The turbulent mean-velocity profile: it is all in the spectrum

(Dated: September 15, 2009)

It has long been surmised that the mean-velocity profile (MVP) of a pipe flow is closely related to the spectrum of turbulent energy. Here we perform a spectral analysis to identify the eddies that dominate the production of shear stress via momentum transfer. This analysis allows us to express the MVP as a functional of the spectrum. Each part of the MVP relates to a specific spectral range: the buffer layer to the dissipative range, the log layer to the inertial range, and the wake to the energetic range. The parameters of the spectrum set the thickness of the viscous layer, the amplitude of the buffer layer, and the amplitude of the wake.

Although most flows in nature and technology are turbulent flows over confining walls, these flows have remained amongst the least understood phenomena of classical physics [1]. Take the simplest example (an example whose applications are legion): the turbulent flow in a long cylindrical pipe with a cross section of radius $R$ and a smooth internal wall. If the flux is kept steady, the velocity of the flow at a distance $y$ from the wall of the pipe may be averaged over a long period of time to obtain a mean velocity $u$. The function $u(y)$ is called the mean-velocity profile (MVP), and there is a MVP for each value of the Reynolds number, $Re \equiv UR/\nu$, where $U$ is the mean velocity of the flow (i.e., the flux divided by the cross-sectional area of the pipe) and $\nu$ is the kinematic viscosity of the fluid [2,3]. (Re quantifies the relative importance of inertia and viscosity in the flow; the higher the Re, the more turbulent the flow.) MVPs were first measured 70 years ago [4] and have recently been the subject of exacting experiments [5] and numerous computational simulations [6,7]. Theory has meanwhile lagged well behind experiments and simulations.

The first theory came soon after the earliest experiments. Ludwig Prandtl showed that when plotted in terms of the dimensionless “wall variables” $\tilde{u}$ and $\tilde{y}$, the MVPs for different values of Re collapse into a single MVP close to the wall (Fig. 1). The wall variables are defined by $\tilde{u} \equiv u/\sqrt{\nu/\rho}$ and $\tilde{y} \equiv (\sqrt{\nu/\rho})/\nu$, where $\rho$ is the density of the fluid and $\nu$ is the shear stress—or shear force per unit area—that develops between the flow and the wall of the pipe. Prandtl also showed that over most of its domain $\tilde{u}(\tilde{y})$ follows the “log law of the wall,”

$$\tilde{u}(\tilde{y}) = -\frac{1}{\kappa} \ln \tilde{y} + B,$$

where $\kappa$ (the “Kármán constant”) and $B$ are dimensionless constants which can be estimated by fitting experimental data [8].

Numerous variants of the log law of the wall have been proposed since the time of Prandtl, and recently it has been argued that the MVPs for different values of Re might not be logarithmic after all. Instead, they might be power laws with Re-dependent exponents and a logarithmic envelope [9]. Yet the original theory of Prandtl and this recent theory of Barenblatt have been predicated on dimensional analysis and similarity assumptions (they differ in the similarity assumptions [3]), without reference to the turbulent spectrum. As a result, these theories cannot be used to relate, for example, the log law of the wall or the constants thereof to the turbulent spectrum. (The turbulent spectrum may be said to embody the eddies of different sizes in the flow.) Our aim here is to find the missing link between the MVP and the spectrum of turbulent energy. Here we perform a spectral analysis to identify the eddies that dominate the production of shear stress via momentum transfer. This analysis allows us to express the MVP as a functional of the spectrum. Each part of the MVP relates to a specific spectral range: the buffer layer to the dissipative range, the log layer to the inertial range, and the wake to the energetic range. The parameters of the spectrum set the thickness of the viscous layer, the amplitude of the buffer layer, and the amplitude of the wake.

