Received March 1, 2012; Accepted June 12, 2012

We examined whether feeding high hydrogen generating resistant starch could suppress subacute hepatic ischemia-reperfusion injury. Rats were fed a control diet with or without 20% high amylose cornstarch (HAS) supplementation for 14 days. On day 12, rats were subject to ischemia-reperfusion treatment. Portal hydrogen concentration was higher in the HAS group compared with the control group. Increased plasma alanine and aspartate aminotransferase activities due to ischemia-reperfusion treatment tended to decrease, and a significant reduction was observed by HAS feeding when compared with the control group. In conclusion, HAS, which enhances hydrogen generation in the hindgut, alleviated subacute hepatic ischemia-reperfusion injury.

Key words: hydrogen; high amylose cornstarch; large intestine; ischemia-reperfusion; antioxidant

Oxidative damage is a cause of various diseases, such as ischemia-reperfusion (IR) injury, atherosclerosis and diabetes [1, 2]. Alleviation of oxidative damage is therefore considered an effective measure in preventing these diseases. Many researchers have been investigating the effectiveness of various antioxidants, such as ascorbic acid, tocopherols, polyphenols, and carotenoids against such diseases. Recently, the antioxidative effects of H² on other organs have been reported in IR-treated rodents administered H² via inhalation of H² gas or administration of H² water [3–9]. It is clear from these studies that H² is an effective antioxidant in vivo. Previously, we found that H² generated from high amylose cornstarch (HAS) and pectin by fermentation in the large intestine alleviated initial acute hepatic IR injury, which was induced by 45 min of reperfusion following 30 min of ischemia [10]. Also, the portal H² concentration in rats fed HAS and pectin was comparable to or more than in those administered H² via inhalation of H² gas [3] or administration of H² water [11]. Therefore, H² production via large-bowel fermentation is a continuous and available means of supplying significant amounts of H² in vivo. However, the effect of H² generated in the large intestine on subacute hepatic IR injury remains unclear.

