Abstract. We derive an anthropic bound on the extra neutrino species, $\Delta N_{\text{eff}}$, based on the observation that a positive $\Delta N_{\text{eff}}$ suppresses the growth of matter fluctuations due to the prolonged radiation dominated era, which reduces the fraction of matter that collapses into galaxies, hence, the number of observers. We show that the probability of finding ourselves in a universe satisfying the current bound is of order a few percents for a flat prior distribution. If $\Delta N_{\text{eff}}$ is found to be close to the current upper bound, the anthropic explanation is not very unlikely. On the other hand, if the upper bound on $\Delta N_{\text{eff}}$ is significantly improved by future observations, such simple anthropic consideration does not explain the small value of $\Delta N_{\text{eff}}$. We also study simple models where dark radiation consists of relativistic particles produced by heavy scalar decays, and show that the prior probability distribution sensitively depends on the number of the particle species.
1 Introduction

The ΛCDM paradigm has been hugely successful in explaining various cosmological observations with high accuracy. Remarkably, with only six parameters, it gives a very nice fit to the observed cosmic microwave background (CMB) temperature and polarization anisotropies [1].

Recently, however, the ΛCDM paradigm is challenged by the findings of possible tensions among different observations. In particular, there seems to be a rather clear tension in the estimate of the Hubble constant, $H_0$. In other words, the Hubble constant measured locally is higher than the value inferred from the Planck CMB observation based on the ΛCDM model. The recent improved analysis of the local measurements of $H_0$ strengthened the tension to be $4.4\sigma$ [2]. While it is not trivial to entirely remove the $H_0$ tension by introducing new physics without invoking other tensions, there are several ways that can ameliorate the tension [3–11].

One of such extensions is to introduce new relativistic particles, the so-called dark radiation. It is customary to express the amount of dark radiation in terms of the extra neutrino species, $\Delta N_{\text{eff}}$. One needs $\Delta N_{\text{eff}} \gtrsim 0.5$ to reduce the $H_0$ tension significantly [7].

There are a variety of candidates for dark radiation. In most of the scenarios, dark radiation consists of unknown massless or extremely light particles such as sterile neutrinos, axions, hidden photons, etc. The existence (or non-existence) of dark radiation has rich implications for physics beyond the SM as well as the evolution of the early Universe. For instance, if dark radiation was in thermal equilibrium with the standard model (SM) particles, they must have sizable couplings that can be constrained by direct search experiments or astrophysics [12–16]. On the other hand, dark radiation may be produced non-thermally by the decay of heavy particles (see e.g. Refs. [17–20]). Indeed, in the string theory, there often appear many light hidden particles (such as axions and hidden photons), and if the inflaton is universally coupled to the light particles including the SM ones, we expect that the Universe is likely filled with hidden particles, which is not consistent with what we observe [21]. Therefore, if the existence of dark radiation is ubiquitous in the landscape, there may be some reason to suppress its abundance.

In this Letter, we examine an anthropic explanation of the dark radiation under the assumption that $\Delta N_{\text{eff}}$ is an environmental parameter which takes random values in the multiverse. A similar assumption is made in the anthropic explanation of the observed small
cosmological constant. Although we do not give a rigorous UV completion that provides such a mechanism to distribute different values of $\Delta N_{\text{eff}}$, it is possible to imagine that the abundances of such light particles depend on their couplings with the inflaton, which may depend on the choice of the universe. We shall study simple toy models along this line, and show that the prior distribution of $\Delta N_{\text{eff}}$ sensitively depends on the number of particle species that constitute dark radiation. Since it is notoriously difficult to quantify various anthropic conditions, we will adopt a very simple ansatz which seems to be successful in explaining the observed cosmological constant [22, 23]: the number of observers in a universe is proportional to the fraction of matter that collapses into galaxies. In fact, we note that one can extend the anthropic argument on the cosmological constant to derive the anthropic bound on $\Delta N_{\text{eff}}$ and its likely values. In this sense, our anthropic explanation of dark radiation is on the same footing with that of the cosmological constant.

