Abstract

Background: The generation of thrombin is a critical process in the formation of venous thrombi. In isolated plasma under static conditions, phosphatidylserine-exposing platelets support coagulation factor activation and thrombin generation; however, their role in supporting coagulation factor binding under shear conditions remains unclear. We sought to determine where activated factor X (FXa), (pro)thrombin, and fibrin(ogen) are localized in thrombi formed under venous shear.

Methodology/Principal Findings: Fluorescence microscopy was used to study the accumulation of platelets, FXa, (pro)thrombin, and fibrin(ogen) in thrombi formed in vitro and in vivo. Co-perfusion of human blood with tissue factor resulted in formation of visible fibrin at low, but not at high shear rate. At low shear, platelets demonstrated increased Ca2+ signaling and PS exposure, and supported binding of FXa and prothrombin. However, once cleaved, (pro)thrombin was observed on fibrin fibers, covering the whole thrombus. In vivo, wild-type mice were injected with fluorescently labeled coagulation factors and venous thrombus formation was monitored in mesenteric veins treated with FeCl3. Thrombi formed in vivo consisted of platelet aggregates, focal spots of platelets binding FXa, and large areas binding (pro)thrombin and fibrin(ogen).

Conclusions/Significance: FXa bound in a punctate manner to thrombi under shear, while thrombin and fibrin(ogen) distributed ubiquitously over platelet-fibrin thrombi. During thrombus formation under venous shear, thrombin may relocate from focal sites of formation (on FXa-binding platelets) to dispersed sites of action (on fibrin fibers).

Introduction

The application of microscopic imaging technologies to in vivo models of thrombus formation has provided new fundamental insight into the roles of platelets and coagulation factors in the thrombus formation process [1,2,3]. These studies have challenged the traditional understanding that platelets control arterial thrombus formation, while the coagulation system is implicated in venous thrombosis, where shear rates are low. For instance, exposure of tissue factor (TF) and activation of TF-induced thrombin generation is now also considered to play a key role in thrombi formed in the arterial circulation [4,5]. Conversely, platelets contribute to the thrombotic process in veins by responding to thrombin and then providing interaction and activation sites for coagulation factors [6]. In vitro studies indicate that platelets mediate thrombin generation and coagulation by exposing phosphatidylserine (PS) on their membrane surface following prolonged increases in cytosolic Ca2+ [7,8,9]. PS provides a binding surface for the assembly of the coagulation tenase and prothrombinase complexes, which convert factor X into activated factor X (FXa) and prothrombin into thrombin, respectively [10,11]. Through static experiments, the concept was developed that the amount and pattern of thrombin generation and, hence, of fibrin clot formation, is stringently controlled by platelets [12,13]. In contrast, other studies have shown that the formation of fibrin is dependent upon the shear rate, with lower shear rates supporting more fibrin generation [14,15]. Therefore, the role of procoagulant platelets in the regulation of thrombus formation under flow conditions is unclear. In the present paper, we utilized in vitro and in vivo approaches to evaluate the ability of PS-exposing platelets to support coagulation factor binding in thrombi formed under shear flow conditions.
**Methods**

**Ethics Statement**

Blood donors gave full informed, written consent in accordance with the Declaration of Helsinki. Experiments were performed under approval of the Medical Ethics Committee of Maastricht University. Animal experiments were approved by the Maastricht University animal experimental and care committee.

