Abstract Platelets buoy up cancer metastasis via arresting cancer cells, enhancing their adhesion, and facilitating their extravasation through the vasculature. When deprived of intracellular and granular contents, platelet decoys could prevent metastatic tumor formation. Inspired by these, we developed nanoplateletsomes by fusing platelet membranes with lipid membranes (P-Lipo) to restrain metastatic tumor formation more efficiently. It was shown nanoplateletsomes bound with circulating tumor cells (CTC) efficiently, interfered with CTC arrest by vessel endothelial cells, CTC extravasation through endothelial layers, and epithelial-mesenchymal transition of tumor cells as nanodecoys. More importantly, in the mouse breast tumor metastasis model, nanoplateletsomes could decrease CTC survival in the blood and counteract metastatic tumor growth efficiently by inhibiting the inflammation and suppressing CTC escape. Therefore, nanoplateletsomes might usher in a new avenue to suppress lung metastasis.

1. Introduction

Though surgical excision and adjuvant therapy can cure well-confined primary tumors, metastatic disease is almost remediless owing to its systemic nature and the resistance of disseminated tumor cells to existing therapeutic agents, accounting for over 90% of cancer-associated mortalities. The progression of much fatal metastasis is spawned by the vascular dissemination of tumor cells, which are also termed as circulating tumor cells (CTCs) and act as harbingers of this process. CTCs that have been shed into the vasculature may contribute to the aggressive metastasis and decreased time of relapse, generating micro-metastasis with markedly different biology from that of the primary tumor. However, compared with the primary tumor, the pathophysiological characteristics of metastatic tumors are less informative and the corresponding treatment strategies are less available due to the heterogeneity within the CTCs. In this context, there is an urgent demand to propose specific preclinical or clinical strategies targeting the early treatment of metastasis in real time.

To date, CTCs have been explored as predictive biomarkers for early prognosis, recurrence risk assessment, and therapeutic monitoring of metastasis. Although several immunocytological technologies, molecular technologies, along with functional assays, have been proposed for CTC detection to indicate the effectiveness of cancer treatment, limited studies based on CTC elimination or inactivation in vivo at the pre-metastasis stage were reported, which is an overarching challenge to be resolved. Hence, it is of great significance to eliminate CTCs or blunt their metastatic ability, yielding a lower possibility of tumor recurrence and metastasis.

Platelets play a profound role in the whole tumor metastasis cascade, including the detachment and dissemination of tumor cells into the blood, the facilitation of the epithelial-to-mesenchymal transition, the generation of the CTC cluster, along with the subsequent metastatic niche. Equipped with a plethora of adhesion receptors, when cancer cells detach and invade into the bloodstream as CTCs, platelets can be activated and attach to cancer cells to generate a protective cloak that helps cancer cells to escape immune surveillance and high shear stress from the bloodstream, seed in distant organs and provide aid along with the subsequent metastatic niche. Platelet membranes express many components that regulate cancer cell adhesion, immune evasion and metastasis, such as P-selectin, PECAM-1, GPIIb/IIIa, GPIb/IX, TLR4, etc. Therefore, drugs or nanomedicines interrupting platelet-CTC interactions may weaken the metastatic ability of CTCs and prevent the formation of tumor metastasis.

Recently, cell membrane-bioinspired nanotherapeutics based on cell–cell interaction have been extensively developed and harnessed for various biomedical applications, such as red blood cell-derived nanoparticles for immune evasion and antigen delivery, or detoxification, leukocyte-derived nanovesicles for anti-inflammatory or tumor-targeted therapy, and platelet membrane-coated nanoparticles for targeted antitumor drug delivery. Cell membrane-bioinspired nanotherapeutics essentially mimic the properties of the source cells from which their membrane originates, conferring a wide range of functions, such as long circulation and disease-targeting. To this end, these biomimetic nanotherapeutics have opened up new avenues to overcome the limitations of current nanotherapeutics, enhance their targeting capability without inducing immune responses. Inspired by the intrinsic properties of platelets and their interactions with CTCs, platelet membrane-based biomimetic nanotechnology has been explored for CTC detection and tumor metastasis treatment. For instance, platelet membrane-clad microchips and platelet-leukocyte hybrid membrane-coated magnetic cores have been employed for CTC separation and detection. In general, two biomimetic strategies have been explored to restrain the metastatic formation or treat tumor metastasis. One strategy is eliminating CTCs by using platelet membrane-coated nanovehicles or microparticles loaded with drugs such as TRAIL, doxorubicin (Dox), etc. These biomimetic drug-loaded nanovehicles could actively target CTCs, kill them and inhibit metastatic tumor formation. The other strategy is platelet decoy strategy by disrupting the interactions between CTCs and platelets. Recently, Ingber’s group has employed platelet decoys by denuding the platelet innards to interfere with platelet-mediated CTC aggregation and inhibit metastatic tumor growth after coinjection with tumor cells and platelets. Nevertheless, the anti-metastasis efficacy is moderate and a large amount of platelet decoys have to be coinjected with platelets to retard metastatic formation. In addition, the preparation of platelet decoys without activating platelets is a challenging. Moreover, the stripped-down platelets are plagued by a limited half-time, thus decreasing their usefulness in the patients. Therefore, biomimetic decoys with high anti-metastasis efficacy, long circulation, fewer platelet resources, and easy production process are urgently needed to blunt CTCs for metastasis treatment.

In this work, we leveraged this platelet-CTC interaction to constitute nanoplateletosomes to actively target CTCs and treat metastasis as nano-platelet decoys. The nanoplateletosomes were developed by fusing natural platelet membranes with synthetic lipid membranes (P-Lipo) through extrusion and taking advantage of both biomaterials. We hypothesized that P-Lipo could provide functional cell surface receptors, which retained their binding capabilities with CTCs or pre-metastasis but were deprived of their intrinsic functional abilities, such as aggregation and activation, to facilitate CTC colonization and extravasation. Featuring the large surface-volume ratio and large quantity, nanoplateletosomes would greatly encase CTCs while not offering a shield against the immune cells. The subversion of the host immune responses was prevented, leading to a remarkable inhibition effect toward the generation of premetastatic tumor cascade. The feasibility of our bioinspired nano-design to achieve enhanced CTC binding and micrometastasis targeting, and restrain CTCs to metastasize in distant tissues as nano-platelet decoys was validated. The anti-metastasis efficacy and underlying mechanism of nanoplateletosomes were investigated in a preclinical metastasis mouse model.

