1 Materials and methods

1.1 Study areas

The fieldwork was carried out along an altitudinal gradient from lowland (400 m a.s.l.; Table S2) to upper montane evergreen forests (3010 m a.s.l.; Table S2). We selected areas of well-preserved natural forests located on the western flanks of the Andes in northern Ecuador; specifically, in the Sierra region in the provinces of Imbabura and Pichincha. Four study sites (Fig. S1) were selected: Río Silanche at 400 m a.s.l (hereinafter: S_400), Milpe at 1100 m a.s.l. (hereinafter: M_1100), El Cedral at 2200 m a.s.l. (hereinafter: C_2200) and Peribuela at 3010 m a.s.l. (hereinafter: P_3010). All sites experience two rainy seasons (March-April and October-November), with a mean annual precipitation (MAP) that varies on average between 900 and 3600 mm, and an adiabatic lapse rate of approx. -5 °C per 1000 m of altitude (Table S2) (Varela and Ron, 2018).

1.2 Sampling strategy

The sampling campaign took place from August 6th to September 28th, 2018, corresponding to the end of the dry season. One plot (20x20 m) was selected for each site, and within each plot, five polyvinyl chloride (PVC) collars were installed to allow in-situ measurements using a static flux chamber method. The collars were inserted at random locations within the plots but guaranteeing at least 7 m distance between each one. The insertion of the collars was performed at least 12 h before the first measurements, by applying even pressure across all points to minimize effects caused by soil disturbance. The chambers consisted of a PVC pipe hermetically sealed on top with a rubber-sealed lid. The chamber area was 0.0191 m² and the internal volume ranged between 3.63 and 3.98 L. Each chamber was equipped with sampling ports mounted with three-way valves, and a vent tube was installed to reduce pressure interferences.

Gas samples were collected mid-morning to avoid extreme temperatures and consider them as representative of a whole day (Collier et al., 2014; Luo and Zhou, 2006). Measurement cycles on each site consisted of four consecutive gas measurements once per day for one hour and during five contiguous days. For these measurements, the collars were left in place for the duration of each measurement cycle; thus, the analysis per stratum lasted 1 week (i.e. 1 month for all measurements in the 4 strata). However, in order to assess both short-term and long-term variations mainly related to weather conditions, the gas measurements were done first in August and consequently repeated in the next month (September).

Adjacent to each chamber (~ 1 m), one pit was dug for soil sampling, and intact soil cores were collected using stainless steel cylinders (diameter: 5.08 cm, height: 5.11 cm). The samples were taken at 5 and 20 cm depth once during the first month (August) of measurements. Each soil core was immediately packed into airtight zip-lock bags and once the sampling campaign was over, they were sent to Belgium (Ghent University) for physicochemical soil analysis. Bulk density (ρ_b) was measured by oven drying (75°C for 48 h) and weighing the soil samples. Soil porosity was derived from Eq. (1), assuming a particle density of 2.65 g cm⁻³. pH was measured by a potentiometric method using a pH-sensitive glass electrode, a standard reference electrode (HI 4222; Hanna Instruments, Bedfordshire, UK), and a volumetric ratio soil:liquid of 1:5 for pH_water (distilled water) and pH_KCl (1M KCl). NO₃⁻ and NH₄⁺ content was determined colorimetrically (Auto Analyzer 3; Bran and Luebbe, Norderstedt, Germany) after extractions performed with 1M KCl at room temperature and neutral pH. C and N concentrations (%C, %N), along with the stable N isotope signatures (δ¹⁵N) of the soil samples, were determined at natural abundance by a Continuous Flow Element Analyzer (Automated Nitrogen Carbon Analyzer), interfaced with an Isotope-Ratio Mass Spectrometer (Sercon 20-20; Sercon, Cheshire, UK). Moreover, the soil samples taken at 5 and 20 cm depth were combined to produce one composite sample associated with each site, and by means of the method described by the International
Organization for Standardization (ISO 11277:2009), soil texture was determined. The classification of the soil was made according to the United States Department of Agriculture (USDA, 2017); and the soil class was determined based on the classification of FAO and UNESCO: World Reference Base for Soil Resources (WRB) (FAO, 2007).

\[
Porosity \% = \left(1 - \frac{\rho_b \left[g \ cm^{-3}\right]}{2.65 \left[g \ cm^{-3}\right]} \right) \cdot 100\% \tag{1}
\]

Daily measurements of soil moisture, expressed as water-filled pore space (WFPS), were taken per site at 5 and 20 cm depth using soil moisture sensors (EC-5, Meter Environment, Pullman, Washington, USA) and data loggers (ProCheck, Meter Environment, Pullman, Washington, USA). Finally, soil temperature was determined daily for each measurement cycle and per chamber, by means of a thermometer inserted at 5 cm depth and approximately 10 cm from each chamber.