2 Anthropic bound on dark radiation

2.1 Probability distribution of $\Delta N_{\text{eff}}$ and $\Omega_\Lambda$

The effective neutrino number in the standard cosmology is $N_{\text{eff}}^{(\text{std})} \simeq 3.046$. The energy density of dark radiation $\rho_{\text{DR}}$ is conveniently described by a change of the effective neutrino number $\Delta N_{\text{eff}} \equiv N_{\text{eff}} - N_{\text{eff}}^{(\text{std})}$ as

$$\Delta N_{\text{eff}} = \frac{4}{7} \frac{\rho_{\text{DR}}}{(\pi^2/30)T_{\nu}^4}, \quad (2.1)$$

where $T_{\nu}$ is the neutrino temperature. We can express the radiation density parameter, $\Omega_{\text{rad}}$, as a function of $\Delta N_{\text{eff}}$:

$$\Omega_{\text{rad}} \simeq \Omega_{\text{rad}}^{(\text{std})} \times (1 + 0.13\Delta N_{\text{eff}}), \quad (2.2)$$

where $\Omega_{\text{rad}}^{(\text{std})} \simeq 4.18 \times 10^{-5}h^{-2}$ is the radiation density parameter in the standard cosmology.

In this Letter, we calculate the conditional probability distribution of $\Delta N_{\text{eff}}$ and the density parameter of the cosmological constant $\Omega_\Lambda$ in the multiverse, assuming that the probability is proportional to the number of observers in each universe. It is estimated by [24]

$$P(\Delta N_{\text{eff}}, \Omega_\Lambda) \propto P_{\text{prior}}(\Delta N_{\text{eff}}, \Omega_\Lambda) \int dM n_G(\Delta N_{\text{eff}}, \Omega_\Lambda, M) N_{\text{obs}}(\Delta N_{\text{eff}}, \Omega_\Lambda, M), \quad (2.3)$$

where $n_G \, dM$ is the comoving number density of galaxies with mass between $M$ and $M + dM$, and $N_{\text{obs}}$ is the number of observers per galaxy with mass $M$ in each universe with $\Delta N_{\text{eff}}$ and $\Omega_\Lambda$. The prior distribution $P_{\text{prior}}$ depends on the production mechanism and will be discussed in the next section.

The number of observers $N_{\text{obs}}$ in a galaxy is expected to be proportional to its mass $M$. We assume that $N_{\text{obs}}$ is insensitive to $\Delta N_{\text{eff}}$ and $\Omega_\Lambda$, because $N_{\text{obs}}$ is determined locally in galaxies decoupled from cosmic expansion, while $\Delta N_{\text{eff}}$ and $\Omega_\Lambda$ change only global properties of the universe. We also assume that the integral in Eq. (2.3) is dominated by large galaxies with mass $M \gtrsim M_G \sim 10^{12}M_\odot$ like the Milky Way. This is because the metals generated by the first-generation stars must be retained in the galaxy for the planetary formation. Under these assumptions, we can rewrite the probability as

$$P(\Delta N_{\text{eff}}, \Omega_\Lambda) \propto P_{\text{prior}}(\Delta N_{\text{eff}}, \Omega_\Lambda) F(M > M_G, \Delta N_{\text{eff}}, \Omega_\Lambda), \quad (2.4)$$
where $F$ is the fraction of matter that clusters into galaxies with mass larger than $M_G$:

$$F(M > M_G, \Delta N_{\text{eff}}, \Omega_\Lambda) \equiv \int_{M_G}^{\infty} dM n_G(M) M.$$  \hspace{1cm} (2.5)$$

This can be estimated by using a spherical collapse model.

The observations of CMB revealed that primordial density perturbations are well approximated by a Gaussian. The time evolution of density perturbations can be studied by the linear perturbation theory. Hence it is reasonable to represent the distribution of density perturbations smoothed over a comoving scale $R$ by

$$P_\delta(R, t, \Delta N_{\text{eff}}, \Omega_\Lambda) \propto \exp\left[-\frac{\delta^2}{2\sigma^2(R, t, \Delta N_{\text{eff}}, \Omega_\Lambda)}\right],$$  \hspace{1cm} (2.6)$$

where $\sigma$ is the variance of the density perturbation and it grows with time.

We are interested in the comoving scale $R_G$ where large galaxies of mass $M_G (\sim 10^{12} M_\odot)$ form after the collapse. It is determined from the mass conservation as

$$R_G(M_G) = \left(\frac{3M_G}{4\pi \rho_{m,0}}\right)^{1/3} \hspace{1cm} (2.7)$$

$$\simeq 1.3 h^{-1} \text{ Mpc} \left(\frac{\Omega_m h^2}{0.12}\right)^{-1/3} \left(\frac{h}{0.7}\right) \left(\frac{M_G}{10^{12} M_\odot}\right)^{1/3},$$  \hspace{1cm} (2.8)$$

where $\rho_{m,0}$ and $\Omega_m$ are the present matter density and density parameter, respectively, and $h$ is the reduced Hubble constant.

