(Dated: January 5, 2022)

The detection of an intermediate-mass black hole population \(10^2 \sim 10^6 \, M_\odot\) will provide clues to their formation environments (e.g., disks of active galactic nuclei, globular clusters) and illuminate a potential pathway to produce supermassive black holes. Ground-based gravitational-wave detectors are sensitive to a subset of such mergers and have been used to detect one \(142_{-16}^{+28} \, M_\odot\) intermediate-mass black hole formation event. However, ground-based detector data contain numerous incoherent short duration noise transients that can mimic the gravitational-wave signals from merging intermediate-mass black holes, limiting the sensitivity of searches. Here we search for binary black hole mergers using a Bayesian-inspired ranking statistic which measures the coherence or incoherence of triggers in multiple-detector data. We use this statistic to identify candidate events with lab-frame total masses \(\gtrsim 55 \, M_\odot\) using data from LIGO’s second observing run. Our analysis does not yield evidence for new intermediate-mass black holes. However, we find support for some stellar-mass binary black holes not reported in the first LIGO–Virgo gravitational-wave transient catalog, GWTC-1.

I. INTRODUCTION

A variety of techniques have been employed to search for \(10^4 \sim 10^6 \, M_\odot\) intermediate-mass black hole (IMBH) candidates including reverberation mapping [1], direct kinematic measurements [2, 3], applying macroscopic galaxy to black hole mass scaling relations \((M_{BH}-\sigma\) and \(M_{BH}-L\) relations) [4, 5], studying X-ray luminosity and spectra [6, 7], gravitational lensing of gamma-ray burst light curves [8], and others [9–11]). However, because IMBHs have smaller gravitational spheres of influence than those of supermassive black holes, it is much more challenging to observe them with these observational techniques [11]. Additionally, the numerous IMBH candidates discovered using these techniques are ambiguous as other sources can describe observations from the candidates (e.g., light sources orbiting clusters of stellar-mass black holes [12, 13], anisotropic emission from neutron stars [14, 15]).

Stellar mass \((M_{BH} < 10^2 \, M_\odot)\) and supermassive black holes \((M_{BH} > 10^6 \, M_\odot)\) have been observed and well studied since the 1970s [16–22]. However, there is a deficiency of observational evidence for black holes in the intermediate-mass range \(10^2 \sim 10^6 \, M_\odot\). The discovery of an IMBH population will bridge this observational gap, probe IMBH formation environments (e.g. accretion disks of active galactic nuclei [23–35], the centers of dense stellar clusters [36–46], Population-III stars [47–51]), and illuminate our understanding of supermassive black hole formation [52–55].

Compact binary coalescences (CBCs) can provide unambiguous gravitational-wave signals for IMBH candidates e.g., the \(142_{-16}^{+28} \, M_\odot\) (90\% credible intervals) remnant observed from the gravitational-wave event GW190521 [56] and other candidates [57–59]. As a binary’s total mass \(M_T\) is associated with its gravitational-wave merger frequency, \(f \sim M_T^{-1}\), ground-based gravitational-wave detectors \((f \sim 10^{-1} \sim 10^3 \, Hz)\) are sensitive to the last milliseconds of merging systems with \(100 \, M_\odot < M_T^{lab} < 400 \, M_\odot\) [60–63], while space-based detectors \((f \sim 10^{-2} \sim 10^1 \, Hz)\) can study the full signals of merging systems with \(10^4 \, M_\odot < M_T^{lab} < 10^7 \, M_\odot\) [62, 64]. Because of the short duration of IMBH gravitational-wave signals in ground-based detectors, data quality is critical for their detection. Gravitational-wave data is characterized by numerous non-stationary terrestrial artifacts called glitches [65–67]. Like signals from IMBH mergers, most glitches last for a fraction of a second, making them difficult to distinguish from astrophysical signals. These glitches can decrease the sensitivity of searches for binary black hole mergers with \(M_T^{lab} \gtrsim 55 \, M_\odot\) [65].

