Dynamics of vesicle reshaping and scission under osmotic shocks†

Christian Vanhille Campos a,b and Andela Šarić a,b

We study the effects of osmotic shocks on lipid vesicles via coarse-grained molecular dynamics simulations by explicitly considering the solute in the system. We find that depending on their nature (hypo- or hypertonic) such shocks can lead to bursting events or engulfing of external material into inner compartments, among other morphology transformations. We characterize the dynamics of these processes and observe a separation of time scales between the osmotic shock absorption and the shape relaxation. Our work consequently provides an insight into the dynamics of compartmentalization in vesicular systems as a result of osmotic shocks, which can be of interest in the context of early proto-cell development and proto-cell compartmentalisation.

1 Introduction

Lipid membranes are one of the most important building blocks in cellular biology, forming the envelope of the cell and defining the structure and function of intracellular units in eukaryotic cells. Given their physio-chemical properties, biological membranes present very particular reshaping capabilities that are intimately related to the proper functioning of the cellular units they constitute. Cell membrane morphology transformations in nature can occur in a number of different ways, which can also include creating of new units such as budding or division. Budding is the process by which a portion of a membrane detaches, usually in the form of a vesicle that is smaller than the mother membrane. Such processes are ubiquitous in cellular biology, playing important roles in vesicle secretion, protein transport, organelle synthesis and endocytosis11. In the division, a lipid vesicle or a cell splits into two closed units of comparable sizes. In more evolved cells this process is usually specifically driven by a set of proteins (such as actomyosin26, ESCRT-III27 or FtsZ28) composing the divisome machinery, responsible for exerting the required forces on the membrane. However, division of vesicles can also occur in spontaneous ways usually caused by environmental changes (shear stress29, osmotic shocks30,31), compositional changes to the membrane (protein addition32,33) or even motility of nascent cells34.

In this context, vesicles are especially relevant as they represent a typical model system to study membrane reshaping events. Moreover, in the context of early life evolution and proto-cells development in particular, vesicles are thought to have played a crucial role, having evolved towards the existing forms of cellular life by compartmentalizing and developing more complex behaviors as a result35,36. There exist a number of experimental, theoretical and numerical works that examine the connection of distinct vesicle reshaping events to their physio-chemical conditions. Previous experimental efforts have focused on understanding the role of the physical properties (e.g. fluidity37, multiphase domain coexistence38,39) and composition (e.g. protein adsorption at high40 and low41 surface density) of membranes in reshaping Giant Unilamellar Vesicles (GUVs). Other experimental approaches have focused on the effect of osmotic shocks and other external forces (e.g. shear stress42) on vesicle morphology. It is thus known that hypertonic shocks (when the solute concentration is larger outside than inside the vesicle) induce strong deformations on GUVs with varying results depending on the specific composition and chemical properties of the membrane43,44,45. Division can thus occur when osmotic stress is coupled with phase separation in the lipid bilayer46. More important for cell compartmentalization and endocytosis, simple osmotic shocks can also drive inward budding of the membrane coupled with absorption of external medium into the newly created inner compartment47,48. Finally, studies have also shown that hypotonic shocks result in pulsatile dynamics of stretch and release for the vesicle until equilibrium is reached between the two solutions49,50.

Regarding theoretical approaches, most advances came at the end of the 20th century, with the introduction of the Helfrich model of bending free energy51. Subsequently, most experimentally observed vesicles conformations were described by applying free energy minimisation principles focusing primarily on the mem-