### 2.2 Evolution of density perturbations

The variance of density perturbation smoothed over a scale $R$ is calculated from the power spectrum $P_\delta(k)$ as

$$\sigma^2(R, t, \Delta N_{\text{eff}}, \Omega_\Lambda) = \int_0^{\infty} \frac{4\pi k^2 dk}{(2\pi)^3} P_\delta(k) W^2(kR),$$  \hspace{1cm} (2.9)$$

$$W(x) = \frac{\sin x - x \cos x}{x^3/3},$$  \hspace{1cm} (2.10)$$

where

$$\langle \delta(k) \delta^*(k') \rangle = (2\pi)^3 P_\delta(k) \delta^{(3)}(k - k'),$$  \hspace{1cm} (2.11)$$

$$\delta(k) = \int d^3x \delta(x) e^{ik\cdot x}.$$  \hspace{1cm} (2.12)$$

Note that the power spectrum $P_\delta(k)$ is the Fourier transform of the correlation function for the density perturbation, which is different from $P_\delta(R)$ in Eq. (2.6).

From the Poisson equation, the density perturbation $\delta$ can be calculated from the gravitational potential $\Phi$ as

$$\delta(k, t) = \frac{2 k^2 a \Phi(k, t)}{3 \Omega_m H_0^2},$$  \hspace{1cm} (2.13)$$
The time-evolution and $k$-dependence of $\Phi$ are conveniently factorized as

$$\Phi(k, t) = \frac{9}{10} \Phi_p(k) T(\kappa) \frac{D(a)}{a},$$  \hspace{0.5cm} (2.14)\

where $T(\kappa)$ is the transfer function, $D(a)$ is the growth function, and $\Phi_p$ is the primordial gravitational potential. The numerical factor $9/10$ represents the evolution of super-horizon modes around the matter-radiation equality. The momentum in the unit of a horizon scale at the matter-radiation equality, $\kappa$, is given by

$$\kappa = \frac{\sqrt{2k}}{a \equiv \Omega_{\text{rad}}/\Omega_m} = \frac{\sqrt{\Omega_{\text{rad}}}}{\Omega_m} \frac{k}{H_0},$$  \hspace{0.5cm} (2.15)\

where $a_{\text{eq}} (= \Omega_{\text{rad}}/\Omega_m)$ is the scale factor at the matter-radiation equality. The matter power spectrum is then related to the power spectrum of the primordial curvature perturbation $P_\zeta$ as

$$P_\delta(k) = \frac{8\pi^2}{25} \frac{k}{\Omega_m^2 H_0^4} P_\zeta(k) T(\kappa)^2 D(a)^2,$$  \hspace{0.5cm} (2.16)\

where

$$P_\zeta(k) \simeq 2.101 \times 10^{-9} \left( \frac{k}{k_{\text{pivot}}} \right)^{n_s - 1},$$  \hspace{0.5cm} (2.17)\

with $k_{\text{pivot}} = 0.05 \text{Mpc}^{-1}$ and $n_s \simeq 0.965$ [1].

The transfer function describes the wavenumber dependence and the growth function describes the scale-factor dependence of the gravitational potential. Here we briefly comment on the qualitative features of these functions. We are interested in a scale $R_G$, which enters into the horizon before the matter-radiation equality. The density perturbation at subhorizon scales grows only logarithmically during the radiation dominated era, which is known as the Meszaros effect. The duration of this effect depends on the scale factor at the matter-radiation equality, $a_{\text{eq}}$, and therefore $\delta \propto \ln \Omega_{\text{rad}}$, where $\Omega_{\text{rad}}$ is related to $\Delta N_{\text{eff}}$ through Eq. (2.2). On the other hand, the density perturbation grows as $a$ (i.e., $D(a) \propto a$) during the matter dominated epoch. For larger $\Omega_{\text{rad}}$, the matter-radiation equality is delayed, and the duration of the matter-dominated epoch decreases. Hence the density perturbation grows less until the present epoch. Combining these effects, we obtain $\delta \propto (\ln \Omega_{\text{rad}})/\Omega_{\text{rad}}$. Below we will estimate $\delta$ (or $\sigma$) quantitatively and will see the result is consistent with this qualitative picture.

The fitting formula for the transfer function can be read from, e.g., Eq. (6.5.12) in Ref. [26]:

$$T(\kappa) = \frac{\ln \left(1 + (0.124 \kappa)^2\right)}{(0.124 \kappa)^2} \sqrt{\frac{1 + (1.257 \kappa)^2 + (0.4452 \kappa)^4 + (0.2197 \kappa)^6}{1 + (1.606 \kappa)^2 + (0.8568 \kappa)^4 + (0.3927 \kappa)^6}},$$  \hspace{0.5cm} (2.18)\

For the modes that enter the horizon before the matter-radiation equality, i.e., $\kappa \gg 1$, we obtain $T(\kappa) \propto \ln \kappa/\kappa^2$. The logarithmic dependence results from the Meszaros effect, where the density perturbation grows only logarithmically during the radiation dominated era.