2. Materials and methods

2.1. Materials

1,2-Distearoyl-sn-glycero-3-phosphoethanolamine-N-[methoxy(polyethylene glycol)] (DSPE-PEG<sub>2000</sub>) and egg yolk lecithin...
(EPC, PL-100M) were purchased from AVT Pharmaceutical Tech Co., Ltd. (China). Prostaglandin E1 (PGE1) was purchased from MedChemExpress (USA). Protease inhibitor mini-tablets, Dulbecco’s modified Eagle medium (DMEM), Roswell Park Memorial Institute (RPMI) 1640 medium, penicillin and streptomycin (10,000 U/mL) were purchased from Thermo Fisher (USA). CD41/CD61 antibody (362802) was from BioLegend (USA). GPVI antibody (STJ192229) was from StJohnsLabs (UK). CD29 antibody (UUY0319031), CD49b antibody (CBDM011909A), and CD42b antibody (CANBO41909A) were from BD Biosciences (USA). CD62P antibody (AB6631) and CD63 antibody (ab134045) were from Abcam (UK). Fluorescence dyes 3,3’-dioctadecyloxacarbocyanine perchlorate salt (DiO), 1,1’-dioctadecyl-3,3’,3’-tetramethylindodicarbocyanine, 4-chlorobenzenesulfonate salt (DiD), 4’,6-diamidino-2-phenylindole (DAPI) were purchased from Meilunbio (China), and CFSE was from eBioscience (USA). Coumarin 6 and Rhodamine B were purchased from Sigma—Aldrich (USA). Rhodamine-conjugated dextran was purchased from Shanxi Xinyan Bomei Biotechnology Co., Ltd. (China). Omni-Easy™ Instant BCA protein assay kit was from

Scheme 1  Schematic illustration of the role of platelet in the whole tumor metastasis cascade. (A) Platelets-promoted tumor metastasis cascade. Platelets can be activated and attach to cancer cells to generate a protective cloak that helps cancer cells to escape immune surveillance and high shear stress from the bloodstream. Additionally, activated platelets could help circulating tumor cells (CTC) arrest by vessel endothelial cells, and CTC extravasation through blood vessels, and provide aid to metastatic lesion growth. (B) Nanoplateletsomes (P-Lipo) inhibit metastasis formation through active targeting and act as a decoy to inhibit the function of platelets. The designed P-Lipo could bind with CTCs, interfere with CTC arrest by vessel endothelial cells, CTC extravasation through endothelial layers, and epithelial-mesenchymal transition of tumor cells. More importantly, P-Lipo could decrease CTC survival in the blood and counteract metastatic tumor growth efficiently by inhibiting the inflammation and suppressing CTC escape.
EpiZyme (USA). EDTA, cholesterol, chloroform, and ethanol were purchased from Sinopharm (China).

2.2. Cells and animals

The 4T1 murine breast cancer cell line was purchased from the Cell Bank of the Chinese Academy of Sciences (Shanghai, China). Human umbilical vein endothelial cell (HUVEC), mouse 4T1 breast tumor cells, and 4T1 cells expressing green fluorescent protein (4T1-GFP) or luciferase (4T1-Luc) were bought from American Type Culture Collection (ATCC, USA). 4T1 and HUVEC cells were cultured in DMEM medium supplemented with 10% fetal bovine serum (FBS), streptomycin (100 U/mL), and penicillin (100 U/mL) at 37 °C in 95% air/5% CO2. 4T1-Luc and 4T1-GFP cell lines were cultured in Roswell Park Memorial Institute RPMI 1640 medium supplemented with 10% fetal bovine serum (FBS), HEPES (25 mmol/L), streptomycin (100 U/mL), penicillin (100 U/mL) at 37 °C in 95% air/5% CO2.

Female BALB/c mice aged 6 weeks were purchased from Shanghai SLAC Laboratory Animal Co., Ltd. and housed under specific-pathogen free conditions. All animal protocols were approved by the Animal Ethics Committee of Fudan University (Shanghai, China).

2.3. P-Lipo preparation

The platelet membrane was derived by a repeated freeze-thawing method as previously described40,41. Briefly, the whole blood collected from healthy BALB/c mice was centrifuged at 100 × g for 20 min (Thermo, USA) to separate platelet-rich plasma (PRP) from red blood cells and white blood cells. Afterward, PBS buffer containing 1 mmol/L EDTA and 2 mmol/L PGE1 was added to the PRP to prevent platelet activation during the extraction process. Platelets were obtained by centrifuging 1 mL of PRP at 800 g for 10 min (Thermo), were suspended in 1 mL of PBS containing 1 mmol/L of EDTA and mixed with protease inhibitor mini-tablets. Platelet membranes were derived by a repeated freeze-thaw process three times, collected by centrifugation at 10,000 × g for 10 min (Thermo), were suspended in 1 mL of water (1 U) for spare.

P-Lipo were prepared by the thin-film hydration method as described previously with minor modifications42–44. Briefly, 4 mg of EPC, 0.4 mg of DSPE-PEG2000, and 0.8 mg of cholesterol were dissolved in 5 mL of chloroform/ethanol mixture (1:1, v/v). The organic solvent was removed through a rotary evaporator at 45 °C for 60 min to form a dry, thin film. The film was hydrated with 0.4 U (P2-Lipo) or 1.6 U (P4-Lipo) of platelet membranes dispersed in 2 mL of PBS buffer. The suspensions were frozen and thawed for ten cycles. Afterward, the suspension was successively extruded through 800, 400, and 200 nm polycarbonate filters (Nuclepore™, Whatman, US) repeatedly by using a Liposome Extruder (HandExtruder™, Genizer, USA). Thus P2-Lipo (0.1 U of platelet membranes per mg of lipid membranes) and P4-Lipo (0.4 U of platelet membranes per mg of lipid membranes) were obtained. Liposomes were prepared as a control with the same method except that no platelet membranes were input.

2.4. Characterization of P-Lipo

Dynamic light scattering (DLS) was used to determine the particle size and zeta potential of P-Lipo using a Zetasizer Nano ZS (Malvern, UK). The morphology of P-Lipo was visualized using a transmission electron microscope (TEM, Tecnai G2S-Twin, FEI, USA) after staining with 2% uranyl acetate and cryogenic transmission electron microscopy (cyro-EM, 200 KV, FEI, USA) as previously described45,46.

2.5. Membrane fusion assay

To test the fusion of platelet membranes and artificial lipid membranes, a Förster resonance energy transfer (FRET) pair lipophilic dyes Coumarin 6 (C6, E6/E19 460/510 nm) and Rhodamine B (Rhb, E1/E19 565/590 nm) were employed. Fluorescence C6-labeled lipid membranes were prepared according to previously reported47. Briefly, EPC, DSPE-PEG, and cholesterol in chloroform/ethanol were spiked with 5.2 μg of C6 before evaporation to form a lipid film. Platelet membranes were labeled with Rhb by incubation with 2 mg/mL of Rhb for 3 min, washed twice to remove free dyes, and then resuspended in PBS buffer. C6-stained lipid membranes (2 mg) were added to 0, 0.25, 0.5, 0.75, 1 and 1.25 U of Rhb-labeled platelet membranes, respectively, followed by hydration, freeze-thaw process, and extruding through 800, 400, and 200 nm polycarbonate filters to facilitate the membrane fusion. The fluorescence emission spectrum of each sample was recorded from 450 to 700 nm at an excitation wavelength of 430 nm on a Cary Eclipse fluorescence spectrophotometer (Agilent, USA). FRET efficiency, defined as the proportion of the donor C6 that has transferred their excess energy to the acceptor Rhb, was calculated using the following equation as previously described as Eq. (1),45:

FRET efficiency(%) = \left(1 - \frac{F_{\text{DA}}}{F_{\text{D}}}\right) \times 100

(1)

where F_{\text{DA}} and F_{\text{D}} were the fluorescence intensities of the donor C6 in the presence and absence of the acceptor Rhb, respectively.

To visualize the membrane fusion more vividly, the colocalization of platelet membranes and lipid membranes was investigated at the single nanoparticle level and cellular levels, respectively. Two lipophilic dyes, DiO (E1/E19 488/501 nm) and DiD (E6/E19 643/665 nm) were employed to label platelet membranes and lipid membranes, respectively. Platelet membranes were labeled with 5 μmol/L of DiO according to the manufacturer’s protocol. The DiD-labeled lipid membranes were prepared as described above. The double-stained P-Lipo was prepared and visualized under a super-resolution microscope system (N-SIM, Nikon, Japan) with a 100 × oil objective. To obtain stable images, the samples were immobilized in 2% agarose to decrease their mobility. The mixture of DiD-labeled lipid membranes and DiO-labeled platelet membranes was treated as a control.