imposed, whereas experimentally-observed relaxation dynamics consider where a constant relaxation rate is assumed and implicitly via a volume control algorithm based on equilibrium on vesicles of different kinds. The volume relaxation is imposed to study the effect of volume changes resulting from osmotic shocks. Yuan et al. [31] models à la Helfrich. One exception to these examples, which help in overcoming the limitations presented by the theoretical considerations associated with curvature [22, 23]. These are again successful in predicting most equilibrium shapes, but provide little help in overcoming the limitations presented by the theoretical models à la Helfrich. One exception to these examples, which manages to reproduce budding events, is the approach taken by Yuan et al. [31]. Here, molecular dynamics simulations are used to study the effect of volume changes resulting from osmotic shocks on vesicles of different kinds. The volume relaxation is imposed implicitly via a volume control algorithm based on equilibrium considerations where a constant relaxation rate is assumed and imposed, whereas experimentally-observed relaxation dynamics can be much more involved than that [22, 23]. In the present work we focus on vesicle reshaping as a result of explicit osmotic shocks. In order to overcome limitations posed by the previous methods, where reshaping dynamics and vesicle breakage were inaccessible, we resort to using molecular dynamics simulations of coarse-grained model lipid bilayers under an explicit gradient of solute particles. This approach allows us to characterize the dynamic process leading to the different morphological transformations of vesicles. We find that hypertonic osmotic shocks can result in the engulfment of external material into inner vesicular compartments while hypotonic shocks on the contrary cause vesicle dilation and oscillatory bursting for sufficiently strong concentration differentials. We observe a separation of time scales in the dynamics of the shock absorption and shape transformations, where the vesicle first absorbs shocks by forming many local deformations and transient shapes, before relaxing to an equilibrium shape. Our study provides new insights into the dynamics leading to vesicle deformations and, in particular, vesicle endocytic events as a result of environmental osmotic stresses.

2 Simulation details

In order to study the effect of osmotic shocks on lipid vesicles we carry out coarse-grained (CG) molecular dynamics (MD) simulations where we explicitly consider the solute modeled as CG particles. The system thus consists of a spherical model membrane surrounded by solute particles on the outside at a concentration $\rho_{\text{out}}$ (see purple particles in Fig. 1) and encapsulating inner solute particles at a different concentration $\rho_{\text{in}}$ (see cyan particles in Fig. 1). All particles are volume-excluded spheres of a diameter $\sigma$, $\sigma$ being the MD unit of length, and mass $m = 1$ embedded in cubic box of constant volume $V = L^3$ with $L = 44 \sigma$ and within periodic boundary conditions. See Figure 1 for the snapshots of the system.
The membrane is modelled using the single particle thick model developed by Yuan et al.\(^\text{[32]}\) which is capable of fission and fusion events and reproduces biologically relevant mechanical properties of membranes. The specific parameters of the model are chosen to encode for a membrane of vanishing spontaneous curvature and bending rigidity of \(\epsilon_{\text{mem}}\) for membranes. The specific parameters of the model are chosen to encode for a membrane of vanishing spontaneous curvature and bending rigidity of \(\epsilon_{\text{mem}}\) for membranes.

The system is always initialised in the same way: i) \(N_{\text{mem}} = 4322\) membrane particles define a relaxed spherical vesicle of mean radius \(R \sim 17 \sigma\) at the center of the box and ii) solute particles take random positions on a hexagonal lattice at set concentrations \(\rho_{\text{in}}\) and \(\rho_{\text{out}}\) inside and outside of the vesicle, respectively, ensuring no overlap occurs with the membrane. In this way, the osmotic conditions of the system are fully defined by two parameters only: the outer solute concentration, \(\rho_{\text{out}}\), and the ratio of concentrations \(\nu = \rho_{\text{in}}/\rho_{\text{out}}\). The latter quantity is often referred to as the theoretical reduced volume. Hence, setting \(\nu < 1\) defines hypertonic conditions while \(\nu > 1\) corresponds to hypotonic conditions. We run simulations using the open source molecular dynamics package LAMMPS\(^\text{23}\) with a Langevin thermostat (at reduced temperature \(T = 1\) and damping coefficient of 1) within the \(NVE\) ensemble, \(E\) being the total energy of the system, for \(3 \times 10^5\) time steps, each of size \(0.01\) MD time units (\(\tau_0 = \sqrt{m / \sigma^2 \epsilon}^{-1}\) with \(\epsilon = k_BT\) the MD energy unit).