---

1 We normalize $D$ such that $D = a$ during the matter dominated era, which is different from the one used in Refs. [24, 25] by a factor of $2a_{\text{eq}}/3$. We normalize the scale factor $a$ such that $a = 1$ at present when the matter energy density is equal to the observed value.
It is convenient to define a new time variable \( x \) as

\[
x \equiv \frac{\rho_{\Lambda}}{\rho_m(t)} = \frac{\Omega_{\Lambda}}{\Omega_m(1 + z)^{-3}}.
\] (2.19)

At the matter-radiation equality, it is given by

\[
x_{\text{eq}}^{-1/3} = \left( x_{\text{eq}}^{(\text{obs})} \right)^{-1/3} \left( \frac{\Omega_{\Lambda}}{\Omega_{\text{rad}}^{(\text{obs})}} \right)^{-1/3} \left( \frac{\Omega_{\text{rad}}}{\Omega_{\text{rad}}^{(\text{std})}} \right)^{-1},
\] (2.20)

and \((x_{\text{eq}}/x)^{-1/3} = (a_{\text{eq}}/a)^{-1}\), where \((x_{\text{eq}}^{(\text{obs})})^{-1/3} \simeq 2820\) and \(\Omega_{\Lambda}^{(\text{obs})} \simeq 0.69\) [1]. The growth factor \(D(a)\) is given by

\[
D(a) = \frac{2a_{\text{eq}}}{3} \left[ 1 + \frac{3}{2} x_{\text{eq}}^{-1/3} G(x) \right],
\] (2.21)

where \(G(x)\) is the growth factor in a flat universe filled with matter and vacuum energy, given by

\[
G(x) \equiv \frac{5}{6} \left( \frac{1 + x}{x} \right)^{1/2} \int_0^x \frac{dx'}{x'^{1/6}(1 + x')^{3/2}},
\] (2.22)

\[
\approx x^{1/3} \left( 1 + \left( \frac{x}{G^3(\infty)} \right)^{2/3} \right),
\] (2.23)

where the second line is a fitting formula with

\[
\alpha = \frac{159}{200} = 0.795,
\] (2.24)

\[
G(\infty) = \frac{5\Gamma(2/3)\Gamma(5/6)}{3\sqrt{\pi}} \simeq 1.44.
\] (2.25)

At the scale we are interested in, we can safely neglect the first term in Eq. (2.21).

The variance of the density perturbation after smoothing over a scale \(R\) (see Eq. (2.9)) is now given by

\[
\sigma^2(R, t, \Delta N_{\text{eff}}, \Omega_{\Lambda}) = \int_0^\infty d\ln k P\zeta(k)W^2(kR) \frac{4}{25} \frac{k^4T^2(\kappa)}{\Omega_{\text{rad}}^2H_0^2} D^2(a),
\] (2.26)

where \(P\zeta(k)\), \(T(\kappa)\), and \(D(a)\) are given by Eqs. (2.17), (2.18), and (2.21), respectively. The dependence of the variance on the parameters can be read by setting \(k = 1/R_{\text{G}}\) in the integrand, and it reads

\[
\sigma(R, t, \Delta N_{\text{eff}}, \Omega_{\Lambda})_{t \to \infty} \simeq \sigma^{(\text{std})}(R_{\text{G}}) \left( 1 + 0.18 \ln \frac{\Omega_{\text{rad}}}{\Omega_{\text{rad}}^{(\text{std})}} \right) \left( \frac{\Omega_{\Lambda}}{\Omega_{\text{rad}}^{(\text{obs})}} \right)^{-1/3} \left( \frac{\Omega_{\text{rad}}}{\Omega_{\text{rad}}^{(\text{std})}} \right)^{-1} \left( \frac{G(\infty)}{G(x_{\text{eq}})} \right),
\] (2.27)

where

\[
\sigma^{(\text{std})}(R_{\text{G}}) \equiv \sigma(R_{\text{G}}, t_p, \Delta N_{\text{eff}} = 0, \Omega_{\Lambda}^{(\text{obs})}) \simeq 3.2,
\] (2.28)
is the variance at present \((t = t_p)\) evaluated by the linear theory, Eq. (2.26), and \(x_p \equiv \Omega^{(\text{obs})}_\Lambda / \Omega_m\). The parameter dependence can be understood by noting how the duration of matter domination depends on the density parameters. The matter radiation equality is delayed if we increase the radiation energy. The cosmological constant comes to dominate earlier if we increase the cosmological constant. Since the matter density fluctuation grows efficiently only in the matter dominated epoch, the increase of the density parameters \(\Omega_{\text{rad}}\) and \(\Omega_\Lambda\) suppress the growth of the density perturbations. The logarithmic dependence on \(\Omega_{\text{rad}}\) is due to the Meszaros effect.