### 1.2.1 Soil-atmosphere exchange

Each day, the chambers were closed for a period of 1 h. Samples of 20 mL were taken with disposable syringes from the headspace air every 20 minutes: \(T_1 = 0, T_2 = 20, T_3 = 40\) and \(T_4 = 60\) min; \(T_1\) or time-zero indicates the sample taken immediately after the chamber was closed. Before each sample collection, the syringe was flushed twice with the air of the chamber to mix the chamber headspace and to avoid any possible stratification of gases.

The 20 mL samples were injected in pre-evacuated 12 mL exetainer vials (over-pressurized), and once the sampling campaign was over, the samples were sent to Belgium (Ghent University) for gas chromatography analysis. For CH\(_4\) and CO\(_2\) analysis, a gas chromatograph (Finnigan Trace GC Ultra; Thermo Electron Corporation, Milan, Italy) equipped with a flame ionization detector (FID) and a thermal conductivity detector (TCD) was used, respectively. For N\(_2\)O, another gas chromatograph equipped with an electron capture detector (ECD) (Shimadzu GC-14B; Shimadzu Corporation, Tokyo, Japan) was used.

### 1.3 Data analysis

The fluxes for each gas (CO\(_2\), CH\(_4\) and N\(_2\)O) were calculated by means of linear regressions using the four consecutive measurements of each measurement cycle. The slope of the regressions represented the flux. Thus, following the ideal gas law, and considering the headspace volume of the chamber and the chamber area, the net gas flux was calculated by Eq. (2) (Collier et al., 2014; Dalal et al., 2008; Kutzbach et al., 2007):

\[
F_c = \frac{\Delta c\ [\text{ppm}]}{\Delta t\ [\text{min}]} \cdot \left(\frac{P\ [\text{atm}]}{RT\ [\text{K}]}\right) \cdot \left(MW\ [\text{g mol}^{-1}]\right) \cdot \left(V_{ch}\ [\text{L}]\right) \cdot \left(A_{ch}\ [\text{m}^2]\right)
\]

where \(F_c\) corresponds to the net gas flux (CO\(_2\), CH\(_4\) or N\(_2\)O), \(\Delta c/\Delta t\) is the rate of change of the gas concentration within the chamber or the slope of the regression line [ppm min\(^{-1}\) or \(\mu\text{L} \text{ L}^{-1}\) min\(^{-1}\)]. \(P/RT\) corresponds to the ideal gas law used to convert concentration from volumetric to mass fraction at local temperature and pressure, \(R = \text{gas law constant} (0.08206 \text{ L atm mol}^{-1} \text{ k}^{-1})\); \(MW\) is the molecular weight of the gas (CO\(_2\)-C and CH\(_4\)-C: 12.01 g mol\(^{-1}\), N\(_2\)O-N: 14.01 g mol\(^{-1}\)), \(V_{ch}\) is the headspace volume of the chamber, and \(A_{ch}\) the area of the chamber. The goodness-of-fit was evaluated for every linear regression using the adjusted coefficient of determination (R\(^2\)), and time series (concentration vs time) with R\(^2\) < 0.65 were excluded from further analysis.
2. Results

2.1 Physicochemical soil properties

All soils along the altitudinal gradient are Andosols and the soil texture was classified (USDA) between loam and sandy loam at all sites (WRB; Table 2). All sites had a relatively acidic soil; pH\textsubscript{water} ranged from strong to medium acidic (4.6 - 5.7), with an increase in acidity with depth, except at P_3010 (Table 2). The most acidic soil was found at S_400 at 5 cm, although not significantly different from M_1100 and C_2200; whereas the least acidic one at P_3010 at 5 cm depth, and only significantly different from M_1100. Except for P_3010, NO\textsubscript{3}-N concentrations were 2-4 times higher at 5 cm compared to 20 cm depth; the highest variability was observed at S_400, and in comparison to the other sites, P_3010 seems to be depleted in NO\textsubscript{3}-N at both depths (0.8 – 3.6 µg g\textsuperscript{-1}). In contrast, the highest concentration of NH\textsubscript{4}-N was obtained at P_3010 at 20 cm, followed by S_400 at 5 cm. However, at all sites, NH\textsubscript{4}-N concentrations at 5 cm were not significantly different from each other. Such as NO\textsubscript{3}-N, NH\textsubscript{4}-N also decreased with depth, except at P_3010 where the increase at 20 cm with respect to 5 cm was almost doubling. Higher N contents were measured at 5 cm compared to 20 cm depth at all sites; and S_400 exhibited the highest content at both depths, 1.3-1.4 times higher than any other N percentage at the same depth, and even 4 times higher than any other N percentage at 20 cm depth. The C content showed a general decrease with depth at all sites, with the highest percentage at S_400 at 5 cm, and the lowest one at M_1100 at 20 cm. Higher δ\textsubscript{15}N signatures were obtained at 20 cm compared to 5 cm depth; at S_400 the soil was most enriched in $^{15}$N, and P_3010 showed the most depleted one.

