**INTRODUCTION**

In recent years, the field of topological semimetals has flourished because of the discovery of many materials that exhibit highly exotic physical properties that are a result of massless quasi-particles, which dominate the transport properties (1–3). For example, three-dimensional Dirac semimetals (3D DSMs) and Weyl semimetals (WSMs) have been shown to host unusual electronic transport properties, as evidenced by their ultrahigh carrier mobility, their extremely large magnetoresistance, and indications of the chiral anomaly (4, 5). The current vast progress in the field draws the prospect of developing new spintronic devices based on topological materials closer (6). To overcome existing limitations, such as the necessity of high magnetic fields to access several topological effects, new and improved materials are of high demand. In particular, materials that exhibit long-range magnetic order in combination with topologically nontrivial band structures are sparse. However, it is exactly these types of materials that may solve present challenges for spintronic applications (7).

3D DSMs exhibit a fourfold degenerate point in their electronic structure, which is a result of a crossing of two doubly degenerate bands. If inversion symmetry (IS) or time-reversal symmetry (TRS) is broken in a 3D DSM, then the doubly degenerate bands become spin-split, resulting in doubly degenerate band crossings called Weyl nodes (8). Although WSMs have been established for some time through IS breaking (9, 10), there are only very few examples of TRS breaking WSMs, examples of which are GdPtBi or cobalt-based Heusler alloys (11, 12). Antiferromagnetic (AFM) DSMs are even found more rarely, one example being CuMnAs (13, 14), where it has been shown that although TRS and IS are broken individually, the product of both still holds, which leads to fourfold degenerate Dirac cones in its AFM structure. Contrary to most 3D DSMs and WSMs, where the band degeneracy is dependent on the orbital character of the bands, materials that crystallize in nonsymmorphic space groups exhibit band degeneracies that are imposed by the space group symmetry (15–17). These degeneracies are guaranteed to be present if a nonsymmorphic symmetry operation relates atoms in the crystal structure and thus predictions on topological features can be solely based on group theory in these cases. This concept has been used to predict DSMs and completely new quasiparticles (the so-called new fermions), beyond Dirac, Weyl, or Majorana fermions (16, 17). These (yet to be discovered) new fermions are not constrained by Poincaré symmetry, only exist in the solid state, and have no high-energy counterparts (16). Their unusual Landau-level structure distinguishes them from normal Weyl points. The concept of creating these new quasi-particles is based on the possibility of achieving three-, six-, or eightfold band degeneracies in nonsymmorphic space groups. However, whether these degeneracies appear at the Fermi level depends on the electron filling, which complicates the search for these topological semimetals (18, 19). To date, only very few materials have been experimentally shown to exhibit bulk band degeneracies protected by nonsymmorphic symmetry, examples of which are ZrSiS and ZrSiTe (19–21). It has also not yet been studied experimentally how magnetism and, thus, TRS breaking affect the band degeneracies that result from nonsymmorphic symmetry, mostly due to a lack of these candidate materials [but a theoretical classification of degeneracies in magnetic groups has recently been performed (22)]. A magnetic nonsymmorphic compound could be a new type of magnetic WSM.
that combines long-range magnetic order with new quasi-particles. In addition, not only does antiferromagnetic order affect TRS, but it can also break or induce further symmetry elements. It has not yet been studied how this influences band structures that are governed by non-symmorphic symmetry.

In times where many topological materials have been realized, the challenge to introduce compounds that combine several different states in a single material and allow for switching between these different topological states remains. Here, we show that the compound CeSbTe exhibits Dirac and Weyl fermions and that both types, non-symmorphic protected and accidental band crossings, are present in the vicinity of the Fermi level. We also show that this material can exhibit more exotic three- and eightfold degeneracies. Although CeSbTe is centrosymmetric,TRS can be broken by applying a very small magnetic field. CeSbTe orders antiferromagnetically below $T_N = 2.7$ K at zero field but undergoes a metamagnetic transition to a fully polarized state under a small field of about 0.25 T. This magnetically fully polarized state with ferromagnetic (FM)–like polarization will be, for simplicity, referred to as FM phase within this manuscript. We show with detailed magnetic measurements combined with ab initio calculations and angle-resolved photoemission spectroscopy (ARPES) measurements that this material allows for easy access to a plethora of different Dirac and Weyl states, of which some have not previously been realized in a real material. Using the recently implemented double group representations ($23–26$), we performed a group theory analysis ($16, 23–26$) that supports our ab initio claims of the existence of protected Dirac and Weyl nodes, as well as three- and eightfold crossings at high-symmetry points or lines, thus presenting the first realization of a non-symmorphic topological material that exhibits degeneracies other than fourfold ones. We also show that AFM order gives access to new fermion states in space groups that have not been previously considered.