### 3 Results

#### 3.1 Characterising osmotic shocks

First we make sure that explicitly simulating solute particles in a closed system with a coarse-grained model lipid vesicle properly reproduces osmotic shocks. For this we measure the initial osmotic pressure measured across the vesicle (see Section I in the Supplementary Information\(^\dagger\) for details on this). Figure 2a presents the dependence of the osmotic shock on the two system parameters: the outer particle absolute concentration, \(\rho_{\text{out}}\), and the ratio of concentrations between the vesicle interior and exterior, \(\nu = \rho_{\text{in}}/\rho_{\text{out}}\). Figure 2b shows the fit agreement between the measured osmotic pressure with the expected value of the osmotic pressure, as given by the equation \(\Pi = RT \rho_{\text{out}}(\nu - 1)^2\). Indeed, beyond a transformation factor due to MD units, we find that we are truly applying an osmotic shock to the vesicle and its magnitude scales as expected theoretically.

#### 3.2 Coarse-grained model membranes recover known equilibrium shapes

We are next interested in investigating whether our system is able to reproduce the relaxation transformations observed experimentally on GUVs\(^\text{[13]}\) predicted theoretically\(^\text{[24,25]}\) or simulated by other means\(^\text{[30,31]}\). We thus look at the equilibrium shapes our simulated vesicles present in hypertonic conditions (larger solute concentration outside than inside the vesicle). While the spectrum of shapes and different morphologies lipid vesicles present when subject to hypertonic shocks is vast and not necessarily restricted to a few discrete options, we can nonetheless categorise our results into several distinct kinds of shapes that help analyse the results. Inspired by previous works using similar classifica-
Fig. 3 Final morphology diagram for hypertonic conditions. We distinguish six different characteristic equilibrium shapes of the vesicle, represented to the right of the figure. The resulting observed morphology for each point in the parameter space \( \{\rho_{\text{out}}, \nu\} \) is color coded accordingly. Dotted lines indicate transitions. The cross and star symbols refer to the dynamics curves below (see Figures 4 and 5). Snapshots are framed using the same color code as the diagram on the left. Particle coloring is used to distinguish multiple vesicles in the same system.

A few important conclusions can be taken from Figure 3: 1) We recover the main equilibrium shapes – namely prolates (labeled here as globular or elongated), discocytes and stomatocytes – observed experimentally \([14,15]\), numerically \([30,31]\) and predicted theoretically \([24–26]\).  2) Importantly, we identify a large subset of the parameter space where the osmotic shock leads the vesicle to inner compartmentalization (labeled as Inner bud in the figures), absorbing exclusively external solute particle into a smaller sub-vesicle inside the original one. Such a process is very similar to experimentally-observed endocytic events that could be relevant to how proto-cells first developed compartmentalization as a form of reaction tanks or proto-organelles in the early stages of life evolution \([14,15]\).  3) The dependence of the final morphology proves to be highly non-trivial and does not only depend on the concentrations ratio \( \nu \), which would lead to a diagram consisting only of horizontal lines as equilibrium curvature models predict \([24,25]\) (see Section V in the Supplementary Information). We thus find that assuming an equilibration of the osmotic shock only via volume adaptation, as previously considered, is not sufficient to properly describe shape transformations in vesicles. In order to unveil the underlying process, we now turn to the dynamics of the system and study how the morphological changes of the vesicle (characterized by its shape, surface area and volume) dynamically relate to the relaxation of the osmotic pressure across the membrane.

1. **Burst**: at high outer solute concentration \( \rho_{\text{out}} \) and very low ratio of inner and outer concentrations \( \nu \), the osmotic shock causes the mother vesicle to burst, often yielding several smaller vesicles containing a mixture of both inner and outer solutions.

2. **Inner bud**: for a large subset of the parameter space where the inner to outer concentration ratio is still small \((\nu < 0.5)\), but the shock is not high enough to cause bursting, the membrane develops one or more inner and smaller sub-vesicle(s) engulfing the solute composition of the environment.

3. **Discocyte**: as the solute concentration \( \rho_{\text{out}} \) is decreased or the ratio \( \nu \) is increased the vesicle instead reaches a flat plate-like shape.

4. **Elongated**: as the concentration ratio \( \nu \) is further increased \((\nu \sim 0.6)\), the vesicle transitions to a prolate configuration, closer to an ellipsoid.