**Materials**

Alexa Fluor (AF) 647 and Oregon Green (OG488) labeled annexin A5, AF546 and OG488 labeled human fibrinogen, Fluo-4 acetoxyxymethyl ester (Fluo-4 AM) and labeled goat anti-rat antibody were from Invitrogen (Leiden, The Netherlands). Rat anti-mouse CD41 monoclonal antibody (mAb) and fluorescein isothiocyanate (FITC) labeled anti-GD61 mAb were from BD Biosciences (San Diego, CA). FITC-labeled anti-human fibrinogen antibody was from WAK Chemie (Steinbach, Germany) and the fibrin-specific mAb (anti-fibrin II β chain, clone T2G1) from Accurate Chemical & Scientific Corporation (Westbury, NY). Recombinant tissue factor (TF, Innovin) was purchased from Dade Behring (Marburg, Germany) and recombinant hirudin (Refludan) from Schering-Plough (Kenilworth, NJ). Fibrillar collagen was from Chrono-Log (Havertown, PA). The fluorogenic thrombin substrate Z-Gly-Gly-Arg amidomethyl coumarin (Z-GGR-AMC) came from Bachem (Bubendorf, Switzerland), plasmin from Enzyme Research Laboratories (South Bend, IN), fibrinogen antiserum from MP Biomedicals (Irvine, CA) and purified human D-dimer from Cell Sciences (Canton, MA). Unlabeled wildtype annexin A5, with high-affinity binding to PS, and the quadruple-mutant, M1234 annexin A5, where all Ca\(^{2+}\) dependent binding sites were mutated to abolish binding to PS, were purchased from Nexins Research (Hoeven, The Netherlands). All other reagents were purchased from Sigma-Aldrich (St. Louis, MO).

**Fluorescently Labeled Coagulation Factors**

Human prothrombin, thrombin and FXa were purified and characterized as described previously [16,17]. Purified factors were active-site labeled with 3′-[acetylthio]acetyl]-D-Phe-Pro-Arg chloromethyl ketone, followed by mild treatment with NH\(_2\)OH and reaction of the thiol generated with 5- and 6-iodoacetamido-2′,7′-dihydrofluorescein (OG488-iodoacetamide) as described [16,17]. It was confirmed that all active-site labeled factors lacked protease activity, but retained normal binding properties [16,17].

**Human Whole Blood Platelet Activation and Thrombus Formation Under Shear**

Blood was obtained by venipuncture from healthy volunteers and collected into a one-tenth volume of trisodium citrate (129 mmol/L trisodium citrate) or a one-sixth volume of acid citrate dextrose (80 mmol/L trisodium citrate, 52 mmol/L citric acid, 183 mmol/L glucose). Glass coverslips or capillaries were coated with fibrinogen (1 mg/mL) or fibrillar collagen (100 μg/mL) for 1 hour at room temperature. Coverslips were assembled into a parallel-plate flow chamber and mounted on the stage of an inverted fluorescence microscope (Diaphot 200; Nikon, Tokyo, Japan) [18]. Citrate-anticoagulated human blood was perfused into the flow chamber via a pulse-free syringe pump. Coagulation was triggered with a second syringe pump, allowing perfusion at one-tenth of the main flow rate with CaCl\(_2\)/TF medium (75 mmol/L CaCl\(_2\), 37.5 mmol/L MgCl\(_2\) and 50 mmol/L TF). Blood perfusion rates were selected to result in initial wall shear rates of 200 s\(^{-1}\), 500 s\(^{-1}\), or 1000 s\(^{-1}\); blood was perfused for a total of 15 minutes at all shear rates. Phase contrast and fluorescence images were recorded with a 40× oil immersion objective using two intensified CCD cameras controlled by Visitech software (Sunderland, UK), as described [2,18].

Changes in cytosolic Ca\(^{2+}\), of adherent platelets were measured during whole blood perfusion. Washed platelets from acid citrate dextrose-anticoagulated blood were loaded with Fluo-4, as described for Fluo-3 [19], and added to citrate-anticoagulated blood from the same donor to yield 20% fluorescent platelets. During blood perfusion, fluorescence images were recorded at 4 frames per second. Using Visitech software, image series were analyzed for regions-of-interest representing one adherent platelet, to give changes in fluorescence (ΔF) per cell. Pseudo-ratioing of ΔF traces resulted in F/Fo curves, representing increases in single-cell fluorescence above baseline and corresponding to increases in intracellular Ca\(^{2+}\), [Ca\(^{2+}\)], [20].