Although a significant fraction of the glitches can be identified by testing them for coherence amongst two or more detectors and performing matched-filtering, these methods are insufficient to identify all glitches [65–67]. One method to discriminate more glitches while searching for CBCs is the Bayesian odds [68–73]. The Bayesian

* avi.vajpeyi@monash.edu
Coherence Ratio $\rho_{BCR}$ [70, 71] is a Bayesian odds comparing the probability that the data contains coherent signals vs. incoherent glitches. In this paper, we use the $\rho_{BCR}$ to rank O2’s coincident CBC gravitational-wave candidates with lab-frame total masses in the range of $55 - 500 M_\odot$. We present the candidates’ $p_S$, the probability that the candidate originates from a coherent gravitational-wave source. Additionally, for comparison, we provide the candidate’s $p_{astro}$ values reported by the LIGO-Virgo-KAGRA (LVK) collaboration in GWTC-1 [74], the PyCBC-team [75–84], by the Institute of Advanced study’s team (IAS) [85–87], and by Pratten and Vecchio [73].

We find that (a) events reported in GWTC-1, including GW170729 (likely the most massive BBH system in GWTC-1) are statistically significant $p_S > 0.9$; (b) three out of the eight IAS events and candidates have $p_S > 0.9$, corroborating IAS’s detection claims for GW170304, GW170727, and GW170817A; and that (c) our ranking statistic does not identify any new IMBH, but does identify an unreported marginal stellar-mass binary black hole candidate, 170222† with $p_S \sim 0.6$.

The remainder of this paper is structured as follows. We outline our methods, including details of our ranking statistic and the retrieval of our candidates in Section II. We present details on the implementation of our analysis in Section III. Finally, we present our results in Section IV and discuss these results in the context of the significance of gravitational-wave candidates in Section V.

II. METHOD

A. A Bayesian Ranking Statistic

The standard framework to identify CBC gravitational-wave signals in data is to quantify the significance of candidates with null-hypothesis significance testing [74, 88]. In this framework, the candidates’ ranking statistic is compared against a background distribution. The independent matched-filter searches, e.g., PyCBC [80], SPIIR [89] and GstLAL [90], and Coherent WaveBurst [91] used by LVK to search for signals in gravitational-wave data all use ranking statistics in such a manner [74]. Both PyCBC and GstLAL’s ranking statistic incorporate information about the relative likelihood that the data contains a coherent signal versus noise. In contrast, cWB’s ranking statistic uses the information of coherent energy present in the network of detectors [74].

Bayesian inference offers an alternative means to rank the significance of candidate events by computing the odds that the data contain a transient gravitational-wave signal versus instrumental glitches [70]. This method relies on accurate models for the signal and glitch morphologies [70]. In principle, Bayesian odds is the optimal method for hypothesis testing [71]. Much of its power comes from the Bayesian evidence, the likelihood of the data given a hypothesis. However, the evidence is not used in current matched filter searches. Here, we explore a hybrid frequentist/Bayesian ranking statistic that makes use of the Bayesian evidence. We compute the Bayesian evidence under the assumption that the data either contain a coherent gravitational-wave signal, noise, or a glitch ($Z^S, Z^N, Z^G$, defined in Appendix A). However, instead of computing true Bayesian odds, we use the evidences as a ranking statistic. We form a bootstrapped distribution of the evidence for simulated foreground and background events to form a frequentist ranking statistic.