5. **Globular**: for moderate values of the concentration ratio \((0.6 \leq \nu \leq 0.75)\) the vesicle is distorted from a normal spherical shape but doesn’t present a clear symmetry break.

6. **Sphere**: at high concentration ratio \((\nu \sim 1)\) the vesicle conserves its sphere-like fluctuating shape independently of the solute concentration \( \rho_{\text{out}} \).
3.3 Surface stretching and volume adaptation are coupled to the shock magnitude

Consistent with previous work,[25,26] we find that, upon osmotic shock, the vesicle deforms by adapting its volume to reduce the pressure on its surface. The previous theoretical work assuming constant surface area and a perfect osmotic term cancellation (see Section V in the Supplementary Information[1]) predicts that the equilibrium shape and its reduced volume, $v_{th}$, will depend solely on the ratio of the solute concentrations on the inner and outer side of the membrane, such that $v_{th} = \rho_{in}/\rho_{out}$. Here the reduced area is defined as the ratio of the equilibrated and initial surface areas, $a_{eq}/A_0$, and analogously the reduced volume as $v_{eq} = V_{eq}/V_0$ (see Sections I and II in the Supplementary Information[1] for more details on the computation of these quantities). However, as shown in Figure 4, we find that the relaxed equilibrium volume does not follow exactly the concentration ratio imposed by the osmotic shock, like theoretical considerations based purely on membrane bending energy and constant surface area would predict.[25,26] The reason behind this discrepancy is the fact that a part of the osmotic shock in our model is absorbed by membrane stretching. This is visible in Figure 4, where it is apparent that a change in volume is associated with the change in the surface area. Note that no change is observed in the vesicle geometry over the initial 100 time steps as this is the time needed for the solute particles to reach the vesicle.

As Figure 4 shows, the actual reduced volume does scale linearly with the theoretically expected one for low values ($v_{th} < 1$) but instead remains always above it and saturates around $v_{th} = 1$. For $v_{th} < 1$, the difference between the expected and observed values overall increases as the solute concentration decreases; for $v_{th} > 1$, instead, $v_{eq}$ does not exactly collapse to one and actually exceeds it. This observation, together with the membrane area change displayed in Fig 4, strongly suggests that a part of the energy provided by the osmotic shock is transformed into area strain, coupling it to the volume evolution in a non-trivial way. This indicates that volume and area relaxation is an intricate process where the equilibrium volume does not only depend on the ratio of inner and outer concentrations ($v_{eq} = v_{th} = \rho_{in}/\rho_{out}$) but rather on the actual magnitude of the osmotic shock.

Membrane stretching is rarely accounted for in theoretical models, which does not allow such models to explore hypotonic conditions. Molecular dynamics simulations can access these conditions as shown by the magenta curves in Figures 4b and 5, corresponding to a Tense sphere: the vesicle maintains its spherical shape but increases its volume via stretching of the membrane. Nevertheless, when assessing the simulation results it is important to consider how the mechanical properties of the simulated membrane compare to those of biologically relevant membranes. In the case simulated here, the compressibility modulus of the membrane is estimated to be around 3 mN/m (assuming a membrane thickness of $\sigma \sim 5$ nm), which is around an order of magnitude lower than, for instance, the three-beads-per-lipid CG lipid membrane model[25] and even further from experimentally measured values for single bilayer vesicles of varying composition (ranging from $\sim 60$ to $\sim 1700$ mN/m).[35,36]

However, the rupture tension (tension beyond which the membrane breaks) that are consistent with the experimental