Thrombi formed in flow chambers were labeled for 5 minutes with indicated OG488-conjugated coagulation factors (0.3–1 μmol/L) or antibodies (20 μg/mL) in combination with AF647-annexin A5 (14 nmol/L). After washing with Tyrode-Hepes buffer (136 mmol/L NaCl, 2.7 mmol/L KCl, 10 mmol/L Hepes, 2 mmol/L MgCl\(_2\), 2 mmol/L CaCl\(_2\), 5.6 mmol/L glucose, 0.1% BSA, 1 U/mL heparin; pH 7.45) to remove unbound fluorescent probes, thrombi were imaged with a 60× oil objective and confocal laser scanning microscope using a BioRad-Zeiss 2100 multiphoton system described previously [2]. Control experiments were performed with heat-treated fluorescent probes, which did not incorporate into the thrombi (data not shown). Single-color fluorescence scanning images were analyzed for fluorescence coverage, intensity, and distribution patterns with Image Pro software (Media Cybernetics, Silverspring, MD). The pixel overlap of two overlay images with different fluorescence colors (Pearson’s correlation coefficient, R) was also calculated. This parameter is a value from −1 to +1 which describes the overlap between two colored patterns and is independent of pixel intensity values.

**Real-Time Measurement of Thrombin Generation During Whole Blood Flow**

Citrate-anticoagulated blood containing the fluorogenic thrombin substrate, Z-GGR-AMC (420 μmol/L), was co-perfused with CaCl\(_2\)/TF over fibrinogen as described above. After perfusion for 10 minutes at 200 s\(^{-1}\), real-time accumulation of fluorescence due to substrate cleavage was recorded under stasis. Fluorescent images were obtained every 2 seconds with Visitech software. Regions of interest corresponding to the site of a thrombus were analyzed for fluorescence changes. Traces were then converted into first-derivative curves using Thrombinoscope (Maastricht, The Netherlands) software developed for thrombin generation measurement in plasma systems [21].

**Measurement of Fibrin Formation from Whole Blood Flow**

To measure fibrin formation under various flow conditions, blood was co-perfused with TF/CaCl\(_2\) for 15 minutes into fibrinogen- or collagen-coated capillaries as described above. Following blood perfusion, capillaries were washed with Tyrode-Hepes buffer, then treated with lysis buffer (20 mmol/L Tris, 300 mmol/L NaCl, 2 mmol/L EGTA, 2% NP-40, 2 mmol/L PMSF) for 5 minutes, followed by treatment with plasmin (1 μmol/L) for 1 hour to degrade fibrin. Eluates from capillaries were collected, separated by SDS-PAGE (6% acrylamide) and western-immunoblotted with fibrinogen antiserum for the 200 kDa fibrin degradation product.
D-dimer. D-dimer levels on blots were compared with a standard curve of purified D-dimer (1–100 ng).

**In Vivo Thrombus Formation**

Thrombus formation was provoked in mesenteric veins of 4–5 week old wild-type C57Bl/6 mice, as described [5]. Mice were anesthetized by subcutaneous injection of ketamine (0.1 mg/g body weight) and xylazine (0.02 mg/g body weight); anesthesia was maintained throughout the experiment. Fluorescently labeled coagulation factors were injected via the tail vein (31–37 μmol/L in 70 μL of 30 mmol/L Hepes and 125 mmol/L NaCl; pH 7.4). In selected experiments, mice were injected with OG488- or AF647-labeled goat anti-rat antibody (40 μg) and rat anti-mouse CD41 mAb (2.5 μg in 70 μL saline). Mesenteric vessels (venules with a diameter of ~100 μm and arterioles with a diameter of ~60 μm [3]) were exteriorized and treated topically with 30 μL of 500 mmol/L FeCl3. The treatment led to the damage and loss of the endothelial cell layer in mesenteric veins as previously shown [5]. Vessels were observed with a 40× water immersion objective on an upright Olympus BX-61WI microscope system (Middlesex, UK). Low fluorescence intensities were visualized with a CCD camera and a high-performance GEN III image intensifier [22]. Immediately after FeCl3 application, simultaneous brightfield and fluorescence images were captured at 30 frames per second by high-speed shutter and wavelength changing systems [23]. Image acquisition was controlled by Slidebook 4.10.12 software (Intelligent Imaging Innovations, Denver, CO) [23].

Recorded images were processed with Slidebook software. Fluorescence intensities were corrected for autofluorescence by eliminating all pixels with a lower intensity than the average background intensity (determined per frame for a user-defined region of interest). Using the threshold criteria, all pixel intensities greater than the background were integrated. No further image processing was done. Exported raw images were analyzed by Metamorph software 7.5.0 (Molecular Devices, Downingtown, PA) to determine the increase in fluorescence of selected thrombi. Masks corresponding to the site of the thrombus were created and sum intensities of pixels above background were calculated. After background subtraction, pixel sizes >3 of all fluorescence features above background were listed. Features were grouped according to pixel size (4–9, 10–30, 31–99, 100–309, etc.), and total numbers of positive pixels per group were determined.

