisfying a weak equidistribution assumption. We show that if the first excess is \( O(n) \) then the second excess cannot be \( o(\sqrt{\log n}) \).

1 Introduction

We start with a counter-intuitive observation and its motivation, which prompted us to probe more deeply into the underlying question.

Consider \( n \) points ("cities", say) in a square of area \( n \). Using the terminology of computer science, we are interested in both the worst-case setting where the points are located arbitrarily in the square, and the average case setting where the points are random, independent and uniformly distributed. Consider a connected network (a road network, say), made up of a finite number of straight line segments and linking these \( n \) points and perhaps other junction points. Recall that the minimum length connected network on a configuration of points \( x_n = \{x_1, \ldots, x_n\} \) is the Steiner tree \( \text{ST}(x^n) \).

It is well known and straightforward to prove \([9, 11]\) that in both the worst case and the average case the (mean) total network length \( \text{len}(\text{ST}(x^n)) \) grows as order \( O(n) \). When designing a network, it is reasonable to regard total network length as a "cost". A natural corresponding "benefit" would be the existence (in some average sense) of short routes between points. Let \( \ell(x_i, x_j) \) be the route-length (length of shortest path) between points \( x_i \) and \( x_j \) in a given network, and let \( |x_i - x_j| \) denote Euclidean distance (so \( \ell(x_i, x_j) \geq |x_i - x_j| \)). A good network should satisfy the following informal criterion:

The short routes property: Averaging over pairs \((i,j)\) chosen uniformly at random, the route-length \( \ell(x_i, x_j) \) between points \( x_i \) and \( x_j \) is not much larger than the Euclidean distance \( |x_i - x_j| \).

A first take on a statistic to measure this property for a connected network \( G(x^n) \) is the ratio statistic, based on averaging the ratios of network route-lengths versus Euclidean distances. Consider a network \( G(x^n) \) to be the configuration of points \( x^n = \{x_1, \ldots, x_n\} \) together with a collection of line segments which combine to connect every \( x_i \) to every other \( x_j \).

**Definition 1** (Ratio statistic). Let \( \text{average}_{(i,j)} \) denote the average over all distinct pairs \((i,j)\). Then

\[
\text{ratio}(G(x^n)) = \text{average}_{(i,j)} \frac{\ell(x_i, x_j)}{|x_i - x_j|} - 1 \geq 0. \tag{1}
\]

Consider a network \( G(x^n) \) based on \( n \) uniform random points \( x^n \subset [0, \sqrt{n}]^2 \), having (say) twice the total length of the Steiner tree. Initially we speculated that in this case the expectation \( \mathbb{E} [\text{ratio}(G(x^n))] \) would at best converge to some strictly positive constant as \( n \to \infty \). However this intuition is wrong:
Counterintuitive observation (see section 5.3). It is possible to construct networks over well-dispersed configurations whose total lengths are greater than the corresponding Steiner tree lengths by only an asymptotically negligible factor, but for which the ratio statistic converges to zero as total network length converges to infinity.

These considerations were originally motivated by analysis of real-world networks. Consider for example the “core” part of the UK rail network; that part which links the 40 largest cities. Given a statistic $R$ designed to capture the “short routes” property, one can then consider how closely the observed value of $R$ approaches optimality. Of course the real network has evolved according to a complex historical process heavily influenced by topography; nevertheless it is of interest to consider whether its value of $R$ is close to the minimum possible value of $R$ taken over all possible networks connecting the 40 cities but of no greater total length.

One is then led to ask what statistic $R$ might best capture the imprecisely expressed “short routes” property, and our consideration of $n$ cities in an idealised square $[0, \sqrt{n}]^2$ is designed to illuminate this question. The above counterintuitive observation can be interpreted as implying that the ratio statistic of Definition 1 is probably not a good choice of statistic, because we prove this observation by constructing networks which are approximately optimal by this criterion and yet are plainly rather different from many plausible real-world networks. What is a good choice of statistic will be discussed in a companion paper, along with some real-world examples.

Informally, the counter-intuitive observation suggests that we can construct networks for configurations of $n$ points which have total network length exceeding that of the Steiner tree by just $o(n)$, and such that the average excess of network distance over Euclidean distance is $o(n^{1/2})$ (bearing in mind that average Euclidean distance for “evenly spread out” configurations should be $O(n^{1/2})$). In fact much more is true: whatever the configuration of $n$ points in $[0, \sqrt{n}]^2$ (hence, even in “worst case” scenarios) we can construct such networks with average excess of network distance over Euclidean distance barely more than $O(\log n)$. This we can work on an additive rather than a multiplicative scale:

**Definition 2** (Excess average length for a network). The excess route length for a network $G(x^n)$ is

$$\text{excess}(G(x^n)) = \text{average}_{(i,j)} \left( \ell(x_i, x_j) - |x_i - x_j| \right). \quad (2)$$

**Theorem 1** (Upper bound on minimum excess network length). For each $n$ let $x^n$ be an arbitrary configuration of $n$ points in a square of area $n$. The following asymptotics hold for large $n$:

(a) Let $w_n \to \infty$. There exist networks $G(x^n)$ connecting up the points such that
(i) \( \text{len}(G(x^n)) - \text{len}(\text{ST}(x^n)) = o(n) \);
(ii) \( \text{excess}(G(x^n)) = o(w_n \log n) \).

(b) Let \( \varepsilon > 0 \). There exist networks \( G(x^n) \) connecting up the points such that

(i) \( \text{len}(G(x^n)) - \text{len}(\text{ST}(x^n)) \leq \varepsilon n \);
(ii) \( \text{excess}(G(x^n)) = O(\log n) \).

This result is proved in Sections 2 and 3. The idea is to build a hierarchical network. Details are given at the start of Section 3, but here is a sketch. At small scales routes use the underlying Steiner tree. At large scales, routes use a sparse collection of randomly oriented lines (a realisation of a stationary and isotropic Poisson line process); this is the key ingredient that permits an excess of at most \( o(w_n \log(n)) \), respectively \( O(\log(n)) \) (Section 2). We believe that only these two scales are needed, but to simplify matters (so as to avoid non-elementary analysis of Steiner trees and geodesics in Poisson line networks) we introduce an intermediate scale consisting of a widely-spaced grid. Thus a route from an originating city navigates through the Steiner tree to a grid line and then along the grid line to a line of the Poisson line process, and then navigates in the reverse sense down to the destination city. (For technical reasons the discussion in Section 3 also introduces occasional small rectangles to permit circumnavigation around Steiner tree “hot-spots”). The key ingredient in the analysis is a calculation concerning the Poisson line process, which has separate interest as a result in stochastic geometry (Theorem 4 below). Consider two points at distance \( r \) apart, and delete all lines from the line process which separate these two points. The resulting pattern of lines partitions the plane into cells; the cell containing the two points has mean boundary length which for large \( r \) is asymptotic to \( 2r + \text{constant} \times \log r \).

Note that randomness arises only through use of the Poisson line process to supply a relatively small number of long straight connections; the point pattern \( x^n \) is arbitrary. The probabilistic method may now be used to prove the existence of a non-random networks satisfying the asymptotics described in Theorem 4 based on applying Markov’s inequality to the expectations \( \mathbb{E} [\text{len}(G(x^n))] - \text{len}(\text{ST}(x^n)) = o(n) \), et cetera.

For lower bounds it is necessary to impose some condition on the empirical distribution of the points in \( x^n \), since if all the points concentrate on a line then the excess is zero! We need a quantitative condition on equidistribution of points over a region, formalised via the following truncated Vasershtein coupling scheme.