2.3 Anthropic bound

When the density perturbation grows and exceeds the critical value \(\delta_c\), an overdense region collapses to form a galaxy. The critical value can be calculated based on the spherical collapse model \([22]\)

\[
\delta_c \simeq \frac{9}{5} 2^{-2/3} G_\infty \simeq 1.63.
\]  

(2.29)

According to \([23]\), the fraction of matter that collapses into galaxies during the entire history of the Universe, \(F\), is given by

\[
F(M > M_G, \Delta N_{\text{eff}}, \Omega_\Lambda) \propto \int_\beta^\infty dy \frac{e^{-y}}{s \sqrt{y + \sqrt{2} \beta}},
\]  

(2.30)

where the parameter \(\beta\) is given by

\[
\beta \equiv \frac{\delta_c^2}{2\sigma^2(R_G, t, \Delta N_{\text{eff}}, \Omega_\Lambda)_{t \to \infty}}.
\]  

(2.31)

Here, \(s\) is a shape parameter that takes account of the fraction of the surrounding underdense region that also collapses into the galaxies. If we set \(s \to \infty\), the result is proportional to the one given by the Press-Schechter formalism. We take \(s = 1\), which is a reasonable case where the overdense region is surrounded by the underdense region with the same volume.

Assuming that the number of observers in a universe is proportional to the mass that collapses into galaxies, we can calculate the probability distribution of \(\Delta N_{\text{eff}}\) and \(\Omega_\Lambda\) by using Eq. (2.4) and Eq. (2.30). The integral in Eq. (2.30) is exponentially suppressed for \(\beta \gg \mathcal{O}(1)\). This means that the fraction of matter that clusters into galaxies with \(M > M_G\) is exponentially suppressed for \(\sigma \ll \delta_c\), while it is of order unity for \(\sigma \gtrsim \delta_c\). Roughly speaking, the condition \(\sigma \gtrsim \delta_c\) is the anthropic bound. Since \(\sigma\) depends on \(\Delta N_{\text{eff}}\) and \(\Omega_\Lambda\), we can estimate their likely values that satisfy \(\sigma \gtrsim \delta_c\). From the simplified expression Eq. (2.27), we can see that \(\Omega_\Lambda\) and \(\Omega_{\text{rad}}(\Delta N_{\text{eff}})\) cannot be much larger than the observed values from the anthropic argument.

The normalized probability distribution of \(\Delta N_{\text{eff}}\) and \(\Omega_\Lambda\) is shown in Fig. 1. We assume a flat prior distribution \(P_{\text{prior}}\) for both \(\Delta N_{\text{eff}}\) and \(\Omega_\Lambda\) in Eq. (2.4). In the upper panel, the contours of \(\log[\Omega_\Lambda \Delta N_{\text{eff}} P(\Delta N_{\text{eff}}, \Omega_\Lambda)]\) are shown. One can see that the most likely values of \(\Delta N_{\text{eff}}\) and \(\Omega_\Lambda\) are larger than those in our universe. In the lower panel, we plot \(\Delta N_{\text{eff}} P(\Delta N_{\text{eff}}, \Omega_\Lambda)\) with \(\Omega_\Lambda = \Omega^{(\text{obs})}_\Lambda\), where the solid line is based on the numerical estimate of Eq. (2.26), while the dashed line is based on the analytic one Eq. (2.27). The two lines agree well with each other. One can see that the typical value of \(\Delta N_{\text{eff}}\) is \(\mathcal{O}(10)\).
Figure 1. The probability distribution of parameters $\Delta N_{\text{eff}}$ and $\Omega_\Lambda$ in the multiverse with a flat prior distribution, $P_{\text{prior}} = 1$. In the upper panel, the contour is plotted for $\log[\Omega_\Lambda \Delta N_{\text{eff}} P(\Delta N_{\text{eff}}, \Omega_\Lambda)]$. We set $\Omega_\Lambda = \Omega_\Lambda^{(\text{obs})}$ in the lower panel. The dashed curve is based on the simplified formula Eq. (2.27).