To further ascertain the colocalization of platelet membranes and lipid membranes in the nanoplateletsome, the double-stained P-Lipo were co-cultured with 4T1 cells for 1 h in an ice bath, washed with PBS, stained with DAPI, and then imaged under the confocal laser scanning microscope with a 63 × oil objective (CLSM, Zeiss LSM 710, Germany). The fluorescence colocalization was analyzed by Image J software.

2.6. Analysis of membrane proteins in P-Lipo

The protein content in P-Lipo was measured by BCA protein assay kit. The protein loading efficiency in P-Lipo after fusion was calculated as follows as Eq. (2):
Membrane proteins in P-Lipo were analyzed via sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE)\(^2\). In brief, samples with the same protein content were heated at 90 °C for 5 min, and separated on a 10% SDS-polyacrylamide gel at 120 V for 1 h, followed by Coomassie blue staining and imaging. Typical membrane proteins on P-Lipo were validated by Western blotting. Briefly, samples were separated by SDS-PAGE as described above, transferred to nitrocellulose membranes (PALL, USA), probed with primary antibodies for CD41/61, GPVI, CD42b, CD29, CD49b, CD62P, CD63, incubated with horseradish peroxidase (HRP)-conjugated secondary antibodies (R&D systems, USA), and detected using Immobilon\(^2\) Western Chemiluminescent HRP Substrate (Millipore, USA).

Proteomic analysis of P-Lipo was performed by label-free quantification proteomics technology to further illustrate the protein composition as previously described\(^3\),\(^4\),\(^6\) (refer to methods in the Supporting Information). To determine the orientation of membrane proteins on P-Lipo, P-Lipo was incubated with anti-CD61-gold conjugates (bs-0342R-Gold, Bioss, 1:5000) for 1 h at 37 °C using CD61 as a typical platelet membrane protein, passed through a Sepharose CL-4B column to remove free anti-CD61-gold conjugates, and then visualized under TEM (Tecnac G2S-Twin, FEI, USA) after staining with 2% uranyl acetate solution (551061, BD, 1:5000) for 30 min at room temperature, washed through dialysis (MWCO 3500 kDa) to remove free anti-CD62b-APC (551061, BD, 1:5000) for 30 min at room temperature, washed through dialysis (MWCO 3500 kDa) to remove free anti-CD62b-APC, and analyzed with flow cytometry (FCM, CytoFlex S, Beckman Coulter, USA). Lipo without staining with anti-CD62b-APC was used as a control.

2.7. **In vitro** CTC capture with P-Lipo

**In vitro** CTC capture with P-Lipo was investigated as previously described\(^9\). Approximately 1 × 10\(^6\) 4T1-GFP cells were resuspended in PBS or in the whole blood diluent to obtain an artificial CTC-containing blood sample. 100 μL of DiD-labeled P-Lipo or Lipo was added to this sample and incubated for 2 h at 4 °C under 100 rpm. The cells were washed three times with PBS and resuspended in PBS. Then, the CTC capture was observed by CLSM (LSM710, Carl Zeiss, Germany) or analyzed on a flow cytometer (CytoFlex S, Beckman Coulter). 4T1-GFP cells without treatment were treated as a control.

To investigate the binding mechanism of P-Lipo with CTCs, P\(^4\)Lipo was pre-incubated with P-selectin inhibitor heparin (20 U/mL\(^6\)) and fucoidan (50 μg/mL\(^6\)), respectively. Afterward, pre-treated DiD-labeled P\(^4\)Lipo were incubated with 4T1-GFP cells in the presence of these inhibitors for 2 h. After washing the cells with PBS twice, the fluorescence intensity of DiD in the cells was measured via FCM (CytoFlex S, Beckman Coulter).

2.8. **In vivo** CTC capture with P-Lipo

The CTC capture ability of P-Lipo in the blood vessels was monitored by **in vivo** FCM (IVFC, custom-built by Med-X Research Institute and School of Biomedical Engineering, Shanghai Jiao Tong University)\(^5\)\(^,\)\(^6\)\(^,\)\(^7\)\(^,\)\(^8\). In brief, 10\(^6\) CFSE-labeled 4T1 cells were injected intravenously (i.v.) via the tail vein to female BALB/c mice to mimic the CTC mouse model. Ten min later, the mice received an intravenous injection of DiD-labeled P-Lipo or Lipo (0.2 mg) and were anesthetized with 1% amobarbital by intraperitoneal injection. Afterward, the mouse was fixed on a glass plate, and the ear was glued to the glass panel with a maximum plane by glycerin. Major veins and arteries of the mouse ear were visualized under a CCD (charge-coupled device) camera, and an artery of 50–70 μm in diameter was selected for data acquisition. During acquisition, the fluorescence of CFSE-labeled 4T1 (510 ± 10 nm) and DiD-labeled P-Lipo (670 ± 20 nm) was excited by two lasers, 488 nm diode-pumped solid-state laser and 633 nm HeNe laser, respectively. When CFSE-labeled 4T1 or DiD-labeled Lipo or P-Lipo was passing through the slit of excitation light, the emitted fluorescence was collected by a photomultiplier tube (PMTs) and presented in the form of a peak. The data was analyzed using DT Measure Foundry. Each mouse was recorded for 10 min.

To further illustrate that P-Lipo could capture CTCs in the blood flow **in vivo**, real-time imaging of CTC capture was acquired with a spinning disk confocal microscope (SDC, SpinSR Olympus), which can provide fast, dual-color imaging to track CTCs in the vessel at a high flow rate. In brief, 10\(^6\) CFSE-labeled 4T1 cells were i.v. injected via the tail vein to female BALB/c mice. After 10 min, the mice received an intravenous injection of DiD-labeled P-Lipo (0.2 mg) and were anesthetized with 1% amobarbital by intraperitoneal injection. The mesenteric blood vessel was selected to track CTC capture and avoid the disturbing of the hair autofluorescence on the body surface. Two lasers (495 and 578 nm) were harnessed for fluorescence excitation, and two photomultiplier tube (PMT) detectors were used for the detection of CTC (519 nm) and P-Lipo (603 nm) fluorescence, respectively. The scanning speed was 4000 rpm with a 20 × objective lens. To avoid excessive burning of blood vessels by the laser, each mouse was recorded for 10 min.

2.9. **In vitro** CTC arrest inhibition by P-Lipo

To investigate the inhibition effect of P-Lipo on the CTC arrest by endothelial cells, Focht Chamber System 2 (FCS2®, Bioptechs Inc, USA) was built for flow cell imaging on inverted microscopes. To mimic the flowing CTC arrest in distant capillary beds, 50 × 10\(^6\) HUVECs were seeded in the lower coverslip and were exposed to the fluid flow containing 10 ng/mL of TNF-α for 12 h. 4T1-GFP cells were collected using trypsin digestion and resuspended in HBSS. Afterward, 4T1-GFP (1 × 10\(^6\) mL) and P-Lipo (or Lipo, 20 μg/mL) were filled into the syringes and connected to the FCS2 chamber via a three-way valve. A constant flow rate was generated by a syringe pump. Once the flow was generated, a high-speed video of moving 4T1-GFP cells was recorded using a trinocular inverted fluorescence phase-contrast microscope (Olympus×71, Japan). After 10 min perfusion, the picture of 4T1-GFP latched onto HUVECs was also gathered and the number of 4T1-GFP was analyzed using ImageJ.