**Definition 3** (Quantitative equidistribution condition). Let \( x^n \) for varying \( n \) form a sequence of configurations in the plane, let \( \mu_n \) be a probability measure on the plane, and and let \( L_n > 0 \). Say \( x^n \) is \( L_n \)-equidistributed as \( \mu^n \) if there exists a coupling of random variables \( (X_n, Y_n) \) such that

(a) \( X_n \) has uniform distribution on the finite point-set \( x^n \),
(b) \( Y_n \) has distribution \( \mu^n \),
(c) \( \mathbb{E} \left[ \min \left( 1, \frac{|X_n - Y_n|}{L_n} \right) \right] \to 0 \) as \( n \to \infty \).

A sufficient condition for the following result is that \( x_n \) is \( L_n \)-equidistributed as the uniform distribution on the square of area \( n \), for some \( L_n = o(\sqrt{\log n}) \). The purpose of introducing the non-uniform distribution \( \mu^n \) in Definition 3 is to permit us to express Theorem 2 below in terms of weaker and more local conditions: for example a consequence of Theorem 2(b) is that we may replace the uniform reference distribution by any distribution \( \mu \) on \([0, 1]^2\) with a continuous density component, rescaled to produce a distribution \( \mu^n \) on \([0, n^{1/2}]^2\).

In particular the geometry of \([0, n^{1/2}]^2\) plays no role in this result.

We choose to express Definition 3 in stochastic terms purely for convenience of exposition. For example, arguments using the connection of total variation to coupling show that \( x_n \) is \( L_n \)-equidistributed as the uniform distribution on \([0, \sqrt{n}]^2\) if the following non-stochastic condition is satisfied: for some sequence of numbers \( \lambda_n \to \infty \) with \( \lambda_n/L_n \to 0 \) and \( n/\lambda_n^2 \) being integral,

\[
\frac{1}{n} \sum \left| \#(x^n \cap \text{box}) - \lambda_n^2 \right| \to 0,
\]

with the sum being taken over \( n/\lambda_n^2 \) boxes partitioning \([0, \sqrt{n}]^2\) into cells of sidelength \( \lambda_n \). Thus a wide range of possible point patterns can be seen to be \( L_n \)-equidistributed in the above sense.

**Theorem 2** (Lower bound on minimum excess network length). Let \( x^n \) be a configuration of \( n \) points in a square \([0, \sqrt{n}]^2\). Let \( L_n = o(\sqrt{\log n}) \). Suppose either

(a) \( x^n \) is \( L_n \)-equidistributed as the uniform distribution on the square of area \( n \);

or (more generally)

(b) for some fixed \( \rho \) and \( \varepsilon \), there is a subcollection \( y^{k(n)} \) of \( k(n) \) points, all lying in a disk \( D_n \) of area \( \pi \rho n \), such that \( k(n) > \pi \rho n \varepsilon \), and such that \( y^{k(n)} \) is \( L_n \)-equidistributed as the uniform distribution on \( D_n \).

Let \( G(x^n) \) be a network based on the full collection of \( n \) points. If \( \text{len}(G(x^n))/n \) remains bounded as \( n \to \infty \), then

\[
\text{excess}(G(x^n)) = \Omega(\sqrt{\log n}).
\] (3)

(Thus, \( \lim \inf_{n \to \infty} \text{excess}(G(x^n))/\sqrt{\log n} > 0 \).)

Configurations \( x^n \) produced by independent uniform sampling from \([0, \sqrt{n}]^2\) satisfy the conditions of this theorem (see Remark 2), but so will many other configurations exhibiting both clustering and repulsion. The proof of the theorem is given in Section 4 and exploits a tension between the two following facts:
(a) An efficient route between \(x_i\) and \(x_j\) must run approximately parallel to the Euclidean geodesic, and hence will tend to make almost orthogonal intersections with random segments perpendicular to this geodesic.

(b) On the other hand, the equidistribution condition means that two points \(x_i, x_j\) randomly chosen from the subcollection must be nearly independent uniform draws from \(D_n\), which permits the derivation of upper bounds on the probability of nearly orthogonal intersections of the form given in fact (a).

Finally, one might hope to improve the result by imposing a more restrictive assumption than the requirement that \(\text{len}(G(x^n))/n\) remains bounded as \(n \to \infty\). This requirement is weaker than either of our two alternative assumptions on \(\text{len}(G(x^n)) - \text{len}(\text{ST}(x^n))\) in the upper bound (since \(\text{len}(\text{ST}(x^n)) = O(n)\)). However, we are unable to improve (3) under either of the two stronger assumptions.

## 2 The Poisson line process network

Our upper bound on minimal excess \((G(x^n))\) is based on a result from stochastic geometry (Theorem 4 below) which is of independent interest.

Recall that a Poisson line process in the plane \(\mathbb{R}^2\) is constructed as a Poisson point process whose points lie in the space which parametrises the set of lines in the plane. We will consider only undirected lines, which will be parametrised by \((r, \theta) \in \mathbb{R} \times [0, \pi]\) where \(r\) is the signed distance from the line to a reference point and \(\theta\) is the angle the line makes with a reference axis. A stationary and isotropic Poisson line process has intensity measure invariant under rotations and translations of \(\mathbb{R}^2\): a stationary and isotropic Poisson line process \(\Pi\) of unit intensity is one for which the number of lines of \(\Pi\) hitting a unit segment has expectation 1 (further facts about Poisson line processes may be found in [10, Chapter 8]). We are interested in the cell containing two fixed points which is formed by the lines of \(\Pi\) that do not separate the two points, because this can be used as the efficient long-distance part of a network route between the two points (see Lemma 3.3). Theorem 4 establishes an asymptotic upper bound for the length of the mean cell perimeter in case of wide separation between the two points; we prepare for this by using a Buffon argument to derive an exact double-integral expression for the mean cell perimeter length:

### Theorem 3 (Mean perimeter length).

Let \(\Pi\) be a stationary and isotropic Poisson line process of unit intensity. Fix two points \(v_i, v_j\) which are distance \(m\) apart. Delete the lines of \(\Pi\) which separate the two points \(v_i, v_j\). The remaining line pattern partitions the plane: the cell \(C(v_i, v_j)\) containing the two fixed points has mean perimeter \(\mathbb{E}[\text{len} \partial C(v_i, v_j)] = 2m + J_m\), where \(J_m\) is given by the double integral
\[ J_m = \mathbb{E} [\text{len } \partial C(v_i, v_j)] - 2m = \frac{1}{2} \int_{\mathbb{R}^2} (\phi - \sin \phi) \exp \left( -\frac{1}{2}(\eta - m) \right) \, dx. \]

Here \( \eta = \eta(x) \) is a sum of distances \(|v_i - x| + |v_j - x|\), while \( \phi = \phi(x) \) is the exterior angle at \( x \) of the triangle with vertices \( x, v_i, v_j \) (see Figure 1).

Figure 1: Definition of \( \eta \) and \( \phi \). Note that \( \phi \) is the sum of the two interior angles \( \psi \) and \( \theta \).

**Proof.** This proof can be phrased in terms of measure-theoretic stochastic geometry, using the language of Palm distributions and Campbell measure. Since we deal only with constructions based on Poisson processes, we are able to adopt a less formal but more transparent exposition, for the sake of a wider readership.

Let \( \text{seg} \) be the line segment of length \( m \) with end-points \( v_i, v_j \). The idea of the proof is to measure \( \mathbb{E} [\text{len } \partial C(v_i, v_j)] \) by computing the expected number of hits on \( \partial C(v_i, v_j) \) made by an independent homogeneous isotropic Poisson line process \( \tilde{\Pi} \), again of unit intensity. Each hit corresponds to one of the points in the intersection point process \( \mathcal{X} = \{\iota(\ell, \tilde{\ell}) : \ell \in \Pi, \tilde{\ell} \in \tilde{\Pi}\} \), where

\[ \iota(\ell, \tilde{\ell}) = \begin{cases} x & \text{if } \ell \cap \tilde{\ell} = \{x\}, \\ \text{undefined} & \text{if } \ell, \tilde{\ell} \text{ are parallel}. \end{cases} \]  

Note that with probability 1 the intersection point \( \iota(\ell, \tilde{\ell}) \) is defined for all \( \ell \in \Pi, \tilde{\ell} \in \tilde{\Pi} \).