B. Formalism

Introduced by Iyi et al. [70], the Bayesian Coherence Ratio for a candidate signal in a network of $D$ detectors is given by

$$\rho_{BCR} = \frac{\hat{n}^S \hat{Z}^S}{\prod_{i=1}^D [\hat{n}_i^G \hat{Z}_i^G + \hat{n}_i^N \hat{Z}_i^N]} ,$$

where $\{\hat{n}_i^S, \hat{n}_i^N, \hat{n}_i^G\}$ are estimates of the astrophysical prior-odds that the data contain a coherent signal, incoherent noise or an incoherent glitch. We assume each detector has the same glitch and noise prior odds of $\{\hat{n}_i^N, \hat{n}_i^G\}$. In the limit where the estimated prior-odds equal the astrophysical prior-odds, the $\rho_{BCR}$ becomes the optimal Bayesian odds described by Ashton et al. [71]. However, as the astrophysical prior-odds are unknown, it is invalid to use the $\rho_{BCR}$ as an odds-ratio to discriminate signals from glitches. Instead, we use the $\rho_{BCR}$ as a ranking statistic to obtain a frequentist significance of a candidate $\rho_{BCR}$-value, $\rho_{BCR}^*$, measured against a background $\rho_{BCR}$ distribution, $\rho_{BCR}^b$.

Since it is impossible to shield ground-based gravitational-wave detectors from gravitational-wave signals, the LVK empirically estimates the background by repeatedly time-shifting strain data by amounts larger than the light-travel time between the two LIGO detectors [74]. We use time-shifted data to generate $\rho_{BCR}^b$.

Following this, each candidate’s single-event false alarm probability $p_1$ of being miss-classified as a glitch is given by

$$p_1 = \frac{\text{Count of } \rho_{BCR}^b \leq \rho_{BCR}^*}{\text{Count of } \rho_{BCR}^b} .$$

Moreover, as we have several candidates ($N$ candidates), each with a $\rho_{BCR}^b$, we account for them by calculating a false-alarm probability with trial factors $p_N$ given by

$$p_N = 1 - (1 - p_1)^N .$$

†170222 is a sub-threshold candidate detected by PyCBC ($t_e = 1171814476.97$) with a $p_S \sim 0.6$. The prefix of GW is not utilized as this is a candidate event.
Finally, we can calculate the probability of the candidate signal event occurring from a gravitational-wave, \( p_S \) with
\[
p_S = 1 - p_N.
\]  

### III. ANALYSIS

We acquire candidate signal triggers (times when the detector’s data has a signal-to-noise ratio above a pre-determined threshold) for \( \rho_{BCR} \) analysis from PyCBC’s search in O2 [75–82, 92]. Some of the triggers are associated with gravitational-wave events and candidates while others are glitches. We also acquire background and simulated triggers from PyCBC’s O2 search to calculate \( \rho_{BCR}^b \) and estimate values for \( \{ \hat{\pi}^S, \hat{\pi}^G \} \) (see Appendix B for details on the estimation process). The triggers are divided into two week time-frames because the detector’s sensitivity does not stay constant throughout the eight-month-long observing period [80].

For our study, we filter PyCBC triggers to include only those in the parameter ranges presented in Table I. This region focuses our analysis on binary black hole mergers with lab-frame total masses above \( \gtrsim 55 M_\odot \), corresponding to binary systems with signal durations \( < 454 \text{ ms} \) and \( q \gtrsim 0.1 \). The filtering process leaves us with 60,996 background, 5,146 simulated, and 25 candidate signal triggers. We additionally include events and candidate events reported by GWTC-1 and the IAS group in our list of candidate signal triggers. A plot of the lab-frame component mass space constrained by our search space is presented in Fig. 1.

To evaluate \( \{ Z^S, Z^G, Z^N \} \) and calculate the \( \rho_{BCR} \) Eq. 1 for triggers, we carry out Bayesian inference with bilby [93, 94], employing dynesty [95] as our nested sampler. Nested sampling, an algorithm introduced by Skilling [96, 97], provides an estimate of the Bayesian evidence and is often utilized for parameter estimation within the LIGO collaboration [93, 98, 99].