2.10. **In vitro** CTC extravasation inhibition by P-Lipo

CTC extravasation across the vascular endothelial cells **in vitro** was evaluated by a transwell culture system\(^5\)\(^,\)\(^6\). Briefly, 30 μL of ice-cold matrigel (Corning) was added to a 24-well transwell insert and solidified at 37 °C for 30 min to form a thin gel layer.
5 \times 10^4 \text{HUVECs} were added into the pre-coated insert, cultured overnight to form an endothelial monolayer, and pretreated with 10 ng/mL of TNF-α for 12 h. Afterward, 10^4 4T1-LUC cells and P-Lipo (or Lipo) (20 μg/mL) suspended in 200 μL of serum-free medium were added in the upper chamber. 600 μL of RPMI-1640 medium containing 20% calf bovine serum was added carefully in the lower chamber. After 12 h incubation, upper chambers were washed with PBS and scraped twice to remove the remaining cells. The transwell insert was immersed in α-luciferin (150 μg/mL), and bioluminescence imaging of the transwells was recorded using an In Vivo Imaging System (PerkinElmer, USA). Then the insert was immersed in 70% ethanol for 10 min to fix the migrating cells through the insert. After drying, the cells were stained with 0.1% crystal violet for 30 min followed by washing with PBS to remove excess dye. Images of cells were taken by an Olympus x71 inverted microscope (Japan). The cells in the donor wells were fixed and stained with crystal violet, as described above. Afterward, the crystal violet in the donor well was eluted using 33% acetic acid and quantified by measuring the OD_{570} nm with a microplate reader (Biorad, USA).

### 2.11. Wound healing inhibition by P-Lipo

To investigate the inhibition effect of P-Lipo on platelet-promoted wound healing of tumor cells, 4T1 cells were seeded into 6-well plates at a density of 10^6 cells per well and cultured at 37 °C in 5% CO2 overnight. Confluent cells were scratched and incubated with PBS, Lipo, P^ plates, and P^Lipo (20 μg/mL) in the presence or absence of platelets (5 \times 10^9/mL) for 12 h at 37 °C. Then the cells were imaged at different time points using an Olympus IXpolor Standard inverted microscope (Japan) and percentage of the scratch area repopulated was calculated using ImageJ software.

To investigate the effect of P-Lipo on platelet-promoted epithelial-mesenchymal transition (EMT) in tumor cells, 4T1 cells were not scratched but treated with PBS, Lipo, P^ plates, and P^Lipo in the presence or absence of platelets as described above. The morphology of 4T1 cells was observed under an Olympus IXpolor Standard inverted microscope (Japan). Afterward, the cells were collected and lysed in a lysis buffer for 30 min on ice. The protein concentration in these samples was measured by a BCA kit. 20 μg of protein samples were separated by SDS-PAGE, transferred to PVDF membranes (Merck) as described above. The membranes were then blocked with protein-free rapid blocking buffer (1×) for 10 min and probed with primary antibodies specific for E-cadherin (GB11868, Servicebio, 1:500), N-cadherin (GB111273, Servicebio, 1:500), Vimentin (GB111192, Servicebio, 1:500), and β-actin (GB12001, Servicebio), followed by staining with horseradish peroxidase (HRP)-conjugated secondary antibodies (GB23303, Servicebio, 1:5000). The signals were visualized using ECL Plus reagents (EpiZyme) under the FluorChem™ M imaging system (ProteinSimple, USA) and quantified using ImageJ software.

### 2.12. In vivo imaging of P-Lipo in lung pre-metastasis

**In vivo** imaging of P-Lipo (or Lipo) in pre-metastasis niches was investigated as previously reported. Each female BALB/c mouse (18–20 g) was injected with 10^6 4T1-LUC cells (200 μL) via the tail vein. Fifteen minutes later, mice were intravenously injected with DiD-labeled P-Lipo (or Lipo) at the lipid dose of 10 mg/kg. The ventral hair was removed using hair removal cream. Two hours later, each mouse received an intraperitoneal injection of 100 μL of α-luciferin at the dose of 150 mg/kg. **In vivo** bioluminescence imaging (BLI) and fluorescence imaging (FLI) were acquired using the IVIS Spectrum (PerkinElmer, USA) 10 min post α-luciferin injection. Afterward, the mice were sacrificed and major organs including the heart, the liver, the spleen, the lung, the kidney, and the brain of mice were harvested. BLI and FLI were performed using the IVIS Spectrum as described above. All quantitative measurements of BLI and FLI signals were obtained using the Living Image v. 4.3 software (PerkinElmer, USA).

### 2.13. Ex vivo imaging of P-Lipo in lung pre-metastasis

The ex vivo imaging of lung metastasis was created as previously reported. Briefly, 10^6 4T1-GFP cells (200 μL) were injected into each BALB/c mouse (18–20 g) via the tail vein. Fifteen minutes later, the mice were intravenously injected with DiD-labeled P-Lipo (or Lipo) at the lipid dose of 10 mg/kg (equal to 10 μg/kg of DiD). To visualize lung capillaries, 100 μL of 70 kDa rhodamine-conjugated dextran (4 mg/mL) was injected via the tail vein. Afterward, the mice were injected with a lethal dose of 1% pentobarbital sodium (i.p.) and mounted on anatomical plates. Surgical scissors were utilized to cut the skin and expose the tracheal. 500 μL of 37 °C 2% low-melting-temperature agarose was injected into the lungs via the trachea until the lungs were inflated. After agarose cooling, the inflated lungs were separated from the mouse and immersed in warm RPMI-1640 to wash off excessive blood. Later on, inflated lungs were immersed into DAPI solution (2 μg/mL in PBS) for 15 min, washed with PBS three times at room temperature. The lobes were separated with scissors and placed into the 24-well imaging plate with the flat surface down to maximize the imaging surface. 100 μL of 37 °C RPMI-1640 was added on top of the lobes, and 15-mm circular microscope cover slides were placed on top of the lobes to prevent it from floating. Imaging was acquired with a spinning-disk confocal laser scanning microscopy (LSCM, A1R HD25, Nikon, Japan).

### 2.14. Anti-metastasis efficacy of P-Lipo

To test the efficacy of P-Lipo on the progression of metastasis, 10^4 4T1-LUC or 4T1-GFP cells suspended in 100 μL of PBS were injected into BALB/c female mice via the tail vein. Then 100 μL of P-Lipo or Lipo (0.2 mg) were intravenously injected via the tail vein at 15 min after 4T1-LUC or 4T1-GFP injection. For 4T1-GFP mouse models, blood was sampled from the mouse eyes on Day 3 after treatment. The blood was treated with red blood cell (RBC) lysis buffer for 5 min on ice to lyse RBCs, and subjected to FCM (CytoFlex S, Beckman Coulter) to monitor 4T1-GFP cells. For 4T1-Luc mouse models, **in vivo** bioluminescence imaging was conducted every 5 days for 15 days to monitor tumor metastasis growth with the IVIS Spectrum (PerkinElmer, USA). BLI was recorded at 10 min after intraperitoneal injection of α-luciferin (150 mg/kg) every time. Fifteen days after treatment, blood was sampled from mouse eyes and blood routine examination was performed by an auto hematology analyzer (BC-2800vet, Mindray, China). Afterward, the mice were sacrificed, and lungs were collected. Lungs were sliced, subjected to hematoxylin-eosin (H&E) and Ki67 staining according to the manufacturers’ protocols, and observed using an Olympus VS200 Research Slide Scanner (Japan). Besides, main organs, including the heart, the
liver, the spleen, and the kidney, were collected for H&E staining according to the routine protocols.