Hepatic IR injury has been demonstrated to occur in a biphasic pattern: first, there is an initial acute phase characterized by hepatocellular damage and generation of reactive oxygen species at 1–6 hr, and then there is a subacute phase characterized by massive neutrophil infiltration and production of inflammatory mediators at 18–24 hr [12–14]. Many studies have demonstrated the effect of H² molecules on initial acute hepatic IR injury. However, to our knowledge, the effect of H² molecules, including H² generated by large intestinal fermentation, on oxidative stress in the subacute phase remains poorly understood. During the subacute phase of injury, the redox burden in damaged tissues is amplified by neutrophils, and then the injury worsens. Therefore, it is important to clarify the effect of H² generated in the large intestine on subacute hepatic IR injury. Increased urinary excretion of 8-hydroxy-2′-deoxyguanosine (8-OHdG), which is an oxidation product of guanine, is observed due to oxidative damage of DNA [15–17]. We presumed that urinary 8-OHdG could be used as a marker of subacute hepatic IR injury. In the present study, to determine the suppressive effect of resistant starch (RS) on subacute hepatic IR injury, we examined the effects of HAS, which results in production of more H² in the large intestine than pectin, on liver damage in a rat model of subacute hepatic IR.
High amylose cornstarch (Hi-maize 1043) was kindly supplied from Nippon NSC Ltd. (Tokyo, Japan). The study was approved by the Nayoro City University Animal Use Committee, and animals were maintained in accordance with the Guidelines for the Care and Use of Laboratory Animals, Nayoro City University. Seven-week-old male Sprague-Dawley rats were obtained from Japan SLC (Shizuoka, Japan). They were housed in individual cages with screen bottoms made of stainless steel in a room maintained at 23 ± 1°C with humidity ranging from 50% to 70% under lighting conditions with 12 hr of light and 12 hr of darkness, daily. The rats were acclimated by feeding a laboratory chow diet (CE-2, CLEA Japan, Inc., Tokyo) for 5–6 days in order to select high H2-generating (HG) rats before they were subjected to the experiments. After the acclimation period, net H2 excretion from expired air and flatus per 5 minutes was measured using a GC (Biogas analyzer BAS-1000, Mitleben, Osaka, Japan). Forty-nine rats were assigned into 4 groups (n = 12–13) so as to balance the net H2 excretion and body weight. Two groups were administered the C diet, and the remaining group was administered the 20% HAS diet for 14 days. The C diet was composed of 250 g/kg casein, 482.5 g/kg cornstarch, 100 g/kg sucrose, 70 g/kg soybean oil, 35 g/kg AIN-93G mineral mix [18], 10 g/kg AIN-93 vitamin mix [18], 2.5 g/kg choline bitartrate and 50 g/kg cellulose. On day 10, net H2 excretion was measured, and urine was collected for 2 days. On day 12, one C group and one HAS group underwent IR treatment. The remaining C and HAS groups were sham operated. Furthermore, urine was collected for 2 days after IR treatment and sham operation. Under pentobarbital sodium anesthesia (70 mg/kg ip), the hepatic artery and portal vein to the left lateral and median lobes were occluded to interrupt blood supply to the liver for 30 min, and then reperfusion was initiated at 37°C. Rats were euthanized at 48 hr after reperfusion for sampling. Sham-operated rats were prepared in a similar manner except without vascular occlusion. One-milliliter samples of blood from the portal vein were successively collected into sealed heparin vials and microtubes for H2 analysis and plasma preparation. A 1 ml sample of the gaseous phase was withdrawn using a gas-tight syringe, and the H2 concentration was determined using GC (Biogas analyzer BAS-1000). The remaining blood was separated by centrifugation (1,200 × g for 20 minutes at 4°C), and plasma samples were stored at –80°C. The liver was perfused immediately after blood withdrawal with cold saline. Immediately after perfusion, the median lobe (ischemic area) was removed, and a portion was rapidly frozen in liquid nitrogen; the samples were then stored at –80°C until oxidative stress analyses. Activities of alanine and aspartate aminotransferase (ALT and AST) in plasma were measured using a commercial kit (Transaminase CII-test Wako, Wako, Tokyo, Japan). Reduced hepatic glutathione (GSH) and oxidized glutathione (GSSG) levels were determined using the method of Anderson [19]. The malondialdehyde (MDA) concentration in the liver was measured according to the procedure of Ohkawa et al. [20]. Hepatic activity of superoxide dismutase (SOD) and myeloperoxidase (MPO) was determined by the method of Sun et al. [21] and Krawisz et al. [22], respectively. Urine 8-OHdG content was measured using a commercial ELISA kit (Highly Sensitive 8-OHdG Check ELISA; Nikken SEIL Co., Ltd, Fukuroi, Japan). Allantoin and creatinine excretion in urine were determined by the methods of Young and Conway [23] and Bonsnes and Taussky [24], respectively. Values obtained from the experiments were expressed as means ± SEM. Data were subjected to Bartlett’s test for homogeneity of variances. For samples with equal variances, one-way ANOVA was used, followed by the Tukey-Kramer post hoc test for multiple comparisons between individual group means. If sample variances were unequal, we used the Steel-Dwass test [plasma ALT and AST activities, net H2 excretion and portal H2 concentration]. Furthermore, to examine the possible role of cecal H2 in alleviating oxidative stress, we used the Mann-Whitney U test using only IR rat data for plasma ALT and AST activity analyses. The Tukey-Kramer test and Mann-Whitney U test were performed using the SAS JMP software (version 8.0.1; Tokyo, Japan), and the Steel-Dwass test was performed using KyPlot (version 5.0; KyensLab Inc, Tokyo, Japan). Significance was defined as a p < 0.05.

In the first 12 days of the experimental period, body weight gain and food intake did not differ among the groups (Table 1). However, body weight gain and food intake from days 13–14 of the experimental period were lower in the IR rats compared with the sham-operated rats. Net H2 excretion on day 10 and portal H2 concentration on day 14 were about 10-fold and 5-fold higher in rats from the HAS group compared with those in the C group, respectively. Plasma ALT and AST activities were significantly higher in the IR-C group compared with the sham group. Plasma ALT and AST activities in the IR-HAS group tended to decrease, and a significant reduction was observed in the IR-HAS group compared with the IR-C group (p = 0.0725 and 0.0167), respectively. Urinary excretion of 8-OHdG corrected with creatinine on days 11–12 and days 13–14 did not
differ among the groups (Table 2). Urinary excretion of allantoin, which is a metabolite of purine bodies, corrected with creatinine also did not change among the groups. No significant differences in SOD activity, glutathione concentration and MDA concentration were observed. Significant differences were observed in hepatic MPO activity between the groups (Table 3). These parameters are related to oxidative stress and inflammation. Hepatic MPO activity was higher in IR rats compared with sham-operated rats, but no significant effect was observed by HAS feeding.