We use a likelihood that marginalizes over coalescence time, the phase at coalescence, and luminosity distance (Eq. 80 from Thrane and Talbot [100]). We use identical parameter estimation priors for the glitch and signal models. We restrict the spin priors to aligned spins to reduce the number of parameters we sample. We define our mass priors to be uniform in chirp mass \( M \) and mass ratio \( q \) to avoid sampling issues that arise from sampling in thin regions of the component mass parameter space [101]. As a post-processing step, we convert posterior samples calculated with uniform \( \{ M, q \} \) priors to uniform component mass priors by re-sampling the posterior samples using the Jacobian given in Eq. 21 of Veitch et al. [102]. The complete list of the priors is in Table II.

The waveform template we utilize is IMRPhenomPv2, a phenomenological waveform template constructed in the frequency domain that models the in-spiral, merger, and ring-down (IMR) of a compact binary coalescence [103]. Although there exist gravitational-wave templates such as IMRPhenomXPHM [104], NRSur7dq4 [105], and SEOBNRv4PHM [106] which incorporate more physics, such as information on higher-order modes, we use IMRPhenomPv2 as it is computationally inexpensive compared to others.

To generate the PSD, we take 31 neighboring off-source non-overlapping 4-second segments of time-series data before the analysis data segment \( d_c \). A Tukey window with a 0.2-second roll-off is applied to each data segment to suppress spectral leakage. After this, we fast-Fourier transform and median-average the segments to create a PSD [107]. Like other PSD estimation methods, this method adds statistical uncertainties to the PSD [108–110]. To marginalize over the statistical uncertainty, we use the median-likelihood presented by Talbot and Thrane [108] as a post-processing step. We find that this post-processing step improves the search efficiency by 49.26% and the details of this calculation are in Appendix C.

The data we use are the publicly accessible O2 strain data from the Hanford and Livingston detectors, recorded while the detectors are in “Science Mode”. We obtain the data from the gravitational-wave Open Science Center [111] using Gwpy [112].

Finally, with the \( \rho_{BCR}^b \) and \( \rho_{BCR}^t \) for each time-frame of triggers, we calculate the candidate signal’s \( p_S \).

| Table I. Trigger-selection lab-frame parameter space (parameters correspond to signals with durations \( \leq 454 \text{ ms} \) and \( q \gtrsim 0.1 \)). |
|-----------------------------------------------|
| Minimum | Maximum |
| Component Mass 1 \( [M_\odot] \) | 31.54 | 491.68 |
| Component Mass 2 \( [M_\odot] \) | 1.32 | 121.01 |
| Total Mass \( [M_\odot] \) | 56.93 | 496.72 |
| Chirp Mass \( [M_\odot] \) | 8.00 | 174.56 |
| Mass Ratio | 0.1 | 0.98 |

| Table II. Prior settings for the lab-frame parameters used during our parameter estimation. The definitions of the parameters are documented in Romero-Shaw et al. [101] Table E1. The trigger time \( t_c \) is obtained from the data products of PyCBC’s O2 search. |
|-----------------------------------------------|
| Parameter | Shape | Limits |
| \( M/M_\odot \) | Uniform | 7–180 |
| \( q \) | Uniform | 0.1–1 |
| \( M/M_\odot \) | Constraint | 50–500 |
| \( d_c/\text{Mpc} \) | Comoving | 100–5000 |
| \( \chi_1, \chi_2 \) | Uniform | -1–1 |
| \( \theta_{ij} \) | Sinusoidal | 0–\( \pi \) |
| \( \psi \) | Uniform | 0–\( \pi \) |
| \( \phi \) | Uniform | 0–2\( \pi \) |
| ra | Uniform | 0–2\( \pi \) |
| dec | Cosine | 0–2\( \pi \) |
| \( t_c/\text{s} \) | Uniform | \( t_c \pm 0.1 \) |
FIG. 1. Lab-frame component-mass boundaries for our search space and parameter estimation prior. Our search is constrained to the parameter space enclosed by the gold-colored hatches, while our prior is constrained to the slightly larger parameter space enclosed by the teal-colored hatches. The purple region labeled “IMBH” is the parameter space where merger remnants may be IMBHs.