The Planck data combined with the BAO observation gives the constraint [1]

$$N_{\text{eff}} = 3.27 \pm 0.15,$$

(2.32)
which is shown as the blue dot with an error bar in the upper panel of Fig. 1. Interestingly, there is currently the so-called $H_0$ tension: the Hubble constant inferred by the Planck and BAO (assuming $\Delta N_{\text{eff}} = 0$) reads $H_0 = (69.32 \pm 0.97)$ km/s/Mpc, while the local Hubble parameter measurement gives $H_0 = (73.45 \pm 1.66)$ km/s/Mpc [27]. The significance of the tension is greater than 4$\sigma$. In fact, $N_{\text{eff}}$ and $H_0$ are correlated with each other in the Planck analysis; $\Delta N_{\text{eff}} > 0$ makes the sound horizon smaller, which can be partially cancelled by larger $H_0$ because the last scattering surface becomes closer to us. The tension can be relaxed if $\Delta N_{\text{eff}} \gtrsim 0.5$. This motivates us to consider a sizable amount of dark radiation.

Now we shall discuss how likely the point $\Delta N_{\text{eff}} = 0.5$ (1) and $\Omega_{\Lambda} = \Omega^{(\text{obs})}_{\Lambda}$ are under the anthropic consideration. First, we note that the probability of finding ourselves in a universe with the present $\Omega^{(\text{obs})}_{\Lambda}$ is about 3$\%$ for the case of $\Delta N_{\text{eff}} = 0$. We define the probability $\Delta N_{\text{eff}} \leq \Delta N_{\text{eff}}^{(\text{max})}$ for $\Omega^{(\text{obs})}_{\Lambda}$ by

$$N^{-1} \int_0^{\Delta N_{\text{eff}}^{(\text{max})}} dN_{\text{eff}} P(\Delta N_{\text{eff}}, \Omega^{(\text{obs})}_{\Lambda}),$$

(2.33)

where

$$N = \int_0^{\infty} dN_{\text{eff}} P(\Delta N_{\text{eff}}, \Omega^{(\text{obs})}_{\Lambda}).$$

(2.34)

Then we find that the probability to find ourselves in a universe with $\Delta N_{\text{eff}} \leq 0.5$ (1) is about 0.03 (0.06). See also the lower panel of Fig. 1. Thus we conclude that $\Delta N_{\text{eff}} = 0.5$ (or 1) is not unlikely based on the anthropic argument.

When we vary both $\Delta N_{\text{eff}}$ and $\Omega_{\Lambda}$, the probability to find ourselves in a universe with $\Delta N_{\text{eff}} \leq \Delta N_{\text{eff}}^{(\text{max})}$ and $0 < \Omega_{\Lambda} \leq \Omega^{(\text{obs})}_{\Lambda}$ is given by

$$\int_0^{\Delta N_{\text{eff}}^{(\text{max})}} d\Delta N_{\text{eff}} \int_0^{\Omega^{(\text{obs})}_{\Lambda}} d\Omega_{\Lambda} P(\Delta N_{\text{eff}}, \Omega_{\Lambda}).$$

(2.35)

We find that this is about 0.003 (0.006) for $\Delta N_{\text{eff}}^{(\text{max})} = 0.5(1)$ and $\Omega^{(\text{obs})}_{\Lambda} = 0.69$.

The CMB-S4 experiment will improve the 1$\sigma$ error for the dark radiation as $\delta(N_{\text{eff}}) = 0.0156$ [28, 29]. If the value of $\Delta N_{\text{eff}}$ in our universe is determined by the anthropic principle, we would expect that the CMB-S4 experiment will find a nonzero value of $\Delta N_{\text{eff}}$. On the other hand, if its result is consistent with $\Delta N_{\text{eff}} = 0$, we may conclude that the amount of dark radiation is not determined by the anthropic principle but is determined by some other mechanism. For example, the energy of inflation may dominantly converted to the SM particles at the time of reheating.

3 Reheating and prior distribution

In this section, we discuss a couple of simple models that predict dark radiation from reheating. Suppose that the inflaton decays into dark radiation as well as the SM particles and that the dark radiation is completely decoupled from the SM sector. The effective number of neutrinos, which is proportional to the energy density of dark radiation, is then determined by the branching ratio into the dark radiation:

$$\Delta N_{\text{eff}} = \frac{43}{7} \left( \frac{43/4}{g_*} \right)^{1/3} \frac{\Gamma_D}{\Gamma_{\text{SM}}},$$

(3.1)
Here, we denote the number of degrees of freedom of SM particles at the time of reheating by $g_*$ ($\simeq 106.75$). The prior distribution of $\Delta N_{\text{eff}}$ is then given by the probability distribution of $\Gamma_D/\Gamma_{\text{SM}}$.