Not all intersection points \( x \in \mathcal{X} \) correspond to hits on \( \partial C(v_i, v_j) \). The condition for \( x = \iota(\ell, \tilde{\ell}) \in \mathcal{X} \) to represent a hit on \( \partial C(v_i, v_j) \) is that \( \ell \) should not hit \( \text{seg} \) (for otherwise it cannot be involved in the construction of \( \partial C(v_i, v_j) \)) and
that \( x \) is not separated from \( \mathcal{S} \) by any line from \( \Pi \setminus \{\ell\} \). Recall that the Slivynak theorem [10, §4.4, example 4.3] implies that \( \Pi \setminus \{\ell\} \) conditional on \( \ell \in \Pi \) is itself a homogeneous isotropic unit-rate Poisson line process. Consequently, under the condition that \( \ell \) does not hit \( \mathcal{S} \), the conditional probability of \( x = \iota(\ell, \bar{\ell}) \in \mathcal{X} \) representing a hit on \( \partial C(v_i, v_j) \) is equal to the probability \( p(x) \) of there being no line in \( \Pi \) which cuts both the segment from \( v_i \) to \( x \) and the segment from \( v_j \) to \( x \).

A classic counting argument from stochastic geometry then reveals that

\[
p(x) = \exp \left( -\frac{1}{2} \left( |v_i - x| + |v_j - x| - m \right) \right) = \exp \left( -\frac{1}{2}(\eta - m) \right).
\]  

Accordingly, if \( \nu \) is the intensity of the point process \( \mathcal{X} \) then we may compute the mean number of hits on \( \partial C(v_i, v_j) \) as

\[
\int \int \nu \mathbb{P} \left[ \ell \not\supset x = \iota(\ell, \bar{\ell}) \in \mathcal{X} \right] \exp \left( -\frac{1}{2}(\eta - m) \right) dx = 2m + \int \int \nu \mathbb{P} \left[ \ell \not\supset \mathcal{S}, \bar{\ell} \not\supset \mathcal{S} \mid x = \iota(\ell, \bar{\ell}) \in \mathcal{X} \right] \exp \left( -\frac{1}{2}(\eta - m) \right) dx.
\]

Here “\( \ell \not\supset \mathcal{S} \)” stands for “the line \( \ell \) does not hit \( \mathcal{S} \)” – noting that the conditioning in this context forces the Poisson line \( \ell \) to pass through \( x \) but does not fix its orientation – and on the right-hand side the summand \( 2m \) corresponds to the fact that hits of \( \bar{\mathcal{S}} \) on \( \mathcal{S} \) count as automatic double hits on \( \partial C(v_i, v_j) \).

Condition on \( x = \iota(\ell, \bar{\ell}) \in \mathcal{X} \) (which is to say, condition on there being Poisson lines \( \ell \in \Pi \), \( \bar{\ell} \in \Pi \) both passing through \( x \)) and consider

(a) the angle \( \xi_1 \) made by \( \ell \) with the line through \( v_i \) and \( x \);

(b) the angle \( \xi_2 \) between \( \ell \) and \( \bar{\ell} \).

By isotropy of \( \Pi \) the random angle \( \xi_1 \) is \( \text{Uniform}(0, \pi) \). Conditional on \( \xi_1 \) and more generally on \( \Pi \) with an \( \ell \in \Pi \) passing through \( x \), the intersection of \( \Pi \) with \( \ell \) is a Poisson point process on \( \ell \) of unit intensity. Moreover if the intersection points are marked with angles of intersection \( \xi_2 \) then the mark \( \xi_2 \) has mark density \( \frac{1}{2} \sin \xi_2 \) over \( \xi_2 \in [0, \pi] \) (consider the length of the silhouette of a portion of \( \ell \) viewed at angle \( \xi_2 \)). Hence the conditional distribution of \( \xi_2 \) for \( x = \iota(\ell, \bar{\ell}) \) has density \( \frac{1}{2} \sin \xi_2 \) over \( \xi_2 \in [0, \pi] \), and so we can compute (working with \( \xi_2 \) modulo \( \pi \))

\[
\mathbb{P} \left[ \ell \not\supset \mathcal{S}, \bar{\ell} \not\supset \mathcal{S} \mid x = \iota(\ell, \bar{\ell}) \right]
= \frac{1}{\pi} \int_{0}^{\phi} \left( \int_{-\xi_1}^{\phi - \xi_1} \frac{\sin \xi_2}{2} d\xi_2 \right) d\xi_1 = \frac{\phi - \sin(\phi)}{\pi},
\]

where \( \phi = \theta + \psi \) is the exterior angle at \( x \) of the triangle formed by \( x, v_i, v_j \) (see Figure 1).
Finally the intensity \( \nu \) of \( \mathcal{X} \) can be computed as \( \frac{\pi}{2} \), for example by computing the mean number of hits of the unit disk by \( \Pi \), then by computing the average length of the intersection of the disk with a line of \( \Pi \) conditional on that line hitting the disk. Thus

\[
J_m = E[\text{len}(\partial C(v_i, v_j))] - 2m
\]

\[
= \nu \int \int_{R^2} P[\ell \not\subseteq \bar{\ell} \not\subseteq x = v(\bar{\ell}, \ell) \in \mathcal{X}] \exp \left( -\frac{1}{2}(\eta - m) \right) dx
\]

\[
= \frac{1}{2} \int \int_{R^2} (\phi - \sin \phi) \exp \left( -\frac{1}{2}(\eta - m) \right) dx \quad (9)
\]

as required.

We now state and prove the main result of this section: an \( O(\log m) \) upper bound on the mean perimeter excess length \( J_m \).

**Theorem 4** (Asymptotic upper bound on mean perimeter length). The mean perimeter excess length \( J_m \) is subject to the following asymptotic upper bound:

\[
J_m \leq O(\log m) \quad \text{as } m \to \infty. \quad (10)
\]

**Proof.** Without loss of generality, place the points \( v_i \) and \( v_j \) at \((-\frac{m}{2}, 0)\) and \((\frac{m}{2}, 0)\). The double integral in (4) possesses mirror symmetry about each of the two axes, so we can write

\[
J_m = 2 \int_0^{\pi/2} \int_0^{\frac{m}{2}} (\phi - \sin \phi) \exp \left( -\frac{1}{2}(\eta - m) \right) r dr d\theta
\]

\[
= 2 \int_0^{\pi/2} \int_0^{\frac{m}{2}} (\phi - \sin \phi) \exp \left( -\frac{1}{2}(\eta - m) \right) r dr d\theta + \int_{\frac{\pi}{2}}^{\pi} \int_0^{\frac{m}{2}} (\phi - \sin \phi) \exp \left( -\frac{1}{2}(\eta - m) \right) r dr d\theta \quad (11)
\]

(11) (using polar coordinates \((r, \theta)\) about the second point \( v_j \) located at \((\frac{m}{2}, 0)\)). The integrand in the second summand is dominated by \( \pi \exp \left( -\frac{r}{3} \right) r \), which is integrable over \((r, \theta) \in (0, \infty) \times (\frac{\pi}{2}, \pi)\). (In this region geometry shows that \( \eta - m > r(1 - \cos \theta) \geq r \).) Thus we can apply Lebesgue’s dominated convergence theorem to deduce that the second summand is \( O(1) \) as \( m \to \infty \), hence may be neglected.