IV. RESULTS

We analyze the O2 candidates with $M_\text{lab}^T > 55 \, M_\odot$ and report candidates with $p_\text{S} \geq 0.2$ in Table III. The $\hat{\pi}_S$ and $\hat{\pi}_G$ values utilized for each time-frame are reported in Appendix D. By imposing a $p_\text{S}$ threshold of 0.5, we present 13 candidate gravitational wave events.

Various search pipeline $p_\text{astro}$ are not mathematically equivalent [113]. Moreover, $p_\text{astro}$ is not equivalent to $p_\text{S}$. However, by comparing candidates’ various $p_\text{astro}$ values with $p_\text{S}$, we can compare how significant each pipeline deems the candidate. For comparison, in Table III we report $p_\text{astro}$ values from GWTC-1 [74], PyCBC OGC-2 [84], PyCBC OGC-3 [84], PyCBC ‘single-search’ [83], IAS [86, 87], and Pratten and Vecchio [73]’s analyses.

A. GWTC-1 Events

All the confirmed gravitational-wave events from binary black hole mergers reported in GWTC-1 and within our prior space (specifically GW170104, GW170508, GW170729, GW170809, and GW170814) have $p_\text{S} > 0.9$, indicating a high probability of an astrophysical signal.

In addition to the above confirmed gravitational-wave events from GWTC-1, we have also analyzed several candidate events from GWTC-1, most of which have low $p_\text{S}$. For example, consider the candidate event 170412 ($t_c = 1176047817$), assigned a $p_\text{astro}$ of 0.06 by GstLAL and has a $p_\text{S}$ of 0.01. This candidate was reported to be excess power caused due to noise appearing non-stationary between 60 – 200 Hz [74]. This candidate demonstrates that $p_\text{S}$ may be utilized to eliminate candidates originating from terrestrial noise sources.

B. IAS Events

Our analysis of the IAS events and candidates with $M_\text{lab}^T > 55 \, M_\odot$ in O2 has resulted in one event with disfavored $p_\text{S} < 0.5$ (GW170425), and five events and two candidates with $p_\text{S} \geq 0.5$ (GW170121, GW170304, 170302, GWC170402, GW170403, GW170727, GW170817A). From this list, four events (GW170121, GW170304, GW170727, GW170817A) have $p_\text{S} > 0.8$ and $p_\text{astro} > 0.9$ reported from other pipelines, making them viable gravitational-wave event candidates.

GWC170402, detected by Zackay et al. [87], is reported to originate from a binary with non-zero eccentricity [87]. As we used a non-eccentric waveform during analysis, we may be under estimating this event’s significance at $p_\text{S} \leq 0.6$. Finally, GW170425 which has $p_\text{S} < 0.25$ also has low $p_\text{astro}$ reported in OGC-2 and OGC-3 [84, 114], suggesting that GW170425 may have been false alarm.

C. New Candidate Events

Although no IMBH detections are made with the $p_\text{BCR}$, a marginal stellar mass black hole merger candidate 170222 has been discovered with a $p_\text{S} \sim 0.6$. This candidate has a SNR $\sim 7.7$, low spin magnitudes, and source-frame component masses of $(47.16^{+8.00}_{-5.77} \pm 35.50^{+5.79}_{-6.35})M_\odot$ (90% credible intervals), making it one of the heavier black-hole mergers from O2 and GWTC-1. This candidate may be of interest as one component black hole may lie in the pair-instability mass gap $(55^{+10}_{-10} \sim 148^{+13}_{-18})M_\odot$ [115, 116]. More details on the candidate are presented in Appendix E. The remaining coherent trigger candidates all have $p_\text{S} < 0.5$, making them unlikely to originate from astrophysical sources.
TABLE III. $p_S$ table for gravitational wave events and candidates in our search space with $p_S > 0.2$, calculated using Hanford and Livingston observatory data. Displayed for comparison are significances of events taken from: GstLAL $p_{\text{astro}}$ [74], PyCBC $p_{\text{astro}}$ [74], IAS $p_{\text{astro}}$ [86, 87], $P(S|d)$ [73], PyCBC ‘single-search’ $p_{\text{astro}}$ [83], PyCBC OGC-2 $p_{\text{astro}}$ [84] and PyCBC OGC-3 $p_{\text{astro}}$ [84]. The $t_c$ column contains the ‘GPS’ coalescence-times of the gravitational wave events. The catalog column displays the first catalog reporting the event on each row (the catalogs labeled IAS-1 and IAS-2 correspond to the candidates published in Venemadhat et al. [86] and Zackay et al. [87]).