### 3.1 Case of a single dark radiation component

In superstring theories, scalar fields with flat potentials, called moduli, arise via compactifications on a Calabi-Yau space, and some of them may be present in the low energy effective field theory [30]. Inflation may be realized in the moduli space, and the decay of the inflaton induces the reheating. Alternatively, coherent oscillations of moduli tend to dominate the energy density of the Universe after inflation and the subsequent moduli decay may reheat the Universe. In either case the reheating occurs due to the moduli decay. In this section we focus on a single modulus that dominates the universe and decays into the SM and dark radiation.

The modulus $T$ has a shift symmetry along its imaginary component, the axion, which remains massless at the perturbative level. We assume that the axion is almost massless, and so, once it is produced it contributes to dark radiation. This is the case if the real component of the modulus is stabilized by supersymmetry breaking effects. Let us consider the following Kähler potential of the no-scale form:

$$K = -3 \log \left[ T + T^\dagger - \frac{1}{3} \left( |H_u|^2 + |H_d|^2 + (c_{\text{SM}} H_u H_d + \text{h.c.}) \right) \right] + \ldots,$$

where we show only relevant terms and omit higher order terms responsible for e.g. the modulus stabilization, and $c_{\text{SM}}$ denotes a coupling constant. For simplicity, we assume that the superpotential and the gauge kinetic function are irrelevant for the modulus decay. Then the modulus decays only into the axion and the Higgs fields. The ratio of the decay rate is given by [18–20]

$$\frac{\Gamma_D}{\Gamma_{\text{SM}}} = \frac{1}{2c_{\text{SM}}^2}.$$

(3.3)

For a more generic Kähler potential, the modulus decay rate into axions is proportional to $(\partial^3 K/\partial T^3)^2 (\equiv c^2)$, which may vary depending on the details of the compactification etc. So let us parametrize the ratio as

$$\frac{\Gamma_D}{\Gamma_{\text{SM}}} = \frac{c^2}{c_{\text{SM}}^2},$$

(3.4)

where we take $c_{\text{SM}} = \mathcal{O}(0.1)$.

We assume that the coupling constant $c$ that determines $\Gamma_D$ is randomly distributed in the multiverse and its probability distribution is given by a flat distribution in the range of $|c| \leq \sigma (= \mathcal{O}(1))$. We fix the decay rate into the SM particles for simplicity. Since the branching ratio into the dark sector is proportional to the coupling constant squared, the probability distribution of $\Gamma_D$ can be read from

$$P(c^2/\sigma^2) = \begin{cases} 
\frac{1}{2\sqrt{c^2/\sigma^2}} & \text{for } c^2/\sigma^2 \leq 1 \\
0 & \text{for } c^2/\sigma^2 > 1,
\end{cases}$$

(3.5)

and is proportional to $1/\sqrt{\Gamma_D} \propto 1/\sqrt{\Delta N_{\text{eff}}}$ for $c^2/\sigma^2 \leq 1$. Thus the distribution of $\Delta N_{\text{eff}}$ is biased toward a smaller value. The probability distribution of $\Delta N_{\text{eff}}$ and $\Omega_\Lambda$ is shown
in Fig. 2 for the case of $P_{\text{prior}} \propto 1/\sqrt{\Delta N_{\text{eff}}}$. We can see that the typical value of $\Delta N_{\text{eff}}$ is $O(1)$ in this case. The probability to obtain $\Delta N_{\text{eff}} \leq 0.5(1)$ is given by 0.10(0.14) based on Eq. (2.33). If we also vary $\Omega_\Lambda$, the probability to obtain $\Delta N_{\text{eff}} \leq 0.5(1)$ and $\Omega_\Lambda \leq 0.69$ is 0.01(0.02) based on Eq. (2.35).
3.2 Case of multiple dark radiation components

We now consider how the probability distribution changes if there are multiple dark radiation components. In fact, the flux compactification of the higher-dimensional space in the string theory predicts a large number of axions and gauged dark sectors in the low-energy effective field theory. Inflation may occur in the axion field space, the so-called axion landscape \[31 – 35\]. For instance, the reheating could occur via the decay into gauge fields. If there are unbroken U(1) gauge fields in the dark sector, they contribute to dark radiation after the reheating. In this case, the number of particle species of the dark radiation, \(N\), can be larger than unity \[36\] and we parametrize the branching into the dark sector as

\[
\frac{\Gamma_D}{\Gamma_{SM}} = \sum_i c_i^2/c_{SM}^2. \tag{3.6}
\]