2.15. Anti-tumor immune response of P-Lipo

To test the anti-tumor immune response of P-Lipo treatment, 10⁴ 4T1-LUC cells were injected into BALB/c female mice and treated with P-Lipo as described above. Blood was sampled from the submaxillary veins at different time points after treatment, treated with RBC lysis buffer, blocked with 5% FBS followed by staining with fluorescent antibodies, and then subjected to a CytoFlex S flow cytometer (Beckman Coulter) for immune cell detection. For T cell detection, blood samples were stained with anti-CD45-PerCP-Cy5.5 (eBioscience, 45-0451-82, 1:500), anti-CD4-FITC (BD, 553650, 1:500), anti-CD8a-PE-Cy7 (eBioscience, 14-0081-82, 1:250) antibodies. For myeloid-derived suppressor cell (MDSC) detection, blood samples were stained with anti-CD45-PerCP-Cy5.5 (eBioscience, 45-0451-82, 1:500), anti-CD11b-FITC (eBioscience, 17-0112-80, 1:500) and anti-Gr1-PE (BD, 553128, 1:500) antibodies. For macrophage detection, blood samples were stained with anti-CD45-PerCP-Cy5.5 (eBioscience, 45-0451-82, 1:500), anti-F4-80-FITC (Biogeneg, 123108, 1:500), anti-CD86-Super bright 600 (Invitrogen, 63-0862-80, 1:500), and anti-CD206-APC (Biogeneg, 141708, 1:500) antibodies.

2.16. Statistical analysis

Data were presented as mean ± Standard deviation (SD). Unpaired Student’s t-test was applied for statistical analyses between two groups, and one-way ANOVA with Tukey post-hoc analysis was used for multiple group comparison. Statistical differences were defined as *P < 0.05, **P < 0.01, and ***P < 0.001. The abbreviation “ns” indicated no significant difference between two groups.

3. Results and discussion

3.1. Preparation and characterization of P-Lipo

P-Lipo was prepared by fusing platelet membranes with artificial lipid membranes, as illustrated in Fig. 1A. Platelets were extracted from the blood of BALB/c mice, which were pre-mixed with heparin to prevent clotting. The adding of prostacyclin E1 (PGE1) and protease inhibitor mini tablets could inhibit the activation of platelets and facilitate platelet resuspension during platelet isolation⁶⁰,⁶¹. The optical microscopy images of the whole blood and extracted platelets were shown in Supporting Information Fig. S1. The extracted platelets had high purity and biconvex discoid structures, 2–3 μm in greatest diameter, and belonging to unactivated platelets. Platelet membranes were deviated by three freeze-thaw cycles and collected by high-speed centrifugation. Meanwhile, a thin artificial lipid film was formed in a round-bottom flask by the removal of organic solvent. The platelet membranes were then added into the flask to hydrate the lipid membranes and fused with the lipid membranes to generate homogenous P-Lipo after a freeze-thaw and extrusion process.

The morphology of P-Lipo under TEM and cryo-EM was shown in Fig. 1B. Compared with the mixture of platelet membranes and lipid membranes, P-Lipo showed a completely different morphology. Before the fusion process, the mixture had an irregular shape and was not of uniform size. After the fusion process, spherical vesicles with a size range of 90–120 nm were formed. Negatively stained P-Lipo appeared a dark halo (indicated with blue arrows) around it that was not present on the Lipo. This halo was similar to that of cell membrane-coated nanoparticles, and it was not present on the non-coated nanoparticles either⁶². Cryo-EM images reserve the most native state and avoid interference from staining artifacts associated with traditional TEM. From cryo-EM images, we could see spherical unilamellar (yellow arrow) and some multilamellar vesicles (red arrow) were present in P-Lipo after fusion. Compared with the Lipo, spherical P-Lipo were decorated with black dots (indicated with light green arrows) similar to those seen in the mixture, indicating that the membrane proteins were possibly embedded into the lipid bilayer of P-Lipo⁶³. TEM and Cryo-EM results demonstrated that platelet membranes were composed of vesicles of different shapes and different sizes (Supporting Information Fig. S2). In the absence of extrinsic lipids, platelet membranes consisted of typical phospholipid bilayers and a particularly thick (15–20 nm) glycoaly⁶⁵ were very difficult to be extruded through the polycarbonate membranes serially and most membrane proteins (>80%) were trapped in the membranes, especially after passing through 0.2 μm polycarbonate membranes. We could not obtain platelet membrane vesicles with similar size to P-Lipo. Thus, in subsequent experiments, platelet membrane vesicles were not included.

The fusion of platelet membranes and artificial lipid membranes was validated by FRET. Artificial lipid membranes and natural platelet membranes were labeled with FRET donor C6 and acceptor RhB probes, respectively. The donor C6 is excited at a maximal wavelength of 460 nm and emits fluorescence at 510 nm. The acceptor RhB is excited at 565 nm and emits at 590 nm. Energy transfer occurs due to the spectral overlap between the emission spectrum of the donor and the excitation spectrum of the acceptor and the spatial distance of the FRET pairs (RhB-C6) close enough once they are fused (Supporting Information Fig. S3A and S3B). FRET between donor and acceptor fluorophores decreases the donor fluorescence and increases the acceptor fluorescence. As shown in Fig. 1C, the fluorescence spectra of P-Lipo demonstrated an increase of the fluorescence signal at 590 nm (RhB) and a decrease at 495 nm (C6) when increasing the input of platelet membranes. The results suggested that the RhB-labeled platelet membranes were fused with C6-labeled lipid membranes successfully. To quantify the FRET effect, FRET efficiency was calculated. FRET efficiency in P-Lipo was increased with the input of platelet membranes (Fig. S3C and S3D). Approximately 90% of FRET efficiency was obtained when 1.25 U of platelet membranes was fused with lipid membranes. This observation confirmed the successful fusion of platelet membranes with lipid membranes.

To further confirm the membrane fusion, the colocalization of platelet membranes and lipid membranes in P-Lipo was observed by a super-resolution microscope which provided molecule-specific information at the single-nanoparticle level. As shown in Fig. 1D, DiO-labeled platelet membranes (green) and DiD-labeled lipid membranes (pinkish-red) largely stayed separately in the mixture before extrusion. After extrusion to form P-Lipo, almost all platelet membranes were overlayed with lipid membranes suggesting that platelet membranes were successfully fused into lipid membranes.

The fusion of platelet membranes and lipid membranes was also confirmed through the binding between P-Lipo and tumor cells (Fig. 1E). It was found that DiO-labeled platelet membranes were colocalized with DiD-labeled lipid membranes on the surface of 4T1 cells, indicating that P-Lipo was composed of both

(C) Transmission electron microscopy images of P-Lipo probed with anti-CD61-gold, followed by negative staining with 2% uranyl acetate (scale bar = 50 nm). (D) Flow cytometry histograms of CD42b expression on the surface of P-Lipo. Unstained Lipo functioned as a negative control. (E) Venn diagram of identified proteins of P-Lipo and platelet membranes (PM) analyzed by liquid chromatography-tandem mass spectrometry. (F) Venn diagram of identified proteins extracted from P-Lipo by cellular component. (G) Functional characterization of the platelet membrane proteins identified in P-Lipo by biological process. (H) A heat map depicting the typical membrane protein levels (normalized to array reference) from P-Lipo and PM.
The apparent binding of P-Lipo to tumor cells also laid the foundation to explore the targeting of P-Lipo to CTCs.