| Event     | Catalog | $p_S$ | p_{pyCBC} | p_{GstLAL} | p_{IAS} | P(S|d) | $P(S|d)_{OGC2}$ | $P(S|d)_{OGC3}$ | $t_c$ |
|-----------|---------|-------|------------|------------|---------|-------|----------------|----------------|------|
| GW170104  | GWTC-1  | 0.97  | 1.00       | 1.00       | 1.00    | 1.00  |               |                | 1167559936.60 |
| GW170121  | IAS-1   | 0.83  | 1.00       | 1.00       | 1.00    | 1.00  |               |                | 1159069154.57 |
| 170209    | -       | 0.32  |            |            |         |       |               |                | 1170659643.47 |
| 170222    | -       | 0.58  |            |            |         |       |               |                | 1171814476.97 |
| 170302    | IAS-1   | 0.78  | 0.45       |            |         |       |               |                | 1172487817.48 |
| GW170304  | IAS-1   | 0.94  | 0.99       | 0.03       | 0.70    | 0.70  |               |                | 1172680691.36 |
| GW170402  | IAS-2   | 0.60  | 0.68       | 0.00       |         |       |               |                | 1175205128.57 |
| GW170403  | IAS-1   | 0.54  | 0.56       | 0.27       | 0.03    | 0.71  |               |                | 1175295989.22 |
| 170421    | -       | 0.27  |            |            |         |       |               |                | 1176789158.14 |

V. CONCLUSION

In this paper, we demonstrate that the Bayesian Coherence Odds-Ratio $\rho_{\text{BCR}}$ [70] can be used as a ranking statistic to provide a measure of significance for gravitational-wave signals originating from CBCs with lab-frame total masses between 55 $M_\odot$ and 400 $M_\odot$, a range that includes IMBHs. To compute the $\rho_{\text{BCR}}$ for candidates, we utilize Bayesian inference to calculate the probability of data under various hypotheses (the hypotheses that the data contains a coherent signal, just noise, or an incoherent glitch). This Bayesian ranking method takes a step towards building a unified Bayesian framework that provides a measure of significance for candidates and estimates their parameters, utilizing the same level of physical information incorporated during detected parameter estimation studies.

In our study, we analyze O2 binary-black hole events and candidates with $M_{\text{lab}} > 55 M_\odot$ reported by the PyCBC search [84], the IAS-team [86, 87] and those reported in GWTC-1 [74]. Using a $p_S$ threshold of 0.5, we find that the GWTC-1 events have high probabilities of originating from an astrophysical source. We also find that some of the GWTC-1 marginal triggers that have corroborated terrestrial sources (for example, candidate 170412) have low $p_S$, indicating this method’s ability to discriminate between terrestrial artifacts and astrophysical signals. Our analysis of the IAS events demonstrates that GW170121, GW170304, GW170727, and GW170817A are likely to originate from astrophysical sources ($p_S > 0.8$), while GW170425 is not ($p_S < 0.25$). Finally, we report a new marginal binary-black hole merger candidate, 170222.

With the rapid rate of development in gravitational-wave Bayesian inference, we anticipate the ability to analyze longer-duration signals, utilize more advanced signal and glitch models, and incorporate data from the entire detector network. In a similar vein, with the accumulation of more gravitational wave events, future $\rho_{\text{BCR}}$ work may utilize astrophysically informed priors during Bayesian inference and more accurate prior odds for each detector.