FIG. 1: Log-linear plots of the MVPs in the “wall variables” $\tilde{u}$ and $\tilde{y}$ for four values of Re. The symbols are from experiments [9] and the solid lines from simulations [7]. Each MVP extends from the wall (which corresponds always to $\tilde{y} = 0$) to the centerline of the pipe (which corresponds to a value of $\tilde{y}$ that depends on Re); the MVPs collapse on a single MVP close to the wall. Focusing on any one MVP, we can parse the horizontal axis from left to right to find the “viscous layer” (where the MVP has a positive curvature), the “buffer layer” (where the MVP has a noticeable negative curvature), the “log layer” (where the MVP follows the log law of the wall [4]), and a “wake” (where the MVP overshoots the log law of the wall close to the centerline of the pipe) [9].
We adopt the phenomenological imagery of “turbulent eddies” and use the spectrum of turbulent energy at the wavenumber $k$, $E(k)$, to determine the velocity of the eddies of size $s$, $v_s$, in the form $v_s^2 = \int_{s}^{\infty} E(k)dk$, where $E(k) = 2/\pi \xi_k^{3/2} k^{-5/3} c_d(\eta k) c_e(Rk)$. Here $\kappa$ is a dimensionless parameter, $\varepsilon$ is the turbulent power per unit mass $\kappa_e \approx \rho^{3/4} \varepsilon^{-1/4}$ is the viscous lengthscale $\kappa$, $R$ is the largest lengthscale in the flow, $\sqrt{(\kappa_\infty \varepsilon)^{3/2} k^{-5/3}}$ is the Kolmogorov spectrum $\chi_\infty \chi_\infty$, and $c_d$ and $c_e$ are dimensionless correction functions—the dissipative-range correction and the energetic-range correction, respectively. For the dissipative-range correction we adopt the usual exponential form, $c_d(\eta k) = \exp(-\beta_d \eta k)$, and for the energetic-range correction the form proposed by Kármán, $c_e(Rk) = (1 + \beta_e (Rk)^{-2})^{-17/6}$, where $\beta_d$ and $\beta_e$ are non-negative dimensionless parameters $\chi_\infty$.

By introducing the dimensionless variable $\xi \equiv \kappa s$, we can write $v_s = (\kappa_\infty \varepsilon s)^{1/3} \sqrt{\pi}$, where $I = \int_{s}^{\infty} I(\eta k/s/R) = 1/2 \int_{1}^{\infty} \xi^{-5/3} \exp(-\xi \beta_d \eta k/s) (1 + \beta_e (s/R)^{2} / \xi)^{-17/6} d\xi$. For $s$ in the inertial range ($\eta \ll s \ll \mathcal{R}$), $I = 1$, and therefore $v_s = (\kappa_\infty \varepsilon s)^{1/3}$, with the implication that the velocity of an eddy of the inertial range (i.e., an eddy of size $\eta \ll s \ll \mathcal{R}$) increases with the size of the eddy. The same result, $v_s = (\kappa_\infty \varepsilon s)^{1/3}$, may be derived from Kolmogorov’s four-fifth law, which also gives the estimate $\kappa_\infty = 4/5 \chi_\infty$. For $s$ outside the inertial range, $I < 1$. It follows that an eddy of the dissipative range or the energetic range (i.e., an eddy of size $s \approx \eta$ or $s \approx \mathcal{R}$, respectively) has a velocity $v_s < (\kappa_\infty \varepsilon s)^{1/3}$—i.e., the eddy is slower than an imaginary eddy of the same size in the inertial range.

Consider now the flow in a smooth-walled pipe. The energy equation gives and expression for $\varepsilon$ in the form $\varepsilon = \tau_1 u'/\rho$, where $\tau_1$ is the turbulent shear stress, $u'$ is the velocity of the eddies, $\varepsilon$ is the distance to the wall $\chi_\infty$. The sum of the turbulent shear stress $\tau_1$ and the viscous shear stress $\nu u'$ is the total shear stress $\tau$, which in a pipe of radius $R$ is given by $\tau = \tau_0 (1 - y/R)$, where $\tau_0$ is the shear stress at the wall $\chi_\infty$. Using the definition of the friction factor, $f \equiv \tau_0 / \rho U^2$, we can write $\tau_0 = \rho f U^2 \chi_\infty$; it follows that

$$\varepsilon = f U^2 (1 - y/R) u' - \nu u'^2. \quad (3)$$

We now seek to derive an expression for the turbulent shear stress $\tau_1$. Let us call $W_y$ the wetted surface at a distance $y$ from the wall of the pipe (Fig.2). The turbulent shear stress that acts on $W_y$ is produced by eddies that straddle $W_y$ and transfer momentum across $W_y$ (Fig.2). Thus an eddy of size $s$ carries fluid of high horizontal momentum per unit volume (about $\rho(u(y+s/2))$) downward across $W_y$ and fluid of low horizontal momentum per unit volume (about $\rho(u(y-s/2))$) upwards across $W_y$, and the eddy may be said to span a momentum contrast $\rho(u(y+s/2) - u(y+s/2)) \approx \rho \varepsilon u'(y)$ $\chi_\infty$. The rate of momentum transfer across $W_y$ is set by the velocity of the eddy, $v_s$ (i.e., the velocity normal to $W_y$). Therefore, the turbulent shear stress produced by an eddy of size $s$ scales as the product of the momentum contrast times the rate of momentum transfer, or $\rho \varepsilon u'(y) v_s$.