In fact we can also show that part of the first summand generates an \( O(1) \) term: the dominated convergence theorem can be applied for any \( \varepsilon \in (0, \pi/2] \) to show that

\[
2 \int_0^{\pi/2} \int_0^{\frac{m}{2}} (\phi - \sin \phi) \exp \left( -\frac{1}{2}(\eta - m) \right) r dr d\theta = O(1),
\]

since the integrand is dominated by \( \pi \exp \left( -\frac{r}{3}(1 - \cos \theta) \right) r \) over the region \((r, \theta) \in (0, \infty) \times (\varepsilon, \frac{\pi}{2})\) (in this region geometry shows that \( \eta - m > r(1 - \cos \theta) >
\]
Thus for fixed $\varepsilon \in (0, \frac{\pi}{2})$ as $m \to \infty$ we have the asymptotic expression

$$J_m = 2 \int_0^\varepsilon \int_0^{m \sec \theta} (\phi - \sin \phi) \exp \left(-\frac{1}{2}(\eta - m)\right) r \, dr \, d\theta + O(1),$$

where the implicit constant of the $O(1)$ term depends on the choice of $\varepsilon > 0$.

Now in the region where $0 < \theta < \varepsilon$ and $0 < r < \frac{m}{2} \sec \theta$ we know that $\phi < 2\theta < 2\varepsilon$, and moreover $\phi - \sin \phi$ is an increasing function of $\phi$. Therefore there is a constant $C_\varepsilon$, converging to zero as $\varepsilon \to 0$, such that in this region

$$\phi - \sin \phi \leq 2\theta - \sin(2\theta) \leq C_\varepsilon \frac{(2\theta)^3}{3} \leq C_\varepsilon \frac{1 - \cos \theta}{\sin \theta}.$$

Hence (as $m \to \infty$ for fixed $\varepsilon > 0$)

$$2 \int_0^\varepsilon \int_0^{m \sec \theta} (\phi - \sin \phi) \exp \left(-\frac{1}{2}(\eta - m)\right) r \, dr \, d\theta$$

$$\leq \frac{2}{3} C_\varepsilon \int_0^\varepsilon \int_0^{m \sec \theta} (1 - \cos \theta) \sin \theta \exp \left(-\frac{1}{2}(1 - \cos \theta)\right) r \, dr \, d\theta$$

$$= \frac{8}{3} C_\varepsilon \int_0^\varepsilon \left( \int_0^{m \sec \theta - 1} se^{-s} \, ds \right) \frac{\sin \theta \, d\theta}{1 - \cos \theta} \quad \text{(using } s = \frac{r}{2}(1 - \cos \theta))$$

$$\leq \frac{8}{3} C_\varepsilon \int_0^{m \sec \theta - 1} \left( \int_0^v se^{-s} \, ds \right) \frac{1}{1 + 4v/m} \, dv \quad \text{(using } v = \frac{m}{2}(sec \theta - 1))$$

$$\leq \frac{8}{3} C_\varepsilon \log \left( \frac{m}{4}(\sec \varepsilon - 1) \right) + O(1).$$

Remark 1. More careful analysis yields useful $o(1)$-asymptotics: in fact it can be shown that as $m \to \infty$ so

$$J_m = \frac{8}{9} (\log m + \gamma + \frac{5}{4}) + o(1),$$

where $\gamma$ is the Euler-Mascheroni constant: $\gamma = \lim_{m \to \infty} (\sum_{1}^{m} \frac{1}{k} - \log m)$.

These $o(1)$-asymptotics show very good agreement with simulation: see for example the simulation reported in the legend of Figure 2.

3  A low-cost network with short routes

In this section we prove Theorem 1 for a given configuration $x^n \subset [0, \sqrt{n}]^2$ we construct networks $G(x^n)$ for which both $\text{len}(G(x^n)) - \text{len}(G(x^n))$ and $\text{excess}(G(x^n))$ are small. The network is constructed by augmenting the Steiner tree network $ST(x^n)$ in a hierarchical manner. The construction is stochastic: we construct a random augmentation for which the mean values of these excess values obey the desired asymptotics and then apply the probabilistic method to establish existence of the desired non-stochastic networks. Working from the largest scale downwards, we construct
Figure 2: Simulation of semi-perimeters for 1000 independent cells for unit-rate Poisson line process, with points located at distance $10^8$ units apart. The figure is subject to vertical exaggeration: $y$-axis is scaled at $10^4$ times $x$-axis. Empirical mean excess semi-perimeter is 27.63 with standard error $\pm 0.28$, versus predicted mean excess semi-perimeter 27.5528 (using $o(1)$-asymptotics).

1. a stationary and isotropic Poisson line process $\Pi$ of intensity $\eta$, where $\eta$ will be small: note that this can be constructed from a unit intensity process by scaling by a magnification factor of $1/\eta$. A simple computation \cite{10}, Section 8.4 shows that the mean total length of the intersection of the resulting line pattern with $[0, \sqrt{n}]^2$ equals $\pi \eta n$.

2. A medium-scale rectangular grid with cell side-length $s_n \sim (\log n)^{1/3}$. Total length of this grid in $[0, \sqrt{n}]^2$ is bounded above by

$$2(1 + \frac{\sqrt{n}}{s_n})\sqrt{n} = o(n).$$

3. The Steiner tree $ST(x^n)$.

4. A small number (at most $n/2$) of small hot-spot cells based on a small-scale rectangular grid with cell side-length $t_n \sim (\log n)^{1/6}$. A cell in this
grid is described as a *hot-spot cell* if it contains two or more points. These hot-spot cells are used to by-pass regions where the Steiner tree might become complicated and expensive in terms of network traversal. We add further small segments connecting each hot-spot cell perimeter to points within the hot-spot cell. Total length of these additions can be bounded by

\[ 4n^2 t_n + n \frac{t_n}{2} = o(n). \]

Thus the mean excess length of this augmented network is \( o(n) + \pi \eta n \). The construction is illustrated in Figure 3. Note that we can choose \( s_n \) and \( t_n \) such that \( n^{1/2}/s_n \) and \( s_n/t_n \) are integers, so that the small-scale lattice is a refinement of the medium-scale lattice, which itself refines the square \([0, \sqrt{n}]^2\).

### 3.1 Worst-case results for Steiner trees

We first record two elementary results on Steiner trees. The first result bounds the length of a Steiner tree in terms of the square-root of the number of points (for the planar case).

**Lemma 3.1.** Consider a configuration \( x^k \) of \( k \) points in a square of side \( r \): there is a constant \( C_1 \) not depending on \( k \) or \( r \) such that

\[ \text{len} \left( \text{ST}(x^k) \right) \leq C_1 \sqrt{kr}. \]  

**Proof.** See [9, Section 2.2].
Lemma 3.2. Consider the Steiner tree $ST(x^n)$ for an arbitrary configuration $x^n$ in the plane. Let $G$ be the restriction of the network $ST(x^n)$ to a fixed open square of side-length $t$. Suppose $k$ points $x_1, \ldots, x_k$ of the configuration $x^n$ lie within the square. Then

$$\text{len}(G) \leq t \left( 4 + C_1 \sqrt{k+1} \right).$$

(14)

Proof. Let $y_1, \ldots, y_m$ be the locations at which $ST(x^n)$ crosses into the interior of the square. (Note: $m = 0$ is possible if $\{x_1, \ldots, x_k\} = x^n$: in this case choose $y_1$ arbitrarily from the perimeter of the square.) Then

$$\text{len}(G) \leq \text{len}(ST(\{x_1, \ldots, x_k, y_1, \ldots, y_m\})) \quad \text{by minimality of } ST(x^n),$$

$$\leq \text{len}(ST(\{x_1, \ldots, x_k, y_1\})) + 4t \quad \text{using square perimeter},$$

$$\leq t \left( 4 + C_1 \sqrt{k+1} \right) \quad \text{using the previous lemma}.$$

\[ \square \]

3.2 Route-lengths in the medium-large network

The part of the construction involving the medium-scale grid and the Poisson line process is useful in variant problems, so we separate out the following estimate involving these ingredients.