Soil temperature decreased with altitude with a gradient of -4.2 °C per 1000 m, with no statistical difference between months (Fig. S2). WFPS increased significantly with depth at all sites during both months (Fig. S3), except at C_2200 in September. The lowest WFPS at 5 cm depth was obtained at C_2200 (16.8% ± 2.5) and P_3010 (14.4% ± 0.3) in August and September, respectively, whereas the highest one at M_1100 at 20 cm in both months (August: 75.9% ± 0.3; September: 71.9% ± 6.3).

2.2 Greenhouse gas fluxes

In general, all sites were sources of CO\textsubscript{2} (Fig. 1a, Table 1). Except for P_3010, mean CO\textsubscript{2} emissions were higher in September compared to August, but due to the high variability in the measurements, there was no significant difference between months at M_1100, C_2200 and P_3010 ($P > 0.05$). The lowest and highest emissions were observed at C_2200 (August and September) and P_3010 (August), respectively. All mean CH\textsubscript{4} fluxes were negative, indicating a net flux from the atmosphere to the soil (Fig. 1b, Table 1). Although the mean CH\textsubscript{4} fluxes (except for P_3010) were higher in September compared to August, there was no significant difference ($P > 0.05$) between months at any site. Finally, the mean N\textsubscript{2}O fluxes showed a general negative trend with increasing altitude (Fig. 1c). A marked net N\textsubscript{2}O consumption was observed at the sites located at 2200 and 3010 m a.s.l.; however, there was no significant difference ($P > 0.05$) in any plot between months. The highest consumption was observed in September at C_2200, followed by P_3010 in August, while the highest emission was in September at M_1100 (Table 1).

Although only monthly average fluxes were discussed, the large variability observed with most of the gas fluxes (Table 1 and Fig. 1) are the result of the spatial (i.e. differences in GHG fluxes between chambers) and temporal (i.e. differences in GHG fluxes per day) variability within each site.
**Fig. S1.** Overview map with the location of the study areas: Río Silanche (400 m a.s.l.; S_400), Milpe (1100 m a.s.l.; M_1100), El Cedral (2200 m a.s.l.; C_2200) and Peribuela (3010 m a.s.l.; P_3010). Study areas projected on a DEM based on SRTM data (Jarvis et al., 2008).
Fig. S2. Monthly average soil temperature (°C)±standard deviations (SD) at Río Silanche (400 m a.s.l.; S_400), Milpe (1100 m a.s.l.; M_1100), El Cedral (2200 m a.s.l.; C_2200) and Peribuela (3010 m a.s.l.; P_3010). Light grey: average soil temperature in August; dark grey: average soil temperature in September.
Fig. S3. Monthly average water-filled pore space (WFPS)±standard deviations (SD) at Río Silanche (400 m a.s.l.; S_400), Milpe (1100 m a.s.l.; M_1100), El Cedral (2200 m a.s.l.; C_2200) and Peribuela (3010 m a.s.l.; P_3010) at 5 and 20 cm depth. Light grey: average WFPS at 5 cm, dark grey: average WFPS at 20 cm.
Table S1. Measured and estimated annual CO₂, CH₄ and N₂O fluxes from tropical forest soils of South America including elevation, mean annual precipitation (MAP), mean annual temperature (MAT) and period of measurement. N.R. stands for not reported.

1 Measured mean annual fluxes.
2 Soil-atmosphere fluxes of CO₂ and CH₄ were measured weekly during June-August 2000, but average values are not reported.
3 Measured CO₂ fluxes from the soil surface.
Average of the annual rainfall measured at the experimental site during 4 years.

Cumulative N₂O fluxes from the 11/05/2010 to the 09/05/2011

Values for undisturbed “native” soil. This study evaluated the climate dependence of heterotrophic soil respiration from a soil-translocation experiment. As a matter of comparison with the others studies, only control cores are depicted, i.e. soil cores re-installed at the same site.
Table S2. Characteristics of the study areas Río Silanche (400 m a.s.l.; S_400), Milpe (1100 m a.s.l.; M_1100), El Cedral (2200 m a.s.l.; C_2200) and Peribuela (3010 m a.s.l.; P_3010), including mean annual precipitations (MAP) and mean annual temperatures (MAT) extracted from the Worldclim data set, using average monthly data from 1970-2000 with a spatial resolution of ~1 km² (Fick and R.J. Hijmans, 2017). Forest classification has been done based on the system used by the country (FAO, 2017; Ministerio del Ambiente, 2015).

| Study area | Forest type | Coordinates | Altitude (m a.s.l.) | MAP (mm) | MAT (°C) |
|------------|-------------|-------------|---------------------|----------|----------|
| S_400      | Lowland evergreen forest of Choco | 00°08’45.58” N 79°08’34.22” W | 400 | 3633 | 23.0 |
| M_1100     | Andean foothill evergreen | 00°02’07.17” N 78°51’59.72” W | 1100 | 2856 | 21.1 |
| C_2200     | Andean montane evergreen | 00°06’47.87” N 78°34’10.88” W | 2200 | 1464 | 16.8 |
| P_3010     | Upper montane evergreen | 00°22’27.35” N 78°18’0.36” W | 3010 | 956 | 12.8 |

Note: the coordinates were taken at the center of the plots.