The diameter size and zeta potential of P-Lipo were measured by DLS. The incorporation of platelet membranes into lipid membranes induced a slight reduction of the average diameter of the resulting P-Lipo, from 121.4 ± 1.4 nm (Lipo) to 111.7 ± 0.4 nm (PL-Lipo) and 102.1 ± 0.9 nm (PH-Lipo), respectively (Fig. 1F). The intensity-based particle size and the zeta potential of platelet membranes were 589 ± 35 nm and −27.1 ± 1.3 mV, respectively. The polydispersity index (PDI) of platelet membranes was 0.775 ± 0.040, indicating platelet membranes had a broad size distribution. This size change is different from cell membrane-coated PLGA nanoparticles, which always exhibit an increase in diameter after cell membrane coating on nanoparticles, but is similar to cell membrane protein-incorporated lipid nanovesicles. The possible cause of this result is that the artificial liposomes and platelet membranes are soft and deformable, and platelet membranes or cell membrane proteins could be easily incorporated into liposomes. On the contrary, PLGA nanoparticles have solid cores, and cell membranes could only be coated on them. The PDI values of both Lipo and P-Lipo were less than 0.2 (Fig. 1G), revealing a high size homogeneity for these liposomes. These results were consistent with TEM and cryo-EM analysis. Compared with Lipo (−41.5 ± 0.4 mV), P-Lipo presented an increase in zeta potential, increasing to −32.8 ± 0.4 mV (PL-Lipo) and −22.9 ± 0.6 mV (PH-Lipo) (Fig. 1H). The increased zeta potential of P-Lipo was attributed to the shielding effect of the membrane proteins towards the negative charge of the phosphate groups. When stored at 4 °C for up to 7 days, both P-Lipo and Lipo showed minor size change (Fig. 1I), indicating that P-Lipo had superb stability in PBS.

3.2. Analysis of membrane proteins in P-Lipo

To examine the platelet membrane content in P-Lipo, membrane protein content in P-Lipo was analyzed using a BCA assay. As shown in Supporting Information Fig. S4A, around 93% of platelet membranes were fused into PL(Lipo), while 63% of platelet membranes were found in PH-Lipo. Part of platelet membranes could be rejected by the polycarbonate filters during the extrusion process when the platelet membrane input increased. The retention of membrane proteins on P-Lipo was further investigated by SDS–PAGE (Fig. 2A). Almost all of the protein bands of platelet membranes can be found in the P-Lipo group.

Untreated CTC-containing blood served as a control.
protein bands were found in the Lipo group. These results indicated most kinds of membrane proteins were retained in P-Lipo after platelet membranes were fused with lipid membranes.

There are platelet surface cluster of differentiation (CD) antigens before activation, like CD41, CD42c, CD42b, and CD61. CD antigens such as CD31, CD62P (P-selectin), and CD63 appeared on the platelet surface during activation. CD41/61, also named GPIIb-IIIa or aIIb, could bind plasma proteins, such as fibrinogen, fibronectin, von Willebrand factor (vWF), and vitronectin, and plays a critical role in platelet aggregation and adhesion, promote

Nanoplateletsomes restrain metastatic tumor formation in a preclinical mouse model
tumor cell metastasis. GPVI (GP6) and CD42 (GPIIb), are known as platelet membrane glycoproteins. GPVI participates in collagen-induced activation and aggregation. CD42b involves platelet adhesion and recovery from vascular injury, especially under high shear blood flow, and promotes tumor cell metastasis. CD29 (ITGB1) and CD49b (ITGA2) are integrins, also known as platelet adhesion CD antigens, widely expressed on platelet surfaces. Western blot analysis confirmed the presence of the platelet-related surface proteins CD41/61, GPVI, CD42b, CD29, CD49b, CD62P, and CD63 on P-Lipo. The results indicate that platelet membranes were derived from partly activated platelets, and platelets were broken and partly activated during repeated freeze-thaw circles.

Immunolabelling with antibodies directed against the extracellular domain of membrane proteins was explored to confirm the orientation of platelet membrane proteins in P-Lipo. As shown in

3.3 Precise CTC capture by P-Lipo in vitro and in vivo

Precise CTC capture by P-Lipo in vitro and in vivo

It is generally believed that platelets serve as physical shields from blood shear and natural killer (NK) cells attack, and enhance tumor metastasis by binding to CTCs. Therefore, we propose the hypothesis that P-Lipo may possess similar functionalities of CTC binding. CLSM and FCM were used to evaluate P-Lipo binding with cancer cells in vitro. As expected, significantly more P-Lipo bound with 4T1-GFP when compared with Lipo, whether in PBS (Supporting Information Fig. S5) or in the artificial CTCs-containing blood environment (Fig. 3A). In the artificial CTCs-containing blood, notable P-Lipo adhered to the surface of tumor cells, especially, and barely latched onto the surface of blood cells, including RBC, white blood cell (WBC), and platelets (Fig. 3A). Scanning electron microscopy (SEM) images revealed that numerous P-Lipo adhered onto the surface of 4T1 cells, but very few Lipo were observed on 4T1 cells (Fig. 3B). Further quantitative analysis by FCM showed that the mean fluorescence intensity of DiD-labeled P-Lipo and P4-Lipo adhered on 4T1-GFP cells was 1.6- and 3.7-fold of that on Lipo (Fig. 3C and D). When DiD-labeled P-Lipo was incubated with 4T1-GFP cells in PBS, the fluorescence intensity of P-Lipo and P4-Lipo bound on 4T1-GFP cells saw growth rates 2.9 and 3.8 times, respectively, compared with that of Lipo (Fig. S5). These results suggest that P-Lipo had a higher CTC capture ability than Lipo.

To investigate which membrane proteins were involved in the adhesion between P-Lipo and CTCs, heparin and fucoidan were applied to pretreat P4-Lipo before incubation with 4T1-GFP cells. Heparin is a known potent inhibitor of P-selectin and has been confirmed to efficiently inhibit metastasis in mouse models. Fucoidan is known as a platelet agonist for the C-type lectin-like receptor. It was shown heparin attenuated the binding of P4-Lipo to 4T1-GFP cells while fucoidan had little impact on it (Fig. 3E), suggesting that P-Lipo binding with CTC was mainly mediated by P-selectin.

The cell apoptosis of CTCs after incubation with P-Lipo in the whole blood diluent was performed by flow cytometry. As shown in Supporting Information Fig. S6, the percentages of the apoptotic cells, including early apoptosis, late apoptosis, and total apoptosis for the P-Lipo groups, were significantly higher than those for the Lipo group. In addition, the percentages of the apoptotic cells, including late apoptosis and total apoptosis for the P4-Lipo group were significantly higher than those for the PBS group. These results indicate that the P4-Lipo binding with CTCs enhanced their apoptosis, which might attribute to that P4-Lipo adherence onto the surface of 4T1 cells broken the protection from nature platelets and facilitated the attack of immune cells in the blood.

recorded to identify CFSE-labeled CTCs and DiD-labeled P-Lipo (or Lipo), respectively. Two peaks overlapped represented the successful capture of CTC by P-Lipo (or Lipo) (purple rectangles in Fig. 4B). As shown in Fig. 4C, the bar chart revealed the number of CTC peak and captured CTC peak (CFSE and DiD double-positive peak). The percentage of double-positive peaks in CTC peaks increased from 17.2 ± 4.2% of Lipo to 48.0 ± 7% of P²-Lipo and 56.8 ± 3.6% of P⁴-Lipo, respectively. The result illustrated that the CTC capture ability of P-Lipo increased with the content of platelet membranes in P-Lipo.