**Fig. 4** Equilibrium reduced volume and relaxation dynamics of the volume and surface area. (a) Resulting reduced volume $v_{eq}$ after relaxation plotted against the expected value $v_{th} = \rho_{in}/\rho_{out}$. Data points are colored according to the outer particle density $\rho_{out}$ (see legend). The dashed line represents $y = x$ and the dotted line $y = 1$. Each point corresponds to the equilibrium average over 5 independent runs. Error bars are negligible. (b) Reduced surface area $a$ and reduced volume $v$ relaxation curves for three representative cases (see legend). Inner bud: $\rho_{out} = 0.18$ $v = 0.31$. Discocyte: $\rho_{out} = 0.12$ $v = 0.31$. Tense sphere: $\rho_{out} = 0.18$ $v = 1.25$. The simulation time $\tau$ on the x-axis is in logarithmic scale and expressed in time steps. The cross and star symbols refer to the corresponding points on the morphology diagram (see Figure 3).
ones. Indeed, for the model used in this work \( a_c \sim 0.09 \) (very similar to that of the Cooke et al. membrane model) of \( a_c \sim 0.08 \) while experiments have measured typical lipid bilayer vesicles to have a critical area strain of \( a_c \sim 0.02 - 0.05 \). This suggests that our simulations are somewhat overestimating membrane stretching (9\% instead of 5\%) but does not invalidate the role of membrane stretching in the response to osmotic shock. In fact, membrane stretching in response to osmotic shock is known to be crucial for the equilibration of osmotic pressures at the cell interface via mechanosensitive channels in unicellular organisms.

Taken together, the above observations indicate that the absorption of osmotic shocks by volume adaptation is more involved than just a volume equilibration at a constant surface area. Indeed, we find that membrane stretching plays a non-negligible role and absorbs part of the energetic shock. Moreover, the magnitude of the volume change depends on the magnitude of the shock, which in turn is dependent on the solute concentration: for a same concentration ratio, the larger the absolute solute concentration the larger the deformation.

3.4 Osmotic shock adaptation is a two-step process: absorption and dissipation

Next we turn to the dynamics of the relaxation process. We observe that the system displays a striking separation of scales in the relaxation process towards equilibrium (\( \Pi = 0 \)), as visible in Figure 5. This Figure shows the measured osmotic pressure and vesicle volume (see Section I in the Supplementary Information) for three representative cases: i) a hypertonic osmotic shock resulting in an inner sub-vesicle (green line, indicated with a cross on the diagram in Figure 5), ii) a hypertonic shock resulting in a discocyte (purple line, indicated with a star on the diagram in Figure 5) and ii) a hypotonic shock resulting in a tense sphere (pink line).

Taken together, these results show the volume and pressure dynamics are coupled and occur on a much shorter time scale than the shape relaxation, since equilibrium for both \( \Pi \) and \( v \) is reached at times shorter than \( \tau \ll 10^5 \) time steps in all cases. Interestingly, such volume dynamics display striking similarities with the osmotic shock relaxation curves presented in the work by Gabba et al., where the authors have observed an analogous decaying profile in the normalized volume evolution of impermeable vesicles subject to hypertonic osmotic shocks, both in vitro and in a physicochemical kinetic model. The hypotonic scenario resulting in a tense sphere is of particular interest, as it presents an incomplete osmotic pressure relaxation: \( \Pi_{eq} \sim 0.25 \sigma^{-3} \). This is caused by the vesicle reaching its maximal allowed volume (for maximal stretching of the lipid membrane, \( a_c \sim 0.09 \)) before the pressure difference is completely cancelled. However, this remaining osmotic stress is not sufficient to overcome the energy barrier for bursting the vesicle, allowing for the observed mor-
phology. For hypotonic shocks of larger magnitude we observe vesicle bursting instead of the tense sphere morphology. This is a distinct feature of hypotonic scenarios, indicating that vesicles are inherently much better prepared to endure hypertonic shocks.

Tracing the behaviour of the mechanical energy of the vesicle during the relaxation process, measured by the reduced bending free energy $F$ in time (refer to Section III in the Supporting Information for a detailed definition and computation details), allows to gain further insight into the relaxation process (Figure 5). For the discocyte and inner bud scenarios (purple and green curves, respectively), we observe a sharp maximum in the bending energy which is concurrent with the volume equilibrium ($\tau \sim 1.2 \times 10^4$ time steps and $\bar{\tau} \sim 4.8 \times 10^4$ time steps respectively, as shown by the two vertical lines on Figure 5a). This indicates that the osmotic shock absorption induces very strong deformations on the vesicle which are then smoothed out over time as the vesicle relaxes to its minimum energy. Notice that for the green curve in Figure 5b this implies an inward budding event which results in a sudden drop of the energy. For the tense sphere the vesicle does not change its shape and remains spherical throughout the simulation, hence the bending energy fluctuates around $F = 1$. Refer to Supplementary Movies 2a-c for a better visualization of the relaxation process.

