The temperature dependent surface relaxation of Ag(111) is calculated by density-functional theory. At a given temperature, the equilibrium geometry is determined by minimizing the Helmholtz free energy within the quasiharmonic approximation. To this end, phonon dispersions all over the Brillouin zone are determined from density-functional perturbation theory. We find that the top layer relaxation of Ag(111) changes from an inward contraction (−0.8%) to an outward expansion (+6.3%) as the temperature increases from $T = 0$ K to 1150 K, in agreement with experimental findings. Also the calculated surface phonon dispersion curves at room temperature are in good agreement with helium scattering measurements. The mechanism driving this surface expansion is analyzed.

I. INTRODUCTION

The equilibrium geometry of a system depends on the temperature due to the anharmonicity of the interatomic potential. The presence of a surface breaks the periodic structure normal to the surface, and anharmonic effects are expected to be larger at the surface than in the bulk $\text{[1]}$. Hence, the surface interlayer separation may change more strongly with temperature than the bulk lattice parameter. Indeed, enhanced anharmonic effects have been observed by recent experiments on several surfaces: Ni(001) $\text{[2]}$, Pb(110) $\text{[3]}$, Cu(110) $\text{[4]}$, Ag(111) $\text{[5]}$, Cu(111) $\text{[6]}$ as well as Be(0001) $\text{[7]}$. Among them, the large thermal expansion observed in the close-packed Ag(111) surface has attracted much attention $\text{[8,9]}$, but at present the interpretation of these results is still controversial.

Using an the embedded-atom method (EAM) in which the parameters of the interatomic potential are determined by fitting bulk properties, Lewis $\text{[8]}$ simulated the thermal behavior of Ag(111) for a large range of temperatures using molecular dynamics. The results for the top layer relaxation differ significantly from those reported by an experimental study $\text{[9]}$: the top interlayer spacing, $d_{12}$, remains smaller than the bulk value even at temperatures as high as 1110 K; while the analysis of experimental results $\text{[9]}$ obtained by the medium energy ion scattering (MEIS), concluded that $d_{12}$ changes from −2.5% contraction to 10.0% expansion as temperature increases from room temperature to 1150 K. Narasimhan and Scheffler $\text{[9]}$ investigated the temperature dependence of $d_{12}$ by minimizing the Helmholtz free energy of the system with respect to $d_{12}$ in a simpli-
tional modes over the BZ for a quantitatively reliable result. The qualitative explanation of the earlier work of Narasimhan and Scheffler [1] is fully confirmed. The disagreement with reported EAM results [10] is argued to due to the approximate nature of EAM and to an incorrect k-point summation in Ref. [10].

II. COMPUTATIONAL DETAILS

To model the surface, we adopt a repeated-slab geometry consisting of seven atomic layers separated by a vacuum region corresponding to five atomic layers. As in a previous treatment [13], the Helmholtz free energy of the slab is given by

$$F\{d\}, T = E\{d\} + F_{\text{vib}}\{d\}, T$$

$$= E\{d\} + k_B T \sum_{q\parallel} \sum_{p=1}^{3N} \ln \left\{ 2 \sinh \left( \frac{\hbar \omega_p(q\parallel,\{d\})}{2k_B T} \right) \right\} , \quad (2.1)$$

where $E$ is the static total energy, as obtained by DFT calculations; $k_B$ and $\hbar$ are the Boltzmann and the Planck constants, and $\{d\}$ represents the set of interlayer distances normal to the surface and the inter-particle distances parallel to the surface. The vibrational free energy is denoted as $F_{\text{vib}}$, and $\omega_p(q\parallel,\{d\})$ is the frequency of the $p$-th mode for a given wave vector $q\parallel$, evaluated at the geometry defined by $\{d\}$; and $N$ is the number of atoms in the slab. The static total energy $E$ in Eq. (2.1) includes all the anharmonic terms of the interatomic potential. The anharmonic nature also appears in the vibrational free energy $F_{\text{vib}}$, since in the quasiharmonic approximation the vibrational frequencies $\omega_p(q\parallel,\{d\})$ are allowed to change with $\{d\}$.