To offer more intuitionistic information of CTC capture by P-Lipo in high-speed blood flow in vivo in real-time, SDC equipped with two cameras simultaneously to provide fast, two-color localization super-resolution imaging was applied to capture the dynamic processes. To decrease the interference of spontaneous hair fluorescence, a peripheral mesentery vessel was chosen as the observation window. In the SDC image (Fig. 4D, and Supporting Movies 1–3), individual CFSE-labeled CTC (green) could be visualized in the blood vessels once the CTC was captured by DiD-labeled P-Lipo (or Lipo), which appeared red. A good colocalization of the intensity profiles for DiD-labeled P-Lipo and CFSE-labeled 4T1 cells in the blood vessel further confirmed the capture of the circulating 4T1 cell by P-Lipo. The SDC imaging matched well with the results from the previous IVFC assay. In the P-Lipo group, most CTCs were stained red, while in the Lipo group, few red signals appeared simultaneously with green CTCs. These results indicated platelet membranes in P-Lipo strengthened the CTC capture ability of P-Lipo.

3.4. In vivo imaging of P-Lipo in lung pre-metastasis

A murine model of lung pre-metastasis was adopted to track the distribution of cancer cells and P-Lipo. As shown in Fig. 5A and B, bioluminescence imaging revealed that 4T1-Luc mainly accumulated in the lung after intravenous injection. In vivo fluorescence imaging demonstrated that P-Lipo was mainly distributed in the liver, lung, and spleen at 2 h after injection. Compared with Lipo, significantly more P-Lipo was located in the lung where the pre-metastasis existed, suggesting platelet membranes assisted P-Lipo getting trapped in the pre-metastasis lung environment. The colocalization of P-Lipo with metastatic tumor cells was further visualized by ex vivo live imaging. 2% agarose was instilled into the lung to avoid lung collapse caused by the open-chest operation and preserved the maximum lung microenvironment ex vivo to achieve the SDC imaging of non-sectioned whole lung lobes. As shown in Fig. 5C and the Supporting Movies 4–5, 4T1-GFP was arrested in the lung capillaries 20 min after injection, and much more P-Lipo surrounded 4T1-GFP, compared with Lipo (Supporting Information Fig. S7). More importantly, at 24 h after injection, although most 4T1-GFP were removed from the circulation, it could be found resident 4T1-GFP in the lung were still surrounded with P-Lipo while they were located separately and did not overlap with Lipo (Fig. 5C and Supporting Information Fig. S8). These results suggest P-Lipo could capture the arrested CTC in the pre-metastasis lung environment.

Supplementary video related to this article can be found at https://doi.org/10.1016/j.apsb.2022.01.005

3.5. CTC arrest inhibition by P-Lipo in vitro

As described above, P-Lipo inherited the essential platelet adhesion proteins on their surfaces and retained some platelet functions, including CTC binding or capture. Then we evaluated the role of P-Lipo as platelet nanodecoys in CTC arrest and extravasation in the pre-metastasis environment. First, a co-culture cell model consisting of HUVECs and 4T1-GFP was built to examine the cell-binding ability of P-Lipo (Supporting Information Fig. S9). Compared with Lipo, P-Lipo showed higher cell-binding with both tumor cells and HUVECs, and P⁴-Lipo showed the most potent binding among these groups. However, in this co-culture cell model, there was no significant difference in P-Lipo binding between HUVEC and 4T1-GFP.

Platelets not only contribute to CTCs’ survival by helping escape from immune surveillance but also enhance tumor-endothelium interactions. To investigate whether P-Lipo impacts CTC arrest by vessel endothelial cells under flow conditions, flowing tumor cells adhered to HUVECs was recorded in the FCS2 chamber, whose structure was shown in Fig. 6A and Supporting Information Fig. S10. In the presence or absence of TNF-α, the amount of 4T1-GFP adhered to HUVECs increased over time, but the presence of P-Lipo made from 0.002 or 0.008 U/mL of platelets significantly decreased 4T1-GFP arrest on HUVECs (Fig. 6B and C). It was shown that platelet decoys made from approximately 0.039 U/mL of platelets could significantly decrease tumor cell arrest by HUVECs, considering there are 0.77 × 10⁵ platelets per microliter of blood. These results indicate P-Lipo inhibited CTC arrest on vessel endothelial cells with high efficiency.

3.6. CTC extravasation inhibition by P-Lipo in vitro

CTC extravasation inhibition by P-Lipo was studied in vitro using a transwell system under physiological and inflammatory conditions as previously reported (Fig. 6D). 4T1-Luc and P-Lipo were incubated with the HUVEC monolayer in the presence and absence of TNF-α. Bioluminescence imaging (Fig. 6E and F) and crystal violet staining (Fig. G) demonstrated that P-Lipo could significantly depress 4T1-Luc migration through the endothelial monolayer in both normal and inflammatory conditions, compared with PBS or Lipo. Importantly, it was also demonstrated that P-Lipo made from 0.002 or 0.008 U/mL of platelets could significantly inhibit 4T1-Luc extravasation through the endothelial monolayer into the donor wells in both normal and inflammatory conditions compared with PBS or Lipo (Fig. 6H). It was shown platelet decoys made from approximately 0.039 U/mL of platelets could significantly suppress tumor cell extravasation. These results suggest P-Lipo could inhibit CTC to extravasate from the endothelial monolayer with high efficiency. A possible explanation is that P-Lipo could bind with CTC and vessel endothelial cells like platelets but interfere with CTC-platelet-endothelial cell interaction, disrupting CTC arrest on endothelial cells and CTC extravasation through vessels.

One of the precise mechanisms of the correlation between platelet-tumor cell interaction and metastasis is that platelets alter EMT in tumor cells and promote tumor invasion and metastasis. To further validate whether P-Lipo could inhibit the platelet-induced EMT process, firstly, a wound healing test was carried out to evaluate the effect of P-Lipo on tumor cell migration in the presence of platelets. As shown in Fig. 6I and J, platelets significantly increased the scratch closure rate of 4T1 cells.
However, compared with PBS and Lipo treatment, P-Lipo treatment significantly decreased the wound healing rate enhanced by platelets. Moreover, for both P-Lipo and P^IL-Lipo groups, there were no significant differences in the percentage of scratch area repopulated between in the presence and absence of platelets. These outcomes indicated P-Lipo could inhibit platelet-enhanced wound healing of tumor cells. It was found that the co-incubation with platelets induced morphological alterations of tumor cells from a pebble-like shape to a spindle shape, which is a typical characteristic of EMT progress. However, P-Lipo treatment noticeably reduced the morphological changes elicited by platelets, indicating that the platelet-induced EMT could be suppressed by P-Lipo treatment (Supporting Information Fig. S11). Next, we further elucidated the tumor cells’ EMT process by analyzing the expression of EMT markers (E-cadherin, N-cadherin, and vimentin) by Western blotting. As shown in Fig. 6K–L, platelets significantly downregulated E-cadherin levels but significantly upregulated N-cadherin and vimentin levels in tumor cells, whereas P^IL-Lipo treatment could restore the protein levels of these markers in the presence of platelets. These results imply that platelet-induced EMT in 4T1 cells could be significantly weakened by P-Lipo.