In the case of the vesicle that relaxes to the discocyte conformation, the equilibrium value of $F \sim 1.8$ agrees very well with the value previously predicted by the analytical models that consider only vesicle curvature. However for the conditions when the inner bud is formed we observe a three stage evolution: first a large amount of energy is absorbed by developing a very strong deformation (peak of $F \sim 3$), which then relaxes as $F$ equilibrates around $F \sim 2$ by developing a large invagination that is still connected to the parent membrane (free energy value predicted by curvature models for a stomatocyte conformation). Contrary to what curvature models can predict, the vesicle does not remain in this local minimum and instead evolves further towards $F < 1$ by developing an inner compartment as the invagination buds off. This inner bud scenario agrees very well with experimentally observed vesicle budding under osmotic stress. Such transformations are however inaccessible to equilibrium curvature models where vesicles are not allowed to break.

4 Conclusions

In this work we have adopted a novel approach in the study of vesicle osmotic shock adaptation by combining molecular dynamics with a coarse-grained lipid membrane model and explicit solute particles. This allows to overcome some of the limitations of previous works while still recovering the main known features of this physical process.

In particular, here we demonstrate that with this approach we have good control over the magnitude of the osmotic shock and vesicles are subject to, which scales appropriately with solute concentrations inside and outside the lipid body (see Figure 2). Moreover, we show that this method allows to investigate known equilibrium vesicle morphologies and how they relate to the osmotic perturbation. Indeed, not only do we recover the main vesicle morphologies predicted and observed experimentally in previous works but we can also precisely map them to the relevant parameters of the system (see Figure 3).

Furthermore, using MD simulations allows for membrane scission, bursting and budding events, typically inaccessible to other modeling approaches. This enables us to investigate biologically relevant topologies such as the inner bud (or vesicle-inside-vesicle), where the perturbed vesicle develops an inner compartment engulfing external solute to accommodate the osmotic shock. In this work we thus define a subset of the parameter space for which endocytosis happens as a result of osmotic shocks (see Figure 3), possibly an important element of proto-cell development in the early stages of life. Likewise, working with a coarse grained MD model allows to explore hypotonic shocks as well and how these result in tense spheres, with increased surface area.

Another important feature of the approach presented in this work is that it allows to track the dynamics of the relaxation process. While molecular dynamics have already been considered in previous studies of vesicular osmotic response, the present work offers important advantages with respect to these in that the relaxation of the osmotic shock here is purely the result of the molecular interactions while in previous works it was imposed. We thus avoid any assumptions regarding the relaxation dynamics and work with membrane transformations defined only by the imposed osmotic shock. This allows us to dynamically characterize the transformation process by following the evolution of relevant physical magnitudes such as the bending free energy, reduced volume or pressure differential across the lipid bilayer (see Figure 3b). As a result, we find that the vesicle evolution upon osmotic upshift is a two-step process where the membrane first absorbs the shock by deforming away form its spherical shape (volume and surface area changes), which results in a sharp increase of the bending energy, then dissipated by reaching the observed equilibrium morphology. Overall, the dynamic insight thus obtained provides valuable information complementing the shortcomings of classical approaches to the problem. In particular, the observed separation of scales in the dynamics suggests that a fast relaxation rate is best suited for volume-control algorithms.

Possible further applications of the combination of the coarse-grained membrane model with explicit solute particles could be to study multiple encodytic events in fluctuating and heterogeneous environments, which could give rise to complex internal vesicle structures of different compositions. The model is also well suited for studying vesicle bursting cycles observed in hypotonic environments or the different morphologies observed for multiphasic and protein charged vesicles, where the dynamical nature of MD simulations should prove useful.