As in the previous case, we assume that the probability distributions of coupling constants \(c_i\) are given by flat distributions in the ranges of \(|c_i| \leq \sigma_i (= \mathcal{O}(1))\). For simplicity, we set a universal value for the range, \(\sigma_i = \sigma\). We also define \(x \equiv \sum_i c_i^2/\sigma^2 \propto \Gamma_D\). Since \(\Delta N_{\text{eff}} \gtrsim \mathcal{O}(100)\) for \(\sum c_i^2 \gtrsim 1\) and \(c_{SM} = \mathcal{O}(0.1)\), we are interested in the regime where \(x \ll 1\). The probability distribution of \(x\) is then calculated from

\[
P(x) = \frac{d}{dx} \frac{\Gamma_D}{\Gamma_{SM}} \left[ \prod_{i=1}^N \frac{dc_i}{2\sigma} \right]_{x<\sum_i c_i^2/\sigma^2} \approx \frac{\pi^{N/2}}{2^N \Gamma(N/2)} x^{N/2-1} \quad \text{for } x \leq 1. \tag{3.7}
\]

Thus the prior distribution is almost flat for \(N = 2\), and it is strongly biases toward a large \(\Delta N_{\text{eff}}\) for \(N > 2\). In this case, the probability to obtain \(\Delta N_{\text{eff}} \leq 0.5\) is strongly suppressed. Thus we conclude that the anthropic argument does not explain the current bound on \(\Delta N_{\text{eff}}\), if the dark radiation that consists of \(N(\gg 1)\) different particle species produced by the heavy scalar decay.

If one assumes that the probability distributions of the coupling constants \(c_i\) are given by Gaussian distributions with zero mean and a universal variance \(\sigma\), the probability distribution of \(x \equiv \sum_i c_i^2/\sigma^2 \propto \Gamma_D\) is then given by the \(\chi^2\)-distribution with \(N\) degrees of freedom:

\[
P(x) = \chi^2(N) = \frac{1}{2^{N/2} \Gamma(N/2)} x^{N/2-1} e^{-x/2}. \tag{3.9}
\]

Note that the result for the case of a single dark radiation component can be read from this formula by setting \(N = 1\). For a small \(x\), the probability distribution is proportional to \(x^{N/2-1}\). Since we are interested in a small \(x\), the result is the same with that for the flat distribution.

4 Discussion and Conclusions

We have discussed the anthropic bound on the amount of dark radiation, assuming that the number of observers in each universe is proportional to the fraction of matter that clusters into galaxies with mass larger than the Milky Way galaxy. The matter-radiation equality

\[^2\text{The closed form of the probability distribution has been derived in Ref. [37] (see also Ref. [38]).}\]
is delayed if we increase the radiation energy. The matter density at subhorizon scales grows only logarithmically before the matter-radiation equality while it grows linearly in terms of the scale factor after that until the cosmological constant comes to dominate. As a result, a larger radiation energy leads to smaller density perturbations and hence a lower fraction of matter that clusters into galaxies. We have found that the number of observers is exponentially suppressed when the effective neutrino number exceeds of order 10. If the prior distribution is flat, the probability to find ourselves in a universe with $\Delta N_{\text{eff}} \leq 0.5(1)$ is about 0.03(0.06), which is comparable to the probability to find ourselves in a universe with the observed cosmological constant or smaller. The anthropic explanation of $\Delta N_{\text{eff}}$ is not unlikely, if it is found to be around the current upper bound.

We have also discussed a couple of examples in which dark radiation is produced during the reheating process. If a modulus is the inflaton or coherent oscillations of the modulus comes to dominate the universe after inflation, the universe will be reheated by the modulus decay. The modulus may also decay into dark radiation in addition to the SM particles. For instance, if the modulus is stabilized by supersymmetry breaking effects, the modulus generically decays into its axionic partners with a sizable branching fraction [18–20]. Alternatively, the modulus may decay into multiple dark photons or axions. Assuming a flat prior distributions for the coupling constants, we have found that the prior distribution of $\Delta N_{\text{eff}}$ is proportional to $(\Delta N_{\text{eff}})^{N/2 - 1}$, where $N$ is the number of particle species that constitute dark radiation. In particular, if $N = 1$, the energy density is biased toward smaller values and the probability to find ourselves in a universe with $\Delta N_{\text{eff}} \leq 0.5(1)$ is about 0.10(0.14). On the other hand, for $N \gg 1$, the prior distribution of $\Delta N_{\text{eff}}$ is strongly biased toward larger values. In this case, the probability to find ourselves in a universe with $\Delta N_{\text{eff}} \lesssim 1$ is strongly suppressed. In the latter case, some mechanism to dominantly reheat the SM sector may be required.