Lemma 3.3. Let $n^{1/2}/s_n$ be an integer. Consider the superposition of the rectangular grid with cell side-length $s_n$ and the Poisson line process of intensity $\eta$, intersected with the square $[0, n^{1/2}]^2$. Let $v_i, v_j$ be vertices of the grid. Then

$$\mathbb{E}[\text{route-length } v_i \text{ to } v_j] \leq |v_i - v_j| + C_2 \frac{1}{\eta} \log(\eta \sqrt{2n})$$

for an absolute constant $C_2$.

Proof. Let $C(v_i, v_j)$ be the cell of $\Pi$ containing $v_i$ and $v_j$ (having deleted lines from $\Pi$ which separate $v_i$ from $v_j$). Let $R(v_i, v_j)$ be the rectangle bounded by $v_i$ and $v_j$; then by convexity the route-length from $v_i$ to $v_j$ is bounded above by

$$\frac{1}{2} \text{len } \partial (R(v_i, v_j) \cap C(v_i, v_j)) \leq \frac{1}{2} \text{len } \partial C(v_i, v_j),$$

whose mean value can be computed by recognising that the Poisson line process is a rescaled version of a homogeneous isotropic unit rate Poisson line process. Hence by scaling the asymptotic upper bound of Theorem 4 we have

$$\mathbb{E} \left[ \frac{1}{2} \text{len } \partial (R(v_i, v_j) \cap C(v_i, v_j)) \right] - |v_i - v_j|$$

$$\leq O \left( \frac{1}{\eta} \log (\eta |v_i - v_j|) \right) = O \left( \frac{1}{\eta} \log (\eta \sqrt{2n}) \right).$$

\[ \square \]
3.3 Navigating the augmented network

We now explain how to move from points of $x^n$ up to a vertex of the medium-scale grid.

Given $x_i \in x^n$, if this is in one of the hot-spot cells then move to the perimeter of the hot-spot cell and thence to a suitable point of departure on the perimeter, with route-length at most $\frac{5}{2} t_n$. Now move along the Steiner tree within the relevant medium-scale grid box to the box perimeter; however by-pass all hot-spot cells. There are $(s_n/t_n)^2 = ((\log n)^{1/3}(\log n)^{1/6})^2 = \log n$ small squares each of which involves a route-length of either $2t_n$ (if a hot-spot box which will be by-passed) or $t_n(4 + C_1 \sqrt{2})$ (if not, by Lemma 3.2). Hence the total trip to the medium-scale grid box perimeter (including emergence from the initial hot-spot, if required) has length at most

$$\frac{5}{2} t_n + t_n(4 + C_1 \sqrt{2}) \times s_n/t_n^2 \sim \frac{5}{2} t_n + (4 + C_1 \sqrt{2}) \times (\log n)^{5/6} = o(\log n).$$

Furthermore the route length from perimeter to vertex of medium-scale grid box is at most $\frac{1}{2} s_n \sim \frac{1}{2} (\log n)^{1/3} = o(\log n)$. So for each $x_i$ there is a medium-scale grid vertex $v_i$ for which route-length from $x_i$ to $v_i$ is $o(\log n)$. Combining with Lemma 3.3 and noting that the medium-scale grid geometry forces $|v_i - v_j| \leq |x_i - x_j| + 2 \frac{\sqrt{2}}{\sqrt{3}}$, we find

$$E\text{[route-length from } x_i \text{ to } x_j \text{]} - |x_i - x_j| \leq \sqrt{2} s_n + o(\log n) + C_2 \frac{1}{n} \log \left(\eta \sqrt{2n}\right).$$

Averaging over the points of $x^n$, it follows that the dominant contribution comes from the cell semi-perimeters, and indeed

$$E\text{[excess}(G(x^n))\text{]} \leq O\left(\frac{1}{n} \log \left(\eta \sqrt{2n}\right)\right),$$

at a cost in terms of network length which exceeds $\text{len}(\text{ST}(x^n))$ by a stochastic quantity of mean $\pi \eta n + o(n)$.

The two different results of Theorem 1 follow by choosing $\eta$ to behave in two different ways:

(a) either $\eta \to 0$, $\eta w_n \to \infty$,

(b) or $\eta = \varepsilon > 0$.

In either case we can apply the probabilistic method to exhibit existence of the required deterministic networks for cases (a) and (b) of Theorem 1. For example in case (a) it is then the case that $E[\text{len}(G(x^n)) - \text{len}(\text{ST}(x^n))] \leq nc_n$ and $E[\text{excess}(G(x^n))] \leq c_n w_n \log n$ for some $c_n \to 0$. But then for any fixed $n$ we can apply Markov’s inequality: $\mathbb{P}[\text{len}(G(x^n)) - \text{len}(\text{ST}(x^n)) > 3nc_n] \leq \frac{1}{3}$ and $\mathbb{P}[\text{excess}(G(x^n)) > 3c_n w_n \log n] \leq \frac{1}{3}$. Hence there is positive probability that the random network satisfies both $\text{len}(G(x^n)) - \text{len}(\text{ST}(x^n)) \leq 3nc_n$ and $\text{excess}(G(x^n)) \leq 3c_n w_n \log n$, hence such a network exists for each $n$.

We can view these applications of Markov’s inequality as indicating a simple rejection sampling algorithm to be used to generate the required sequence of networks.
4 A lower bound on average excess route-length

In this section we prove Theorem 2. The proof is divided into four parts. Firstly (Subsection 4.1) we show how to reduce the problem to an analogous case in which the excess is computed for two random points drawn independently and uniformly from the whole disk $D_n$ of area $\pi \rho n$ given in condition (b) of the theorem. Then (Subsection 4.2) we show that the network geodesic must run almost parallel to the Euclidean geodesic if the excess is small. On the other hand (Subsection 4.3) we can use the uniformity of the two random points to control the extent to which network segments can run both close to and nearly parallel to the Euclidean geodesic. Finally (Subsection 4.4) we use the opposing estimates of Subsections 4.2 and 4.3 to derive a proof of the theorem using the method of contradiction.

4.1 Reduction to case of a pair of uniformly random points

First we indicate how condition (a) of Theorem 2 implies condition (b). Under condition (a) we can use the coupling between $X_n$ and $Y_n$ to show that $\# \{x^n \cap D_n \}/n \rightarrow \pi \rho$: therefore for large $n$ the number of points in $x^n \cap D_n$ is approximately $\pi \rho n$. On the other hand the same coupling can be used to bound the total variation distance between the two conditional distributions $L(Y_n \mid X_n \in D_n)$ and $L(Y_n \mid Y_n \in D_n) = \text{Uniform}(D_n)$, and to show that this bound tends to zero. We can then use rejection sampling techniques to couple $L(Y_n \mid X_n \in D_n)$ and $\text{Uniform}(D_n)$ so that the truncated Vasershtein distance tends to zero as $n \rightarrow \infty$; as the distance is a metric we can combine this coupling with the (conditioned) coupling of $L(X_n \mid X_n \in D_n)$ and $L(Y_n \mid X_n \in D_n)$ to obtain a coupling which satisfies condition (b).