In order to identify the dominant eddies that straddle $W_y$ (i.e., the eddies that dominate the momentum transfer across $W_y$), recall that $v_s$ (and therefore $s v_s$) increases with $s$. It follows that the larger the eddy the larger the turbulent shear stress produced by the eddy. Nonetheless, eddies much larger than $y$ do not properly straddle $W_y$ and can provide only a negligible velocity normal to $W_y$, and therefore a negligible turbulent shear stress. (This observation is purely a matter of geometry.) We conclude that the dominant eddies that straddle $W_y$ are the eddies of size $s = y$. The turbulent shear stress at a distance $y$ from the wall is thus given by $\tau_1 = \kappa_{\tau} \rho y v_y u'(y)$, where $\kappa_{\tau}$ is a dimensionless proportionality constant.

We are now ready to obtain an equation for the MVP. We substitute (3) in $v_y = (\kappa_\infty \varepsilon y)^{1/3} \sqrt{\pi}$, substitute the resulting expression for $v_y$, $\nu v_y u'$, and substitute the resulting expression for $\tau_1$ in (2). After some algebra, we write the final result in terms of $Re = U R / \nu$ and the dimensionless variables $\hat{y} \equiv y/R$ and $\hat{u} \equiv u/U$:

$$\kappa^2 \nu^2 \hat{y}^2 u'^2 + Re^{-1} \hat{u}' - f(1 - \hat{y}) = 0, \quad (4)$$

where $\kappa = (\kappa_{\tau} \nu^2)^{1/4}$, $\hat{u}' = \varepsilon \hat{u}' / \nu \hat{y}$ and $I = \int (\eta / \hat{y})$. To obtain an equation for $\eta / \hat{y}$ we substitute (3) in $\eta = \nu^{3/4} \varepsilon^{-1/4}$ and change variables to $\hat{y}$ and $\hat{u}$:

$$\eta / \hat{y} = Re^{-1/2} (f Re \hat{u}' (1 - \hat{y}) - \hat{u}'^2) \hat{y}^{-1/4} \hat{y}^{-1}. \quad (5)$$

If for a fixed $Re$ we let $\hat{y} \rightarrow 0$, then $\eta / \hat{y} \rightarrow \infty$ (from (5)), $I \rightarrow \int (\infty, \hat{y}) = 0$, and (4) simplifies to $\hat{u}' = f Re$, which is the law of the viscous layer. If for a fixed $\hat{y} \rightarrow 1$ we let $Re \rightarrow \infty$, then $\eta / \hat{y} \rightarrow 0$ (from (5)), $I$ is in the inertial range (where $I = 1$), and (4) simplifies to $\hat{u}' = \sqrt{\hat{y}} / \kappa \hat{y}$, which we recognize as the log-law of the

![FIG. 2: Schematic for the derivation of the turbulent shear stress. $u(y+s/2)$ is the mean velocity at a distance $y+s/2$ from the wall; $u(y-s/2)$ is the mean velocity at a distance $y-s/2$ from the wall.](image-url)
wall with a Kármán constant \( \kappa = (\kappa_e \kappa_r^3)^{1/4} \). Note that the log law of the wall prevails where \( \tilde{y} \) is in the inertial range; it follows that the dominant eddies in the log layer are eddies of the inertial range. The presence of \( \kappa_e \) and \( \kappa_r \) in the expression, \( \kappa = (\kappa_e \kappa_r^3)^{1/4} \), reminds us of the underpinnings of the theory: the spectrum and the momentum transfer, respectively. As \( \kappa_e \) is fixed by Kolmogorov’s four-fifth law, which gives \( \kappa_e = 4/5 \) \cite{19}, the Kármán constant \( \kappa \) is but an alternative form of the momentum-transfer constant \( \kappa_r \). From \( \kappa_r = 0.42 \) (the experimental value \[5\]), we have \( \kappa = 0.34 \).