**Statistics**

Statistical significance was determined by Tukey’s multiple comparison test and ANOVA.

**Results**

**Thrombus Formation and Platelet Activation Under Shear**

To develop a reproducible method of thrombus formation under shear, human whole blood was co-perfused with CaCl2/TF into fibrinogen-coated flow chambers. Imaging after 15 minutes of perfusion revealed that the fibrinogen surface was covered with platelet-rich thrombi and fibrin fibers at low shear (200 s⁻¹), while at 500 s⁻¹ only thrombi were formed, and at 1000 s⁻¹ a monolayer of platelets was present (Fig. 1A). In the presence of the thrombin inhibitor, hirudin, only a monolayer of platelets was observed on fibrinogen at 200 s⁻¹ (Fig. 1A). To evaluate the extent of fibrin formation on fibrinogen surfaces, thrombi were lysed and the fibrin degradation product, D-dimer, was evaluated by western blotting. In accordance with previous studies [14,15], D-dimer levels were maximal at low shear (200 s⁻¹), indicating that fibrin formation was greatest at the lowest shear rate (Fig. 1B). A parallel set of results was observed on collagen surfaces (Fig. S1). We next aimed to determine if thrombi formed at 200 s⁻¹ could support thrombin generation. Blood containing a fluorogenic thrombin substrate, Z-GGR-AMC, was co-perfused with CaCl2/TF into the fibrinogen-coated chamber. Following 10 minutes of perfusion at 200 s⁻¹, thrombi were fluorescently imaged. Measurement of the cleavage of the substrate (as indicated by an increase in fluorescence) pointed to a transient accumulation of thrombin, which was ablated in the presence of hirudin (Fig. 2A,B). To determine the platelet response during blood perfusion, platelet activation was monitored by loading cells with Fluo-4, an intracellular Ca²⁺ probe. Fluo-4 loaded cells were added to whole blood and perfused with CaCl2/TF over fibrinogen. Calcium responses were monitored with fluorescence microscopy. Adherent platelets demonstrated an increase in cytosolic Ca²⁺ under shear, with the highest amplitude Ca²⁺ response observed at 200 s⁻¹ (Fig. 2C-E). The increased response at low shear was partially dependent upon the generation/availability of thrombin, as hirudin treatment significantly reduced Ca²⁺ responses at 200 s⁻¹. As high cytosolic Ca²⁺ can lead to PS exposure, adherent platelets were stained with OG488-annexin A5, which binds PS with high affinity. The number of PS-exposing platelets was greatest at low shear, and was reduced in the presence of hirudin (Fig. 2F). Together, these results demonstrate that platelet-fibrin
Thrombi formed at low shear contain PS-exposing platelets and promote TF-induced thrombin generation.

Characterization of Coagulation Factor Distribution on Thrombi Under Shear

We next aimed to determine the localization of coagulation factors and the site of thrombin generation during thrombus formation. Thrombi were formed by perfusion of whole blood and CaCl₂/TF at 200 s⁻¹ over fibrinogen, and were labeled with fluorescently labeled coagulation factors or antibodies in combination with AF647-labeled annexin A5 (Fig. 3A). Staining with fluorescently labeled anti-CD61 (integrin β₃) mAb showed the presence of platelet aggregates (20–45 μm in size), surrounded by annexin A5-binding platelets (not shown). We next evaluated the binding of FXa, which has been shown to assemble on the platelet surface as part of the prothrombinase complex. The labeling of OG488-FXa substantially overlapped with PS-exposing (annexin A5-binding) platelets. Quantitatively, this was demonstrated by a high Pearson’s overlap coefficient $R_r$ between labels of 0.56 (Fig. 3C). OG488-FXa binding was restricted to small structures, resulting in a fluorescence surface area coverage of 9.6 ± 1.2% (Fig. 3B).