We now note that it is sufficient to consider the analogous result for a configuration $x^n$ of $n$ points in the disk $D_n$. For then we can apply the result to the lesser configuration $y^{k(n)}$ (for $k(n)$ as given in condition (b) of Theorem 2) and obtain

$$\text{excess}(G(y^{k(n)})) = \Omega(\sqrt{\log k(n)}) = \Omega(\sqrt{\log \pi \rho n \varepsilon}) = \Omega(\sqrt{\log n}),$$

while

$$\text{excess}(G(y^{k(n)})) = \frac{n(n-1)}{k(n)(k(n)-1)} \text{excess}(G(x^n)) \leq \frac{1}{\pi \rho \varepsilon (\pi \rho \varepsilon - 1/n)} \text{excess}(G(x^n)),$$

from which Theorem 2 follows.

We therefore consider $x^n \subset D_n$ being $L_n$-equidistributed as the uniform distribution on $D_n$. So by definition there is a coupling $(x_1, y_1)$ (here we omit dependence on $n$) where $X_1$ has uniform distribution on $x^n$, $Y_1$ has uniform distribution on $D_n$ and

$$\Delta_n = \mathbb{E} \left[ \min \left( 1, \frac{|X_1 - Y_1|}{L_n} \right) \right] \rightarrow 0 \text{ as } n \rightarrow \infty. \quad (15)$$
Write \((X_2, Y_2)\) for an independent copy of \(X_1, Y_1\). In the definition of excess it makes no asymptotic difference if we allow \(j = i\) in average \((i,j)\), so we may take

\[
\text{excess}(G(x^n)) = \mathbb{E}[\ell(X_1, X_2) - |X_1 - X_2|].
\]  

Set

\[
A_n = [|Y_1 - X_1| \leq L_n] \cap [|Y_2 - X_2| \leq L_n]
\]

so that by Markov’s inequality

\[
\mathbb{P}[A_n] \geq 1 - 2\Delta_n.
\]

Define \(\ell(Y_1, Y_2)\) by supposing that \(Y_i\) is plumbed in to the network using a connection by a temporary line segment with endpoints \(Y_i\) and \(X_i\). A direct computation shows that on the event \(A_n\)

\[
\ell(Y_1, Y_2) - |Y_1 - Y_2| \leq (\ell(X_1, X_2) + |X_1 - Y_1| + |X_2 - Y_2|) - (|X_1 - X_2| - |X_1 - Y_1| - |X_2 - Y_2|)
\]

\[
\leq \ell(X_1, X_2) - |X_1 - X_2| + 4L_n.
\]

Consequently

\[
\mathbb{E}[\ell(Y_1, Y_2) - |Y_1 - Y_2|; A_n] \leq \text{excess}(G(x^n)) + 4L_n.
\]

By hypothesis \(L_n = o(\sqrt{\log n})\), and so the proof of Theorem 2 reduces to showing that the left side (the excess for two random points chosen uniformly in the disk) is \(\Omega(\sqrt{\log n})\).

### 4.2 Near-parallelism for case of small excess

We now substantiate our previous remark that the network geodesic must run almost parallel to the Euclidean geodesic if the excess is small.

It is convenient to situate the disk \(D_n\) in the complex plane \(\mathbb{C}\) so as to have a compact notation for rotations. For \(t > 0\) we define \(Z_t\) and \(\Phi\) by

\[
\exp (i\Phi) = \frac{Y_2 - Y_1}{|Y_2 - Y_1|},
\]

\[
Z_t = Y_1 + t \times \exp (i\Phi).
\]

Let \(\gamma : [0, \ell(Y_1, Y_2)] \to \mathbb{C}\) be the unit-speed network geodesic running from \(Y_1\) to \(Y_2\) (using the temporary plumbing to move from \(Y_1\) to \(X_1\) and then again from \(Y_2\) to \(X_2\)). Then (bearing in mind that \(|\gamma'(t)| = 1\))

\[
\ell(Y_1, Y_2) = \int_0^{\ell(Y_1, Y_2)} |\gamma'(s)| ds \geq \int_0^{\ell(Y_1 - Y_2)} |\gamma'(\tau(t))| \tau'(t) dt,
\]

where \(\tau(t)\) is the first time \(s\) at which \(\langle \gamma(s) - Y_1, \exp (i\Phi) \rangle = t\). (Note that our networks are formed from finite collections of line segments. Hence \(\tau'\) will
be defined and finite save perhaps at a finite number of times.) This and the following constructions are illustrated in Figure 4.

Defining \( \theta(t) \) by \( \sec \theta(t) = \tau'(t) \), and using \( \sec \theta \geq 1 + \frac{1}{2} \theta^2 \), we deduce

\[
\ell(Y_1, Y_2) \geq |Y_1 - Y_2| + \frac{1}{2} \int_0^{\theta(t)} \theta(t)^2 dt. \tag{22}
\]

Furthermore we can use Pythagoras and the geodesic property of Euclidean line segments to show the following. Let \( H(t) \) be the maximum \(|r|\) for which, for some \( s \),

\[
\gamma(s) = Z_t + ir \exp(i\Phi).
\]

If the excess for the network geodesic from \( Y_1 \) to \( Y_2 \) is bounded above by \( \ell(Y_1, Y_2) - |Y_1 - Y_2| \leq \chi \) then \( H(t) \leq \sqrt{2t\chi + \chi^2} \).

Let \( Y_{t,\chi} \) be the smallest \(|\delta|\) such that some network segment intersects the perpendicular \( \{Z_t + ir \exp i\Phi : r \in \mathbb{R}\} \) at angle \( \pi/2 + \delta \) and at distance at most \( \sqrt{2t\chi + \chi^2} \) from \( Z_t \) (thus \( \delta \) is the angle of incidence of this network segment on the perpendicular). If \( \ell(Y_1, Y_2) - |Y_1 - Y_2| \leq \chi \) and \( |Y_1 - Y_2| \geq \kappa \sqrt{m} \), we can
use (22) to deduce
\[\ell(Y_1, Y_2) - |Y_1 - Y_2| \geq \frac{1}{2} \int_0^{\kappa \sqrt{m}} \mathcal{Y}_{t, \chi}^2 dt - \frac{1}{2} \left(\frac{\pi^2}{4}\right) \times (|X_1 - Y_1| + |X_2 - Y_2|)\,.
\]
(The second summand allows for the temporary plumbing in of connections $X_1Y_1$ and $X_2Y_2$, for which the angle $\theta(t) \in (0, \frac{\pi}{2})$ is not controlled by permanent network segments). So introduce the event
\[B_{\kappa, \chi} = [\ell(Y_1, Y_2) - |Y_1 - Y_2| \leq \chi, |Y_1 - Y_2| \geq \kappa \sqrt{m}] \quad (23)
\]
and recall from Equation (17) the event $A_n = \cap_{i=1}^2 [ |Y_i - X_i| \leq L_n]$. Taking expectations, we deduce
\[\mathbb{E}[\ell(Y_1, Y_2) - |Y_1 - Y_2| ; B_{\kappa, \chi} \cap A_n] \geq \frac{1}{2} \int_0^{\kappa \sqrt{m}} \mathbb{E}[\mathcal{Y}_{t, \chi}^2 ; B_{\kappa, \chi} \cap A_n] dt - \frac{\pi^2}{4} L_n\,.
\]
Using integration by parts to replace the expectation by a probability,
\[\mathbb{E}[\ell(Y_1, Y_2) - |Y_1 - Y_2| ; B_{\kappa, \chi} \cap A_n] + \frac{\pi^2}{4} L_n \geq \int_0^{\kappa \sqrt{m}} \int_0^\infty \mathbb{P}[\mathcal{Y}_{t, \chi} > u] \cap B_{\kappa, \chi} \cap A_n] u \, du \, dt
\]
\[= \int_0^{\kappa \sqrt{m}} \int_0^\infty (\mathbb{P}[B_{\kappa, \chi} \cap A_n] - \mathbb{P}[^\mathcal{Y}_{t, \chi} \leq u] \cap B_{\kappa, \chi} \cap A_n]) u \, du \, dt
\]
\[\geq \int_0^{\kappa \sqrt{m}} \int_0^\infty \max (\mathbb{P}[B_{\kappa, \chi} \cap A_n] - \mathbb{P}[\mathcal{Y}_{t, \chi} \leq u], 0) u \, du \, dt \,.
\]
(Note also that from the definitions of $B_{\kappa, \chi}$ and $A_n$, using (18), (19) and Markov’s inequality
\[1 - \mathbb{P}[B_{\kappa, \chi} \cap A_n] = 1 - \mathbb{P}[A_n] + \mathbb{P}[A_n \setminus B_{\kappa, \chi}] \leq 2\Delta_n + \mathbb{P}[^\mathcal{Y}_{t, \chi} < \kappa \sqrt{m}] + \frac{\text{excess}(G(x^n)) + 4L_n}{R} \,.
\]
To make progress we now need to find an upper bound for $\mathbb{P}[\mathcal{Y}_{t, \chi} \leq u]$ and this is the subject of the next section.