The law of the viscous layer and the the log law of the wall may be made invariant to changes in \( \text{Re} \) and \( f \), in the form \( \tilde{u}' = 1 \) and \( \tilde{u}' = 1/\kappa \tilde{y} \), by choosing \( \tilde{y} \equiv 
 \text{Re}\sqrt{\text{f}} \tilde{y} = \text{Re} \sqrt{\text{f}} y/R \) and \( \tilde{u} \equiv \tilde{u}/\sqrt{\text{f}} = u/U \sqrt{\text{f}} \), which we recognize as the wall variables. In the wall variables \[4\] becomes

\[
\kappa^2 f^2 \tilde{y}^3 \tilde{u}'^2 + \tilde{u}' - (1 - \tilde{y}/\text{Re}\sqrt{\text{f}}) = 0, \tag{6}
\]

where \( I \equiv I(\eta/y, \tilde{y}/\text{Re}\sqrt{\text{f}}) \), and \[5\] becomes

\[
\eta/y = (\tilde{u}'(1 - \tilde{y}/\text{Re}\sqrt{\text{f}}) - \tilde{u}'^2)^{-1/4} \tilde{y}^{-1}. \tag{7}
\]

From these equations it is apparent that in the wall variables there is a single MVP except close to the centerline of the pipe, where \( \tilde{y} \approx \text{Re}\sqrt{\text{f}} \) (or \( y \approx R \)).

We now ascertain under what conditions \[6\] and \[7\] are compatible with a nonvanishing turbulent shear stress close to the wall. Suppose that at a point \( \tilde{y} \ll \text{Re}\sqrt{\text{f}} \) (or \( y \ll R \)) we have \( I = I(\eta/y, 0) > 0 \), and therefore \( \tau_i > 0 \). Then, we can eliminate \( \tilde{u}' \) from \[6\] and \[7\] to obtain

\[
\tilde{u}' = \left( \frac{(\eta/y)^{4/3} + \kappa^{4/3} I^2(\eta/y, 0)}{\kappa^{2/3}(\eta/y)^{4/3} I(\eta/y, 0)} \right)^{1/2}. \tag{8}
\]

Plots of \( \tilde{y} \) vs. \( \eta/y \) (Fig. 3) reveal that for any given \( \kappa \) and \( \beta_d \) there exists a minimum value of \( \tilde{y} \), to be denoted \( \tilde{y}_v \). Therefore, for \( \tilde{y} < \tilde{y}_v \) it must be that \( I = 0 \), \( \tau_i = 0 \), and \( \tilde{u}' = 1 \). As this latter equation is the law of the viscous layer, we identify \( \tilde{y}_v \) with the thickness of the viscous layer \[8\]. Note that \( \tilde{y}_v \) depends on the dissipative-range parameter \( \beta_d \) (Fig. 3), and that for \( \beta_d = 0 \) there is no viscous layer (\( \tilde{y}_v = 0 \)).

We are now ready to compute the MVP. For simplicity we use the Blasius relation for the friction factor, \( f = 0.033 \text{Re}^{-1/4} \) \[9\]. Values of the spectral parameters \( \beta_d \) and \( \beta_e \) from the fitting of spectra are of \( \text{O}(1) \) \[10\]; here we use \( \beta_d = 1 \) and \( \beta_e = 4 \). The thickness of the viscous layer is set by \( \beta_d \) and \( \kappa \); for \( \beta_d = 1 \) and \( \kappa = 0.42 \), \( \tilde{y}_v = 3.9 \) (Fig. 3b). Therefore, for \( \tilde{y} < 3.9 \) we can write \( \tilde{u}(\tilde{y}) = \tilde{y} \), and for \( \tilde{y} > 3.9 \) we must compute \( \tilde{u}(\tilde{y}) \) by integrating \[9\] with boundary condition \( \tilde{u}(3.9) = 3.9 \). The results are shown in Fig. 4a. Given the spectrum, the theory yields the entire MVP with all of its distinctive features. The specific connection between each one of these features and the spectrum will become apparent in what follows.

To elucidate the effect of the energetic-range correction, we recompute the MVP using \( \beta_d = 7 \) (a larger value than before) and \( \beta_e = 0 \) (the smallest possible value, which corresponds to having no energetic-range correction). The results (Fig. 4a) indicate that the energetic-range correction steepens the MVP in the wake. The dominant eddies in the wake must therefore be eddies of the energetic range. These eddies are slowed down by the energetic-range correction (and made less adept at transferring momentum). This effect explains the steepening of the MVP in the wake.

We have seen that the dissipative-range correction sets the thickness of the viscous layer (Fig. 3a). To understand the effects of the dissipative-range correction, we recompute the MVP using a few values of \( \beta_d \), including \( \beta_d = 0 \) (the smallest possible value, which corresponds to having no dissipative-range correction). The results (Fig. 4b) indicate that the dissipative-range correction causes the buffer layer to form, so that for \( \beta_d = 0 \) there is no buffer layer. (The buffer layer is the part of the MVP where the MVP has a negative curvature \[3\].) The dominant eddies in the buffer layer must therefore be eddies of the dissipative range. These eddies are slowed down by the dissipative-range correction; the larger the eddies, the less they are slowed down, and the more adept they remain at transferring momentum. As the size of the dominant eddies increases with the distance to the wall, the MVP becomes less steep as we traverse the buffer layer from the outer edge of the viscous layer to the inner edge of the log layer (where the eddies are fully inertial). This effect explains the negative curvature of the MVP in the buffer layer.