3.7. P-Lipo decreased disseminated 4T1 invasion and metastasis in vivo

Before the anti-metastasis study, the pharmacokinetics of DiD-labeled P-Lipo containing different amounts of platelet membranes was investigated. As shown in Supporting Information Fig. S12, P-Lipo, and P^IL-Lipo demonstrate similar long circulation profiles to Lipo. There were no significant differences in the pharmacokinetic parameters (e.g., MRT, AUC, t_{1/2} and C) between P-Lipo and Lipo. However, the AUC and t_{1/2} for P^IL-Lipo were significantly lower than those for Lipo (Supporting Information Table S1), indicating a high platelet membrane content in P-Lipo could accelerate the blood clearance of P-Lipo to some extent. The long retention of P-Lipo in the blood could provide it more chance to catch CTCs or access pre-metastasis.

P-Lipo could not only capture both flowing CTCs and arrested CTCs, but also decrease CTC arrest and extravasation from the HUVEC monolayer. To test the ability of P-Lipo to reduce the formation of metastasis in vivo, 4T1-GFP cells and P-Lipo were injected into BALB/c mice successively. After 3 days, the percentage of 4T1-GFP in the blood after lysing the erythrocytes was monitored by FCM. The gating strategy for FCM analysis was shown in Fig. 8A. Before the anti-metastasis study, the pharmacokinetics of DiD-labeled P-Lipo containing different amounts of platelet membranes was investigated. As shown in Supporting Information Fig. S12, P^IL-Lipo, and P^IL-Lipo demonstrate similar long circulation profiles to Lipo. There were no significant differences in the pharmacokinetic parameters (e.g., MRT, AUC, t_{1/2} and C) between P-Lipo and Lipo. However, the AUC and t_{1/2} for P^IL-Lipo were significantly lower than those for Lipo (Supporting Information Table S1), indicating a high platelet membrane content in P-Lipo could accelerate the blood clearance of P-Lipo to some extent. The long retention of P-Lipo in the blood could provide it more chance to catch CTCs or access pre-metastasis.

To further validate whether P-Lipo could inhibit CTC colonization and metastasis formation, the anti-metastasis efficacy of P-Lipo was assessed in a lung metastasis mouse model (Fig. 7D–J). BLI demonstrated that the growth of 4T1-Luc metastasis had a similar tendency for the PBS, Lipo, and P^IL-Lipo groups, indicating that Lipo and P^IL-Lipo had no significant inhibition on CTC colonization and outgrowth (Fig. 7D and E). However, P^IL-Lipo showed significant suppressive effects on 4T1-Luc metastasis growth in the lung. In addition, H&E staining (Fig. 7F, H, and I) showed that the lungs developed significantly more metastases throughout the entire lobes and bronchi in the PBS and Lipo groups compared with the P-Lipo groups. The P^IL-Lipo group showed scattered large tumor nodules in the lung, and the P^IL-Lipo group displayed sporadic tumor nodules in the lung. Ki-67 staining (Fig. 7G and J) revealed significantly lower proliferation of tumor cells in the P-Lipo groups compared with the PBS group or the Lipo group. Considering platelet decoys could not inhibit tumor metastasis without co-incubation with platelets19, these results suggest that P-Lipo could strongly suppress tumor metastasis as nanodecays with high efficiency.

To test the anti-tumor immune response, the change of immune cells in the peripheral blood after treatment was analyzed via FCM. The gating strategy for FCM analysis was shown in Fig. 8A. As shown in Fig. 8B, there were no significant differences in the percentage of CD8^+ and CD4^+ T cells in the blood from different groups at different time points after treatment. No significant differences were found in the ratio of CD8^+ to CD4^+ T cells in the blood from different groups after treatment either. Interestingly, at the early stage of pre-metastasis (4 h and 1 day after CTC inoculation), P^IL-Lipo treatment significantly increased MDSC levels in the blood compared with PBS treatment. However, on Days 6 and 9 after treatment, P^IL-Lipo treatment significantly suppressed MDSC levels in the blood to the normal level compared with PBS treatment, indicating P^IL-Lipo could inhibit the function of MDSC of promoting tumor escape, metastasis and drug resistance30. Compared with PBS treatment, P^IL-Lipo treatment significantly increased M1 macrophage level (4 h and 3 days after CTC inoculation) and M2 macrophage level (1 and 3 days after CTC inoculation) in the blood at the early stage. These results suggested that P-Lipo treatment could decrease the inflammation at the early stage by upregulating M2 macrophages and suppress tumor cell escape at the latter stage by downregulating MDSC to inhibit CTC colonization and metastasis formation.

Furthermore, routine blood examination demonstrated that hematological indexes had obvious alternations at 15 days after different treatments (Fig. 8C). The tumor-bearing mouse who received PBS and Lipo treatment revealed significantly elevated WBC, lymphocytes (Lymph), mononuclear leucocytes (Mon), granulocytes (Gran), and reduced platelets (PLT)31 compared with the Blank (normal) group. Both P^IL-Lipo and P^IL-Lipo treatments significantly decreased WBC, Lymph, and Mon to the normal fluctuation range compared with PBS treatment or Lipo treatment but had no damage to major organs (Supporting Information Fig. S13). Moreover, compared with PBS treatment, P^IL-Lipo treatment could significantly decrease Gan and hemoglobin (HGB) levels, and P^IL-Lipo treatment could significantly decrease Gan level and increase PLT level. Of note, chronic inflammation may lead to alterations in epithelial cytoarchitecture and enhance genetic mutations along with epigenetic aberrations of epithelial cells5. This alteration in tissue homeostasis will induce a feed-forward chronic inflammatory response, firing up the metastasis of the tumor. Hence, the obtained nanoplateletsomes could suppress the inflammation, and reduce platelet depletion during CTC colonization. In general, P-Lipo treatment could inhibit the inflammation by upregulating M2 macrophages and decreasing WBC, Mon, Lymph, and Gran, suppress tumor cell escape by downregulating MDSC and decreasing the platelet depletion, resulting in decreased CTC survival in the blood and suppressed CTC colonization and metastasis formation. The potential anti-metastasis efficacy could be due to the following reasons. Firstly, P-Lipo takes advantage of both platelet membranes and artificial lipid membranes. It could not only have functional cell...
surface receptors endowed from natural platelets to capture CTCs, but also have long circulation property similar to PE-glylated liposomes, which could provide P-Lipo more chance to capture CTCs or access pre-metastasis. Secondly, compared with natural platelets or platelet decay, P-Lipo has a large surface-volume ratio and a large quantity. It was estimated that the surface-volume ratio and the number of P-Lipo were $1.92 \times 10^5$ and $1.47 \times 10^5$ folds those of platelets that were used for P-Lipo preparation, respectively (Supporting Information discussion). P-Lipo would have more opportunities to encase CTCs than natural platelets while not offering a shield against the immune cells like natural platelets. Thus, P-Lipo could compete with natural platelets in vivo, disrupting the platelet-CTC interaction, acting as reversible inhibitors of platelet activation cascades, and breaking the protection of platelets to cancer cells. Finally, the subversion of the host immune responses was prevented by P-Lipo, leading to an outstanding inhibition effect toward the generation of premetastatic tumor cascade.

4. Conclusion

We developed a bioinspired nanoplateletosome, which inherited the function of platelet membrane proteins. It has been demonstrated that these nanoplateletosomes could not only bind with CTCs in vitro and in vivo, but also interfere with CTC arrest by vessel endothelial cells, CTC extravasation through endothelial layers, and EMT of tumor cells as decoys in vitro. Furthermore, in vivo data demonstrated that nanoplateletosomes could decrease CTC survival in the blood, counteract metastasis formation, and slow down the metastasis progress by inhibiting the inflammation and suppressing CTC escape. Therefore, nanoplateletosomes without any drug loading provide a novel strategy for the treatment of tumor metastasis.