### 4.3 Upper bounds using uniform random variables

Firstly we compute an upper bound on the joint density of the quantities $Z_t$ and $\Phi$ from the previous section, illustrated in Figure 5.
Lemma 4.1. Suppose $Y_1, Y_2$ are independent uniformly distributed random points in a disk $D_n$ of radius $\sqrt{n\rho}$ and centre 0 in the complex plane $\mathbb{C}$. With $Z_t$ and $\Phi$ defined as in (20), the joint density of $Z_t$ and $\Phi$ is given over $\mathbb{C} \times [0, 2\pi)$ by
\[
I[z - te_\phi \in D_n] \frac{(t + s(z, \phi))^2}{2\pi^2 \rho^2 n^2} dz d\phi,
\]
where $e_\phi = e^{i\phi}$ is the unit vector making angle $\phi$ with a reference $x$-axis, and $s(z, \phi)$ is the distance from $z$ to the disk boundary $\partial D_n$ in the direction $\phi$ (thus in particular $z + s(z, \phi)e_\phi$ is on the disk boundary).

Proof. Express the joint density for $Y_1, Y_2$ as a product of a uniform density over $D_n$ for $Y_1$ and polar coordinates $r, \phi$ about $Y_1$ for $Y_2$:
\[
I[y_1 \in D_n] \frac{dy_1}{\pi \rho n} I[y_1 + re^{i\phi} \in D_n] \frac{r dr d\phi}{\pi \rho n}.
\]
Obtain the result by integrating out the $r$ variable and transforming the $y_1$ variable to $z$ by $z = y_1 + te^{i\phi}$. \qed
Corollary 1. The density for $Z_t$ and $\Phi \mod \pi$ is

$$f(z, \phi) = \left( \mathbb{I}[z - te_\phi \in D_n] \frac{(t + s(z, \phi))^2}{2} + \mathbb{I}[z + te_\phi \in D_n] \frac{(t + s(z, \pi + \phi))^2}{2} \right) \times \mathbb{I}[0 \leq \phi < \pi] \frac{dz \, d\phi}{\pi^2 \rho^2 n^2}. \quad (27)$$

with an upper bound

$$f(z, \phi) \leq 4 \times \mathbb{I}[0 \leq \phi < \pi] \frac{dz \, d\phi}{\pi^2 \rho n}. \quad (28)$$

Proof. Equation (27) follows immediately from adding the two expressions from Equation (26) for $\phi \mod \pi$. The upper bound follows by noting

1. the maximum will occur when $z - te_\phi$ runs along a diameter as $t$ varies;
2. furthermore when one of $z \pm te_\phi$ lies on the disk boundary;
3. and furthermore when $z = 0$ is located at the centre of the disk (so $t = s(z, \pm \phi) = \sqrt{\rho n}$).

Now consider the line segment $S_{t,\chi}$ centred at $Z_t$, with end-points given by the pair $\pm i \sqrt{2t \chi + \chi^2} \exp(i\Phi)$; and consider the rose-of-directions empirical measure of angles made by intersections of network edges with this segment:

$$\mathcal{R}_{t,\chi}(A) = \# \{ \text{network intersections on } S_{t,\chi} \text{ with angle of incidence lying in } A \} \quad (29)$$

(here angles are measured modulo $\pi$, and $A \subseteq [0, \pi]$). We may apply a Buffon-type argument to bound $E[\mathcal{R}_{t,\chi}(A)]$ using Inequality (28). Consider the contribution to the expectation from a fixed line segment of the network of length $\ell$:

the result of disintegrating the integral expression for this according to the value of $\phi$ is an integral of $f(z, \phi)$ with respect to $z$ over a region formed by intersecting the disk with a parallelogram of base side-length $\ell$ and height $2 \sqrt{2t \chi + \chi^2} \sin \alpha$ (here the angle $\alpha$ depends implicitly on $\phi$ and $z$). Of course the integral vanishes if $\phi \notin A$. Thus Inequality (28) yields a bound

$$E[\mathcal{R}_{t,\chi}(A)] \leq \frac{4}{\pi^2 \rho n} \times \int_{G(x^n)} \int_A 2\sqrt{2t \chi + \chi^2} \sin \alpha \, \alpha \, dz.$$

For constant $\chi$, the event $[\Upsilon_{t,\chi} \leq u]$ is the event $[\mathcal{R}_{t,\chi}(\frac{\pi}{2} - u, \frac{\pi}{2} + u) \geq 1]$ and so

$$P[\Upsilon_{t,\chi} \leq u] \leq E[\mathcal{R}_{t,\chi}(\frac{\pi}{2} - u, \frac{\pi}{2} + u)] \leq \frac{16}{\pi^2 \rho} \frac{\text{len}(G(x^n))}{n} \sqrt{2t \chi + \chi^2} \times u. \quad (30)$$
4.4 Calculations

We have assembled the ingredients for the proof of Theorem 2 and so now can perform the calculations to get a quantitative lower bound.

We proceed by contradiction. Suppose that excess\( (G(x^n)) = o(\sqrt{\log n}). \)
Inspecting (25) we see that we can choose \( \chi = \chi_n = o(\sqrt{\log n}) \) and some small \( \kappa > 0 \) such that for all sufficiently large \( n \)
\[
P[B_{\kappa, \chi} \cap A_n] \geq 2^{-1/3}. \tag{31}
\]
So we can combine (19) and (24) (and the fact that \( \pi^2/4 < 3 \)) to get
\[
excess(G(x^n)) + 7L_n \geq \int_0^{\kappa \sqrt{p_0}} \int_0^{\infty} \max \left( 2^{-1/3} - P[\Upsilon_{t, \chi} \leq u], 0 \right) u \, du \, dt.
\]
By (30) and hypothesis of Theorem 2 there exists a constant \( B \) such that
\[
P[\Upsilon_{t, \chi} \leq u] \leq \sqrt{\frac{B}{12}} \sqrt{2t \chi + \chi^2} \times u.
\]
Applying the formula \( \int_0^\infty \max(0, \alpha - \beta u) u \, du = \frac{\alpha^3}{6\beta^2} \) we see
\[
excess(G(x^n)) + 7L_n \geq \frac{1}{B} \int_0^{\kappa \sqrt{p_0}} \frac{1}{2t \chi + \chi^2} \, dt = \frac{\log(k \sqrt{p_0} + \frac{\chi}{2}) - \log \frac{\chi}{2}}{2 \chi B}. \tag{32}
\]
Recall this holds under the assumption that \( \chi_n = o(\sqrt{\log n}) \) and that \( \kappa > 0 \) is constant. We are given that \( L_n = o(\sqrt{\log n}) \), and we have supposed for the purposes of contradiction that excess\( (G(x^n)) = o(\sqrt{\log n}). \) But then (32) takes the form
\[
o(\sqrt{\log n}) \geq \frac{\Omega(\log n)}{o(\sqrt{\log n})},
\]
which is impossible. We deduce we must have excess\( (G(x^n)) = \Omega(\sqrt{\log n}). \)

5 Closing remarks and supplements

5.1 Spatial network design

Within the realm of spatial network design, the closest work we know is that of Gastner and Newman [1], who consider the similar notion of a distribution network for transporting material from one central vertex to all other vertices. They give a simulation study (their Figure 2) of a certain algorithm on random points, and comment
\[
\text{Thus, it appears to be possible to grow networks that cost only a little more than the [minimum-length] network, but which have far less circuitous routes.}
\]
Our Theorem [1] provides a strong formalisation of this idea.