In marked contrast, OG488-prothrombin, a substrate of the prothrombinase complex, distributed over thrombi and fibrin fibers. As prothrombin can be enzymatically cleaved into thrombin in the presence of active proteases, labeling was performed in the presence of the serine protease inhibitor PPACK. Our results show that the distribution of OG488-prothrombin in...
the presence of PPACK overlapped with the binding distribution of AF647-annexin A5 (Fig. 3A), resulting in an increase in the overlap coefficient $R_r$ of prothrombin and annexin A5 labeling (Fig. 3C). Moreover, the OG488-prothrombin fluorescence surface area coverage was drastically reduced in the presence of PPACK (Fig. 3B). To confirm that prothrombin cleavage was responsible for the altered label distribution, we investigated the binding of OG488-active site-labeled thrombin. Our results demonstrate that OG488-active site-labeled thrombin bound ubiquitously to fibrin-platelet structures, as evidenced by a fluorescence area coverage of 35.0 ± 4.0% and a low overlap ($R_r = 0.10$) with annexin A5 (Fig. 3).

Utilizing OG488-labeled human fibrinogen or fluorescently coupled antibodies to fibrinogen, the distribution of fibrinogen (ogen) was determined on thrombi formed under shear. Fluorescent fibrinogen bound ubiquitously to the platelet thrombi and fibrin fibers (Fig. 4A,B), as evidenced by a high surface area coverage (43.5 ± 7.7%) and low overlap with annexin A5 (0.17). Similarly, fluorescently-labeled antibodies against fibrinogen or fibrin bound in a ubiquitous manner to platelet-fibrin thrombi, resulting in a low overlap with annexin A5 (0.20 and 0.12 for anti-fibrinogen and anti-fibrin antibodies, respectively; Fig. 4C). In contrast, a substantial overlap was observed when thrombi were dual stained with OG488-prothrombin and AF547-fibrinogen ($R_r = 0.79$).

To determine the role of PS-exposing platelets in fibrin generation in the low shear model of thrombus formation, flow experiments were performed using blood pre-treated with wild-type or mutant annexin A5 (0.28 μmol/L). When blood containing wild-type annexin A5 was co-perfused with CaCl$_2$/TF over fibrinogen and post-labeled with OG488-fibrinogen, there was a marked decrease in OG488-fibrinogen labeling and absence of fibrin formation (Fig. 5). In contrast, pretreatment of blood with M1234 annexin A5 mutant (lacking the four Ca$^{2+}$ binding sites required for interaction with PS) had no effect on fibrin formation or the distribution of OG488-fibrinogen on the thrombus surface (Fig. 5). Collectively, these results reveal the distinct distribution of FXa, prothrombin, and thrombin on thrombi formed under shear, and confirm the important role of exposed PS for fibrin formation under flow.

**Heterogeneous Incorporation of Coagulation Factors in Venous Thrombi in Vivo**

To evaluate the incorporation of coagulation factors into thrombus formed in vivo, thrombus formation was studied by brightfield and fluorescence microscopy following FeCl$_3$-induced damage of mouse mesenteric veins with mean wall shear rates of $\sim 345$ s$^{-1}$ [5]. Video images were recorded following injection of OG488-labeled fibrinogen, prothrombin, FXa or anti-CD41 (integrin $\alpha_{IIb}$) mAb. Images showed accumulation of labeled platelets and coagulation factors following vascular damage (Fig. 6). Although the rate of label accumulation was similar for all probes, marked differences were observed in the patterns of label incorporation (Fig. 6). Whereas labeled fibrinogen and prothrombin distributed as large fluorescent structures of the size of the whole thrombus, labeling of FXa and platelets (anti-CD41 mAb) was confined to numerous 15–45 μm sized structures. As confirmed by morphometric analysis of the label distribution...
Our study was designed to investigate the distribution of coagulation factors on thrombi under shear. Our data demonstrate that FXa and prothrombin (in the presence of PPACK) bound in a punctate manner on the thrombus surface under shear, overlapping substantially with annexin A5-binding, PS-exposing platelets. This finding is in accord with previous studies using purified systems under static conditions that have shown that the tenase and prothrombinase complexes assemble on peripheral blood cell surfaces [10,24,25,26]. Our observation that fibrin formation was abrogated in the presence of supraphysiological concentrations of annexin A5 [27,28], demonstrates the functional role of coagulation factor interactions with exposed PS during thrombus formation.