At a given temperature $T$ and zero pressure, the equilibrium geometry is determined by the minimum of the Helmholtz free energy, i.e., $\partial F/\partial d = \partial E/\partial d + \partial F_{\text{vib}}/\partial d = 0$. It is not practical to minimize the Helmholtz free energy with respect to all the lattice parameters $\{d\}$ within the present ab initio approach. We therefore assume here that the vibrational free energy $F_{\text{vib}}$ depends parametrically only on the interlayer distance between the top layers, $d_{12}$. All other interlayer distances and inter-particle distances are assumed to vary with temperature as in the bulk [1]. The equation which determines the temperature dependent equilibrium $d_{12}$, then reads

$$\frac{\partial E(d_{12})}{\partial d_{12}} = - \frac{\partial F_{\text{vib}}}{\partial d_{12}} = - \sum_{q} \sum_{p} \frac{\partial \hbar \omega_p(q)}{\partial d_{12}} n_p(q) , \quad (2.2)$$

where $n_p$ is the occupation number of the $p$-th mode defined by

$$n_p = \frac{1}{2} + \frac{\hbar \omega_p(q) / k_B T - 1}{e^{\hbar \omega_p(q) / k_B T - 1}} . \quad (2.3)$$

The static total energy $E$ is calculated by density-functional theory within the local-density approximation [14]. Fully separable norm-conserving pseudopotentials [15] are used in our calculations together with a plane wave basis set with a kinetic energy cut-off of 55 Ry. BZ integrations are performed with the smearing technique of Ref. [16] using the Hermite-Gauss smearing function of order one, a smearing width $\sigma = 50$ mRy, and a 16-point grid in the irreducible wedge of the BZ. The phonon frequencies of the system are calculated by density-functional perturbation theory [12]. The dynamical matrices are calculated on a 4×4 grid of points in the surface BZ of the 7-layer slab and Fourier interpolated over a 48-point grid of $q_{||}$ vectors in the irreducible wedge of the surface BZ, in order to calculate the vibrational contribution to the free energy.

III. RESULTS

We first calculated the surface relaxation of Ag(111) by minimizing the static total energy and neglecting the vibrational contributions. The obtained results are: $\Delta d_{12}/d_B = -1.0\%$, $\Delta d_{23}/d_B = -0.2\%$, where $d_B$ is the interlayer spacing in the bulk. Starting from this static equilibrium geometry, the Helmholtz free energy of the slab is evaluated as a function of the top layer interspacing $d_{12}$. The temperature dependence of the equilibrium $d_{12}$ is then obtained from Eq. (2.2). All other interlayer spacings are assumed to expand according to the temperature dependence of the bulk.

![FIG. 1. Temperature dependence of surface layer relaxation of Ag(111). Our calculated results are denoted by the filled circles. Open circles are the results of Ref. [10], open triangles are EAM simulations [11]. The experimental results [10] are shown by filled diamonds.](image)

Figure 1 shows the calculated results (filled circles) together with the experimental data [10] (filled diamonds)
and other calculations \cite{9,10}. The temperature is scaled with respect to the experimental melting temperature ($T_m = 1234$ K \cite{12}). It can be seen that in the low temperature range ($T/T_m < 0.6$), the present calculation gives a thermal expansion similar to that of Ref. \cite{9}. At higher temperatures, the calculations of Ref. \cite{9} overestimate the thermal expansion of Ag(111). The present calculation, which includes all the vibrational modes of the slab in the whole BZ, displays a much smaller top layer expansion than obtained in the “three-mode approximation” \cite{9}, thus bringing the theoretical predictions in much closer agreement with experimental results: $\Delta d_{12}/d_0$ changes from $-0.8\%$ inward contraction (including zero-point vibrations) at $T = 0$ K to $+6.3\%$ outward expansion at $T = 1150$ K (the corresponding experimental figures vary from $-2.5\%$ to $+10.0\%$ \cite{13}). The EAM simulation in Ref. \cite{10}, on the contrary, shows no enhancement of thermal expansion of the interlayer spacing in the whole temperature range, i.e., the $d_{12}$ value always remains smaller than the interlayer spacing in the bulk.