It is apparent from Fig. 4b that the constant \( B \) of the log law of the wall is set by \( \beta_d \). A plot of \( B \) as a function of \( \beta_d \) is shown in Fig. 4b.

Interestingly, the MVP for \( \beta_d = 0 \) (no dissipative-range correction) can be obtained analytically everywhere save the wake. In fact, for \( \beta_d = 0 \) and \( \tilde{y} \ll \text{Re}\sqrt{\text{f}} \) (or \( y \ll R \)), \( I = 1 \) and \[10\] simplifies to \( \kappa^2 \tilde{y}^3 \tilde{u}'^2 + \tilde{u}' - 1 = 0 \), which

\[
\text{FIG. 3: (a) Plots of (8) for } \kappa = 0.42 \text{ and three values of } \beta_d. \quad \text{(b) Plots of the thickness of the viscous layer } \tilde{y}_v \text{ as a function of } \beta_d \text{ for three values of } \kappa.}
\]

\[\text{FIG. 4: (a) Plots of (8) for } \kappa = 0.42 \text{ and three values of } \beta_d. \quad \text{(b) Plots of the thickness of the viscous layer } \tilde{y}_v \text{ as a function of } \beta_d \text{ for three values of } \kappa.}
\]
if the Kolmogórov spectrum were valid even for vanishingly small eddies (inset of Fig. 4). For $0 \ll y \ll \text{Re}^{1/4}$ (or $0 \ll y \ll R$), (9) simplifies asymptotically to $\tilde{u} \sim (1/\kappa) \ln \tilde{y} + B$, with $B = (-1 + \ln 4\kappa)/\kappa$. Thus, for $\beta_d = 0$ and $\kappa = 0.42$, $B = -1.15$ in accord with Fig. 4.

We have established the long-surfaced link between the mean velocity profile and the turbulent spectrum. To test our results, we have shown that the usual model of the spectrum (a power-law inertial range with corrections for the dissipative range and the energetic range) is in itself sufficient to compute with no additional assumptions a mean velocity profile complete with viscous layer, buffer layer, log layer, and wake. The thickness of the viscous layer, the two constants of the log law of the wall, and the amplitude of the wake are all set by the mean velocity profile and the turbulent spectrum. To test our results, we have shown that the usual model of the spectrum (a power-law inertial range with corrections for the dissipative range and the energetic range) is in itself sufficient to compute with no additional assumptions a mean velocity profile complete with viscous layer, buffer layer, log layer, and wake. The thickness of the viscous layer, the two constants of the log law of the wall, and the amplitude of the wake are all set by the mean velocity profile and the turbulent spectrum.

log layer are eddies of the inertial range. More broadly, the close relation between the mean velocity profile and the turbulent spectrum indicates that in turbulence, as in continuous phase transitions, global variables are governed by the statistics of the fluctuations.

[15] On the Kolmogórov spectrum and anisotropy, see B. Knight, L. Sirovich, Phys. Rev. Lett. 65, 1356 (1990); T. S. Lundgren, Phys. Fluids 14, 638 (2002); T. S. Lundgren, ibid. 15, 1024 (2003). The view of anisotropy as a perturbation superposed on the isotropic flow (see, e.g., L. Biferale, I. Procaccia, Phys. Rep. 414, 43 (2005)) might break down close to a wall, where the exponents themselves might change, albeit slightly (see M. Casciola, P. Gualtieri, B. Jacob, R. Piva, Phys. Rev. Lett. 95, 024503 (2005)).
[16] The four-fifth law reads $\bar{u}_s^3 = -(4/5) \varepsilon s$, where the left-hand side is the third-order structure function. The estimate $[\bar{u}_s^3] = u_s^3$ leads to $\varepsilon = (5/4) u_s^2 / s$, or $\kappa_s = 4/5$.
[17] We retain only the 1st term of the Taylor series because (a) additional terms would necessitate BCs other than the no-slip BC and (b) in our final solution for $u(y)$ the 2nd term $\leq 11\%$ of the 1st term for all $y$.
[18] Experimental and computational estimates of $\kappa_s$ are invariably of $O(1)$ but differ slightly for different types of...
flow; K. R. Sreenivasan, Phys. Fluids 10, 528 (1998). The implication here is that the Kármán constant may depend mildly on the type of flow.