Plasma ALT and AST activities are used clinically as a marker of hepatic injury. In the present study, low plasma ALT and AST activities in IR rats fed the HAS diet were observed compared with those fed the control diet. Therefore, it is possible that hepatic injury was alleviated by H₂ molecules generated in the large intestine. H₂ generated in vivo should relieve hepatic IR injury in the subacute phase as well as the initial acute phase. We previously found that pectin and HAS increase cecal H₂ production and relieve initial acute hepatic IR injury in rats [10]. Recently, many studies have reported that H₂ molecules exert an antioxidant effect in vivo. Ohsawa and his collaborator demonstrated the alleviation effect of H₂ gas on IR injury of the brain [3], liver [5] and heart [4]. Furthermore, a similar effect was shown for the myocardium and intestine [25, 26] via administration of H₂-rich saline. In the liver, IR injury has been demonstrated to occur in a biphasic pattern: an initial acute phase characterized by hepatocellular

damage at 3–6 hr and a subacute phase characterized by massive neutrophil infiltration at 18–24 hr, [12, 13], which is similar to the conditions used in our present experiment. However, the effect of H2 molecules, including H2 generated by large intestinal fermentation on oxidative stress in a subacute phase, remains poorly understood. Our present study is the first to demonstrate the suppressive effect of H2 on hepatic IR injury in the subacute phase.

Plasma ALT and AST activities after 48 hr of reperfusion in the present study were lower than after 24 hr of reperfusion in our previous study [10]. This may indicate that the liver had recovered from injury due to relieved oxidative stress during the 24–48 hr period of reperfusion. The production of reactive oxygen species by neutrophils exacerbates inflammation [27]. Hepatic MPO activity, which indicates the presence of neutrophils, was higher after 48 hr of reperfusion due to the IR treatment. This result was consistent with the report of Kawaguchi et al., in which the hepatic MPO content after 48 hr of reperfusion was shown to be high due to IR treatment [28]. However, in the present study, HAS feeding had no significant effect on hepatic MPO activity. Because H2 exerts an antioxidant effect in the initial acute phase, the effect of H2 generated from HAS in the subacute phase may be dependent on low inflammation in the initial acute phase. That is, the migration and infiltration of neutrophils may occur less frequently during low inflammation in the initial acute phase. A few studies have reported the relationship between large intestinal fermentation and liver MPO activity; however, further study, including histological evaluation, is required to evaluate the effect of H2 derived from dietary fiber and HAS in the subacute phase on recruitment of neutrophils. Also, oxidative stress markers (hepatic glutathione, MDA levels and SOD and MPO activities) were not affected by HAS feeding. When rats were subjected to IR treatment (reperfusion time, 15 min–24 hr), the oxidative stress markers were altered, as an oxidative status was caused. This discrepancy is likely to be caused by the different reperfusion times. HAS might have no effect on these markers in this study because the rats had enough time to recover from oxidative stress. In this study, we also examined whether HAS feeding inhibited urinary excretion of 8-OHdG, which is an oxidation product of guanine, in IR rats. Increased urinary excretion of 8-OHdG is observed due to oxidative damage of DNA, caused by various factors such as brain IR [15], diabetes [16, 17] and atherosclerosis [17]. Unfortunately, no change in the urinary oxidation product could be detected as a result of IR and HAS treatment in the present study. We used urine collected during the 0–48 hr period of reperfusion, and it included urine samples collected during the 0–24 hr period of reperfusion. Urine collected between 0–24 h may exhibit a change in 8-OHdG excretion due to IR treatment and HAS.

In conclusion, we found that high H2 generating HAS alleviated subacute hepatic IR injury as well as initial acute IR injury. However, various substances such as short-chain fatty acids as well as H2 are produced by fermentation in the large intestine. Therefore, further study is required to evaluate the effect of H2 derived from dietary fiber and RS in the large intestine on the subacute phase.