What is the mechanism giving Ag(111) such an enhanced thermal expansion? Figure 2 shows the variation of the static energy, $E$, the Helmholtz free energy, $F$, and the vibrational free energy, $F_{vib}$, with the top-layer interspacing $d_{12}$, for $T = 500$ K. The equilibrium geometry, $d_{12}$, is determined by two factors: one is the static total energy, $E$, which governs the binding strength of the surface with the substrate and the anharmonicity of the interlayer potential normal to the surface; the other is the decrease of the vibrational free energy, $F_{vib}$, which reflects the “softening” of the vibrational frequency with the increase of $d_{12}$. We note that $F_{vib}$ does not always decrease with the increase of lattice parameters, for example, in the anomalous thermal expansion of bulk silicon \cite{14}. As $d_{12}$ increases from the static equilibrium value, $d_{12}^0$, the interlayer potential increases while the vibrational free energy decreases, determining a new equilibrium spacing $d_{12}$, larger than $d_{12}^0$.

![Figure 2](image.png)

**FIG. 2.** Variation of the static total energy $E$, vibrational free energy $F_{vib}$ and the Helmholtz free energy with the surface interlayer spacing $d_{12}$ at $T=500$ K.

Figure 3 shows how the temperature dependent equilibrium $d_{12}$ is obtained from Eq. (2.2). The dashed line is the variation of $\partial E/\partial d_{12}$ with $d_{12}$. The dot-dashed line is the derivative of $E$ with respect to $d_{12}$ when anharmonic terms in $E$ are neglected by quadratically expanding it around the static equilibrium geometry. The solid lines are $\partial F_{vib}/\partial d_{12}$ at different temperatures. The equilibrium geometry of $d_{12}$ is determined by the intersection of $\partial E/\partial d_{12}$ and $-\partial F_{vib}/\partial d_{12}$. It can be clearly seen that by increasing the temperature, the intersection of $\partial E/\partial d_{12}$ and $-\partial F_{vib}/\partial d_{12}$ gives an increasing value of equilibrium distance $d_{12}$. Furthermore, the anharmonicity of the static energy $E$, dashed line, is essential in determining the enhanced thermal expansion at high temperature, that would be much reduced if this anharmonicity were neglected (dot-dashed line).

![Figure 3](image.png)

**FIG. 3.** Variation of $-\partial F_{vib}/\partial d_{12}$ (solid lines) and $\partial E/\partial d_{12}$ (dashed line) with $d_{12}$. The harmonic results of $\partial E/\partial d_{12}$ are shown by the dot-dashed line. The equilibrium $d_{12}$ is obtained by the intersection of the solid lines and the dashed line.

The driving force for expansion comes from the temperature variation of the vibrational free energy. Equation (2.2) reveals that the value of $-\partial F_{vib}/\partial d_{12}$ at a given temperature is determined by $\partial \omega_p/\partial d_{12}$ which represents the “softening” of $\omega_p$ with the increase of $d_{12}$. Such “softening” of the frequencies is characterized by the shift of the phonon density of states (DOS).
FIG. 4. The phonon density of states (DOS) of different atomic layers. Solid lines are for $d_{12}=2.32$ Å, dashed lines are for $d_{12}=2.42$ Å.

Figure 4 shows the shift of layer localized phonon DOS with $d_{12}$. The solid line corresponds to $d_{12} = 2.32$ Å and the dashed line corresponds to $d_{12} = 2.42$ Å. Clearly, the DOS of the middle layer of the slab is quite bulk like, and the shift with $d_{12}$ is very small, while the surface-layer DOS is significantly different from that of the middle layer and is very sensitive to $d_{12}$. By increasing $d_{12}$, the vibrational frequencies of the first layer “shift” downward, which results in a decrease of the vibrational free energy as shown in Fig. 2. The vibrations of atoms in the second layer also “soften” by increasing $d_{12}$ and contribute to the decrease of the vibrational free energy.

FIG. 5. The shift of phonon DOS at surface from different vibrational modes with different $d_{12}$. The solids are for $d_{12}=2.32$ Å and dashed lines are for $d_{12}=2.42$ Å.