ACKNOWLEDGMENTS

The authors gratefully thank the PyCBC team for providing the gravitational-wave foreground, background, and simulated triggers from PyCBC’s search of O2’s data. We also warmly thank Ian Harry and Thomas Dent for answering questions about the PyCBC search’s data products.
We gratefully acknowledge the computational resources provided by the LIGO Laboratory—Caltech Computing Cluster and supported by NSF grants PHY-0757058 and PHY-0823459, and thank Stuart Anderson for his assistance in resource scheduling.

All analyses (inclusive of test and failed analyses) performed for this study used 1.3M core-hours, amounting to a carbon footprint of $\sim 167$ t of CO$_2$ (using the U.S. average electricity source emissions of 0.429 kg/kWh [117] and 0.3 kWh for each CPU).

This work is supported by the Australian Research Council (ARC) Centre of Excellence CE170100004. This material is based upon work supported by NSF’s LIGO Laboratory, the LIGO Scientific Collaboration, and the Virgo Collaboration. The U.S. National Science Foundation funds LIGO. Virgo is funded by the French Centre National de Recherche Scientifique (CNRS), the Italian Istituto Nazionale della Fisica Nucleare (INFN), and the Dutch Nikhef, with contributions by Polish and Hungarian institutes.

Appendix A: Bayesian Evidence Evaluation

1. Noise Model

We assume that each detector’s noise is Gaussian and stationary over the period being analyzed [107]. In practice, we assume that the noise has a mean of zero that the noise variance $\sigma^2$ is proportional to the noise power spectral density (PSD) $P(f)$ of the data. Using the $P(f)$, for each frequency-domain data segment $d_i$ in each of the $i$ detectors in a network of $D$ detectors, we can write

$$Z_i^N = \mathcal{N}(d_i|\mu = 0, \sigma^2 = P(f)), \quad (A1)$$

where $\mathcal{N}$ is a normal distribution.

2. Coherent Signal Model

We model coherent signals using a binary black hole waveform template $\mu(\vec{\theta})$, where the vector $\vec{\theta}$ contains a point in the 11-dimensional space describing aligned-spin binary-black hole mergers. For the signal to be coherent, $\vec{\theta}$ must be consistent in each 4-second data segment $d_i$ for a network of $D$ detectors. Hence, the coherent signal evidence is calculated as

$$Z_i^S = \int_\vec{\theta} \prod_{i=1}^{D} \left[ \mathcal{L}(d_i|\mu(\vec{\theta})) \right] \pi(\vec{\theta}|H_S) \, d\vec{\theta}, \quad (A2)$$

where $\pi(\vec{\theta}|H_S)$ is the prior for the parameters in the coherent signal hypothesis $H_S$, and $\mathcal{L}(d_i|\mu(\vec{\theta}))$ is the likelihood for the coherent signal hypothesis that depends on the gravitational-wave template $\mu(\vec{\theta})$ and its parameters $\vec{\theta}$.

3. Incoherent Glitch Model

Finally, as glitches are challenging to model and poorly understood, we follow Veitch and Vecchio [68] and utilize a surrogate model for glitches. The glitches are modeled using gravitational-wave templates $\mu(\vec{\theta})$ with uncorrelated parameters amongst the different detectors such that $\vec{\theta}_i \neq \vec{\theta}_j$ for two detectors $i$ and $j$ [68]. Modeling glitches with $\mu(\vec{\theta})$ captures the worst-case scenario: when glitches are identical to gravitational-wave signals (excluding coherent signals). Thus, we can write $Z_i^G$ as

$$Z_i^G = \int_\vec{\theta} \mathcal{L}(d_i|\mu(\vec{\theta})) \pi(\vec{\theta}|H_G) \, d\vec{\theta}, \quad (A3)$$

where $\pi(\vec{\theta}|H_G)$ is the prior for the parameters in the incoherent glitch hypothesis $H_G$.