An algorithm for minimizing excess for a given length is described in [8], where results for a 39 point configuration are shown. But neither this nor [1] has led to study of \( n \to \infty \) asymptotics.
5.2 Fractal structure of the Steiner tree on random points

A longstanding topic of interest in statistical physics is that of the continuum limits of various discrete two-dimensional self-avoiding walks arising in probability models, e.g.

- uniform self-avoiding walks on the lattice,
- paths within uniform spanning trees in the lattice,
- paths within minimum spanning trees in the lattice.

This study has recently been complemented by spectacular successes of rigorous theory [5]. It is conjectured that routes in Steiner trees on random points have similar fractal properties [7]: route-length between points at distance $n$ should grow as $n^{\gamma}$ for some $\gamma > 1$. However, as our construction shows, such results have little relevance to spatial network design.

5.3 The counterintuitive observation

The counterintuitive observation following Definition 1 follows quickly from the work of Theorem 1. Suppose the configuration $x^n$ is well-dispersed, in the weak sense that for some $\gamma \in (0, 1)$ we find the number of point pairs within $n^{\gamma/2}$ of each other is $o\left((\frac{n}{2})^{\gamma - 1}\right)$ (certainly this is the case for most patterns generated by uniform random sampling from $[0, \sqrt{n}]^2$). Consider a network $G(x^n)$ produced by augmenting the Steiner tree according to the construction in the proof of Theorem 1. Using the properties of this construction, the following can be shown

$$\mathbb{E}\left[ \text{ratio } (G(x^n)) \right] = \mathbb{E}\left[ \text{average } \frac{\ell(x_i, x_j)}{|x_i - x_j|} - 1 \right]$$

$$\leq \text{constant \times o}(n^{\gamma - 1}) + (1 - o(n^{\gamma - 1})) \left( \frac{O(\log \sqrt{2n})}{n^{\gamma/2}} \right)$$

$$\leq \mathcal{O}\left( \max\left( \frac{1}{n^{1-\gamma}}, \frac{\log n}{n^{\gamma/2}} \right) \right).$$

5.4 Derandomisation

Theorem 1 is a purely deterministic assertion, though our proof used randomisation (supplied by the Poisson line process). It seems intuitively plausible that one could give a purely deterministic proof, say by replacing the Poisson line process with a suitable sparse set of deterministically positioned lines having a dense set of orientations.

5.5 Quantifying equidistribution

The classical equidistribution property
the empirical distribution of \( \{n^{-1/2}x_i^n, 1 \leq i \leq n\} \) converges weakly to the uniform distribution on \([0, 1]^2\).

Replacing one sequence of \( L_n \) by another slower-growing sequence makes equidistribution a stronger assumption, and so our assumption in Theorem 2(a) (equidistribution for some \( L_n = o(n^{1/2}) \)) is stronger than the classical equidistribution property. Indeed Theorem 2 fails under the classical equidistribution property, as the following example shows.

**Example 5.1.** Let \( L_n = n^\gamma \) for some \( \gamma \in \left(\frac{3}{8}, \frac{1}{2}\right) \). There exist networks \( G(x^n) \) which are \( L_n \)-equidistributed as the uniform distribution on the square of area \( n \), for which \( \text{len}(G(x^n)) = o(n) \) whilst \( \text{excess}(G(x^n)) \to 0 \).

For example: partition \([0, n^{1/2}]^2\) into subsquares of side \( L_n/\log n \), construct the complete graph on all centres of such subsquares, allocate the \( n \) points evenly amongst subsquares and position them arbitrarily close to the centres.

As is apparent from the non-stochastic condition implying \( L_n \)-equidistribution, there is a wide variety of configurations satisfying \( L_n \)-equidistribution. Here we consider the particular case of independent uniform sampling, and show that this generates an \( L_n \)-equidistributed sequence of configurations.

**Remark 2.** Sample the configuration \( x^n \) independently and uniformly from \([0, \sqrt{n}]^2\). Let \( L_n \to \infty \), perhaps arbitrarily slowly. Then the probability that the configuration \( x^n \) is \( L_n \)-equidistributed with the uniform distribution converges to 1. This follows by dividing \([0, \sqrt{n}]^2\) into cells of side-length asymptotic to \( L_n/\sqrt{2} \), by conditioning on \( x^n \), and by “blurring” the points of \( x^n \) by replacing each point \( x \in x^n \) by an independent draw taken uniformly from the cell containing \( x \). Then a uniform random draw \( Y_n \) of one of the blurred points can be coupled to lie within \( L_n \) of a uniform random draw \( X_n \) from the finite configuration \( x^n \). A simple argument using the Binomial distribution then shows that the total variation distance between \( Y_n \) and \( \text{Uniform}([0, \sqrt{n}]^2) \) tends to zero; it follows that \( X_n \) can be coupled to a \( \text{Uniform}([0, \sqrt{n}]^2) \) random variable \( Y_n \) so that

\[
\mathbb{E} \left[ \min \left( 1, \frac{|X_n - Y_n|}{L_n} \right) | x^n \right] \to 0,
\]

where the convergence takes place in probability.

### 5.6 Poisson line process networks

Remark 1 indicates that more can be said about the mean semi-perimeter

\[
\frac{1}{2} \mathbb{E} [\text{len}(\partial C(v_i, v_j))],
\]

and this will be returned to in later work. For example, consider the network formed entirely from a Poisson line pattern. If the pattern is conditioned to
contain points \(v_i, v_j\) then the perimeter \(\partial C(v_i, v_j)\) will be close to providing a genuine network geodesic.

Note that questions about \(C(v_i, v_j)\) bear a family resemblance to the D.G. Kendall conjecture about the asymptotic shape of large cells in a Poisson line pattern. However \(C(v_i, v_j)\) is the result of a very explicit conditioning and hence explicit and rather complete answers can be obtained by direct methods, in contrast to the striking work on resolving the conjecture about large cells \([6, 4, 3, 2]\).

5.7 An open question

In the random points model we can pose a more precise question. Over choices of network \(G\) subject to the constraint

\[
\mathbb{E} [\text{len}(G(x^n)) - \text{len}(ST(x^n))] = o(n),
\]

or the constraint

\[
\mathbb{E} [\text{len}(G(x^n))] = O(n),
\]

what is the minimum value of \(\mathbb{E} [\text{excess}(G(x^n))]\)? Our results pin down this minimum value, in the latter case to the range \([\Omega(\sqrt{\log n}), O(\log n)]\) and in the former case the range \([\Omega(\sqrt{\log n}), o(\log n)]\). But it remains an open question what should be the exact order of magnitude.