Figure 5 shows the “shift” of the phonon DOS in the top layer with $d_{12}$ for different vibrational modes. It can be seen that as $d_{12}$ increases from 2.32 Å to 2.42 Å, not only the vibrational modes that are perpendicular to surface, but also those parallel to surface, shift downward. The shift of the perpendicular modes reflects the anharmonicity of the interlayer potential $E$ normal to the surface, while the shift of the parallel modes is due to the flattening of the corrugation of the potential parallel to the surface. The latter effect implies that anharmonicity of the interatomic potential at a surface is a somewhat complicated effect where the $x$, $y$, and $z$ degrees of freedom are not independent. The modes perpendicular to the surface (corresponding to the Rayleigh wave) are mainly located in the low frequency range and provide a smaller contribution to the DOS. The parallel modes have relatively higher frequencies and occupy a larger portion of the total DOS.

As discussed above in Fig. 2, the increase of $-\partial F_{\text{vib}}/\partial d_{12}$ with temperature determines the expansion of $d_{12}$. 
FIG. 6. Contributions to the vibrational free energy from different vibrational modes

In Figure 6 the different contributions to $-\partial F_{vib}/\partial d_{12}$ coming from perpendicular and parallel modes are analysed. It can be seen that the contribution of the parallel modes to $-\partial F_{vib}/\partial d_{12}$ is larger than the one of perpendicular modes and that the difference between the contributions from parallel and perpendicular modes increases with temperature. This is in agreement with previous findings [9,13]. Note, however, that this effect is not general and in other systems, as for instance the Be(0001) surface [19], the “softening” of parallel modes plays a minor role. Altogether, the enhanced thermal expansion of $d_{12}$ at Ag(111) surface is governed by the anharmonicity of the interlayer potential normal to the surface as well as the “softening” of the parallel modes with the increase of $d_{12}$.

Finally we show in Figure 7 the surface phonon band structure corresponding to the geometry obtained for $T = 300$ K. The thickness of the slab has been extended to 30 atomic layers in order to decouple the surface vibrations that penetrate deeply in the bulk, by inserting in the middle of our slab a number of layers with bulk-like force constants. The lowest surface-mode branch $S_1$ which lies below the bulk bands is the Rayleigh wave. It is primarily associated with vibrations normal to the surface (shear-vertical (SV) mode, compare also Fig. 5). The gap mode $S_3$ is primarily a “shear-horizontal” (SH) mode which is associated with vibrations in the direction transverse to $q ||$ and parallel to the surface. The surface modes $S_2$ and $S_4$ are primarily longitudinal modes which are associated with vibrations along the direction parallel to $q ||$. The calculated frequencies of the Rayleigh mode $S_1$ are in good agreement with experimental data from helium scattering [21].

IV. CONCLUSION

Our calculation of the thermal properties of Ag(111) surface are in quantitative agreement with the enhanced thermal expansion found in the experiments. This behavior is found to be determined by two effects: i) the anharmonicity of the interlayer potential normal to the surface and ii) the decrease of the vibrational free energy with increasing $d_{12}$. The latter effect reflects not only the anharmonicity of the interlayer potential normal to the surface, but also the flattening of the corrugation of the interlayer potential parallel to the surface with the increase of $d_{12}$. A recent calculation using the EAM [10] shows that the interlayer spacing $d_{12}$ increases very weakly between $T = 0$ K and 1100 K. This significant difference to our ab initio result is due to two reasons: i) The $k$-summation in Ref. [10] was done incorrectly, i.e., the ratio of weights at $\bar{\Gamma}$, $\bar{K}$ and $\bar{M}$ should be 1:2:3, not 1:6:6, and at the fcc (111) surface the vibrational modes at $\bar{M}$ and $\bar{K}$ are different. ii) the EAM lacks some important aspects of the quantum mechanical nature of electrons [21].

“Embedded atom method” is one name out of several names for essentially the same approach. Others are e.g. bond cutting model, effective medium theory, glue model. All these “bond cutting models” neglect in their standard applications the shell structure of atoms (s, p, d, ... electrons) and describe the interaction between atoms by a sum of pair potential and effective atomic-many-body contributions. Thus, when the kinetic energy of electrons and/or a hybridization of s, p, d, ... orbitals is changing, “bond cutting models” are likely to fail.