Appendix B: Tuning the prior-odds

After calculating the $\rho_{BCR}$ for a set of background triggers and simulated triggers from as stretch of detector-data (a data chunk), we can compute probability distributions for the background and simulated triggers, $p_b(\rho_{BCR})$ and $p_s(\rho_{BCR})$. We expect the background trigger and simulated signal $\rho_{BCR}$ values to favor the incoherent glitch and the coherent signal hypothesis, respectively. Ideally, these distributions representing two unique populations should be distinctly separate and have no overlap in their $\rho_{BCR}$ values. The prior odds parameters $\hat{\pi}^S$ and $\hat{\pi}^G$ from Eq. 1 help separate the two distributions. Altering $\hat{\pi}^S$ translates the $\rho_{BCR}$ probability distributions while adjusting $\hat{\pi}^G$ spreads the distributions (refer to Appendix A of Isi et al. [70]). Although Bayesian hyper-parameter estimation can determine the optimal values for $\hat{\pi}^S$ and $\hat{\pi}^G$, an easier approach is to adjust the parameters for each data chunk’s $\rho_{BCR}$ distribution. In this study, we tune $\hat{\pi}^S$ and $\hat{\pi}^G$ to maximally separate the $\rho_{BCR}$ distributions for the background and simulated triggers.

To calculate the separation between $p_b(\rho_{BCR})$ and $p_s(\rho_{BCR})$, we use the Kullback–Leibler divergence (KL
The $D_{K,L}$ = 0 when the distributions are identical and increases as the asymmetry between the distributions increases.

We limit our search for the maximum KL-divergence in the $\hat{\pi}^S$ and $\hat{\pi}^G$ ranges of $[10^{-10}, 10^0]$. We set our values for $\hat{\pi}^S$ and $\hat{\pi}^G$ to those which provide the highest KL-divergence and calculate the $\rho_{BCR}$ for candidate events present in this data chunk. Note that we conduct the analysis in data chunks of a few days rather than an entire data set of a few months as the background may be different at different points of the entire data set.

**Appendix C: Marginalizing over PSD statistical uncertainties**

To generate the results presented in Table III, we applied a post-processing step to marginalize the uncertainty in the PSD. In Fig. 2, we demonstrate the impact of the post-processing step. Marginalizing over uncertainty in the PSD yields an improvement in the separation of the noise and signal distributions (left plot). Quantitatively, at a threshold $\rho_{BCR}^T = 0$ the post-processing step results in a reduction in the number of background $\rho_{BCR} > \rho_{BCR}^T$ from 60.7% to 25.28% in the August 13 - 21, 2017 time-frame of data. For the entirety of O2, PSD marginalization resulted in a 49.26% improvement in search efficiency.

**Appendix D: Tuned prior odds**

O2 lasted several months, over which the detector’s sensitivity varied. Hence, a part of our analysis entailed tuning the prior odds for obtaining a signal and a glitch, $\hat{\pi}^S$ and $\hat{\pi}^G$, as described in Section II. Table IV presents the signal and glitch prior odds utilized for each time-frame of O2 data.

Tuning the prior odds can dramatically affect the $p_S$. For example, consider Table V, which reports tuned $p_S$ and un-tuned $p'_S$ (where $\hat{\pi}^S = 1$ and $\hat{\pi}^G = 1$) for various events and candidates. By tuning the prior odds, the $p_S$ for some IAS events (for example, GW170403 and GW170817A) can change by more than 0.5, resulting in the promotion/demotion of a candidate’s significance.

**Appendix E: A closer look at 170222**

PyCBC found the candidate 170222 with $M_c = 49.46$ and $q = 0.68$, values contained inside the 90% credible intervals of our posterior probability distributions for TABLE IV. The prior odds used for each time-frame of data from O2. Each time frame commences at the start date and concludes at the following time-frame’s start date.

| Start Date | $\hat{\pi}^S$ | $\hat{\pi}^G$ |