While FXa and prothrombin labeling was punctate, thrombin and fibrin(ogen) were ubiquitously distributed over fibrin-platelet structures, with a large surface area coverage and low overlap with annexin A5. Thrombin interacts with fibrin(ogen) though multiple low and high affinity binding sites [33,34]. Importantly, a high affinity thrombin binding site exists on an alternatively spliced variant of fibrinogen (c9-fibrinogen), which is present in ~10% of circulating fibrinogen molecules and becomes incorporated into fibrin [35,36,37]. Thrombin bound to this high affinity site on fibrin(ogen) has been shown to be enzymatically active and protected from inhibition by the heparin-antithrombin complex [33,38]. Therefore, our findings of thrombin distribution on platelet-fibrin clots, suggest that fibrin

Figure 4. Spatial localization of fibrin(ogen) and procoagulant platelets during thrombus formation. Thrombi were formed by a 15 minute co-perfusion of whole blood and CaCl2/TF at 200 s⁻¹ over fibrinogen. Dual-labeling was with AF647-annexin A5 (14 nmol/L, red) and the indicated fibrin(ogen) labels (green). A, Confocal fluorescence images in green are shown for OG488-fibrinogen (FG, 0.3 μmol/L), anti-fibrinogen antibody (α-FG, 20 μg/mL), or anti-fibrin antibody (α-Fibrin, 20 μg/mL). Images in red indicate staining of PS-exposing platelets. B, Fluorescence surface area coverage for each OG488 label and annexin A5. C, Pearson’s correlation coefficient (Rr), between annexin A5 and each green label. Mean ± SEM (n = 3–5 experiments).

Data are presented as integrated fluorescence intensity per microscopic field. Results of one representative experiment are shown.

doi:10.1371/journal.pone.0010415.g005
may play an important role in localizing thrombin to clots. Our results point to an initial binding of prothrombin to the FXa-containing prothrombinase complex at PS-exposing platelets (thrombin formation), followed by redistribution of active thrombin to the platelet-fibrin thrombus.

Previous in vivo experiments with wild-type C57Bl/6 mice have shown that FeCl₃-induced thrombus formation in the mesenteric venules relies on the exposure of collagen, activation of the TF/activated factor VII pathway, thrombin, and platelet activation [2,5]. While exposed extracellular matrix proteins play an essential role in mediating the first steps of platelet recruitment in damaged vessels, fibrinogen plays a predominant role in platelet aggregate formation. Rapid deposition of fibrinogen is observed in FeCl₃-induced damage of mesenteric venules [39], allowing deposited fibrinogen to become a substrate for subsequent platelet recruitment, adhesion, and aggregation. Under low shear venous conditions, an essential role has been established for fibrinogen in supporting platelet aggregation and adhesion to the growing platelet plug through interactions with αIIBβ₃ [40,41,42,43]. Our in vitro work points to a role for fibrinogen in supporting thrombin localization during thrombus formation. We therefore designed a series of experiments to characterize the distribution of coagulation factors on thrombi formed by FeCl₃-provoked damage of mesenteric venules in vivo. In parallel with our in vitro studies, a punctate distribution of FXa was observed, in accord with the notion that FXa binding is localized to the platelet surface during thrombus formation. Importantly, our in vivo data demonstrate that fibrinogen and prothrombin incorporated into large structures and were distributed throughout the thrombi. Taken together, our studies point to an important role for fibrinogen in retaining the key coagulation enzyme thrombin on clots formed under shear.

Supporting Information

Figure S1 Thrombus formation and fibrin deposition on collagen under shear. Human whole blood was co-perfused with CaCl₂/TF over collagen for 15 minutes at a shear rate of 200 s⁻¹, 500 s⁻¹, or 1000 s⁻¹. Experiments were performed in the presence of vehicle or hirudin (2.9 μmol/L). A, Photo micrographs of platelet adhesion and fibrin formation. B, Following perfusion, flow chambers were washed and sequentially treated with lysis buffer and plasmin. Samples were analyzed for fibrin formation by western blot analysis, as measured by the fibrin degradation product, D-dimer. Found at: doi:10.1371/journal.pone.0010415.s001 (2.78 MB TIF)