RESULTS

Figure 1 shows a drawing of the crystal structure of CeSbTe; an image of a typical single crystal is shown in the inset. Contrary to a previous study (27), which reported that CeSbTe crystallized in the orthorhombic space group $Pnma$ (no. 62), we found that it crystallizes in the tetragonal space group $P4/nmm$ (no. 129), as evidenced by the refined neutron diffraction data (Fig. 1). Single-crystal x-ray diffraction (SXRD) and precession electron diffraction (PED) yielded the same result (see the Supplementary Materials for details). With PED, we did not detect any of the additional reflections that would be expected for space group $Pnma$ (fig. S1). Thus, CeSbTe is an isostructural and isoelectronic version of the noddal line semimetal ZrSiS ($20, 28$). The crystal structure is composed of CeTe bilayers that are separated by a square-net layer of Sb; the layers stack along c (see the inset of Fig. 1). The Ce atoms form a square network arrangement, and the intralayer distance of Ce atoms is 4.37 Å, whereas the interlayer distance is 5.26 Å within a bilayer and 6.02 Å across a bilayer. ZrSiS and related compounds have been shown to exhibit a diamond-shaped Dirac line node and fourfold degenerate nodes at the X, R, M, and A points of the Brillouin zone (BZ) ($20, 21$). The latter ones are a result of the nonsymmorphic glide planes in the space group $P4/nmm$, and the resulting Dirac cones and nodes have been discussed and illustrated many times ($21, 29$). Although the Dirac line node is gapped by spin-orbit coupling (SOC), the degeneracies that result from nonsymmorphic symmetry are not affected by SOC. The nonsymmorphic degeneracies can be above, below, or right at the Fermi level, depending on the $c/a$ ratio of the lattice constants ($19$). For further information on the crystal structure and sample quality, see high-resolution transmission electron microscopy images with atomic resolution in the Supplementary Materials.

The clarification of the crystal structure allows us to calculate the electronic band structure, to find out whether the system is not only structurally but also electronically similar to ZrSiS and related non-symmorphic Dirac materials. A close-up of the calculated electronic structure, without considering magnetic order, can be found in Fig. 2A, showing the expected nonsymmorphically protected fourfold degeneracies at M (all crossings in the figure are protected by the non-symmorphic symmetry), and a more detailed discussion will follow later in the paper. Because density functional theory (DFT) on f electron systems has been proven to be challenging, we performed ARPES measurements on the paramagnetic phase (samples were measured at room temperature without a magnetic field) to qualitatively confirm the predicted electronic structure. Because we measured at a fixed momentum and thus cannot be certain about the $k_z$ position we are probing, we chose the FM direction to compare measured and predicted bands, because the electronic structure is more 2D, that is, has less $k_z$ dispersion along this direction, in contrast to other cuts that are shown in the Supplementary Materials. This can be seen in Fig. 2A, where the calculated bands along $\Gamma M$ and $\Gamma Z$ are plotted in one diagram. Figure 2B shows the measured dispersion along $\Gamma M$. Almost all bands are clearly resolved in the measurement. Some bulk bands are not visible, which we attribute to matrix element effects (see the Supplementary Materials for more ARPES data along different high-symmetry lines). To get a better understanding of the discrepancies between prediction and measurement, we extracted the intensity maxima from the measured data and show them in red circles on top of the data in Fig. 2C. We additionally performed a surface state calculation, as shown in Fig. 2D. The red bands indicate surface-derived states, which are commonly observed in ZrSiS-type materials, and are a result of the loss of nonsymmorphic symmetry at the surface ($29$). A comparison between the surface calculation and the measured data clearly shows an agreement between experiment and DFT. Thus, DFT gives a qualitatively correct description of the electronic structure. We are
The crossings at M are numerated analogous to the measured data. Here, the experimental observation of the calculation of magnetically ordered phases later in the manuscript. The calculation of the paramagnetic phase but will be included for the energy of the fit.

CeSbTe contains one localized 4f states. Note that the 4f states were modeled as core states in the calculation of the paramagnetic phase but will be included for the calculation of magnetically ordered phases later in the manuscript. The 4f states are highlighted in blue on the right side and with dashed lines on the left side. The observed crossings at M are numerated. The crossings at M are numerated analogous to the measured data.

even able to resolve some delicate features close to the Fermi level, such as a nonsymmetric degenerate point at X (see Fig. S5). We also observe a flat, nondispersive band at around 3.1 eV below the Fermi level. We attribute these states to the localized Ce 4f3/2 band, which would be expected to be around this energy in a Ce3+ compound that contains localized 4f states. Note that the 4f states were modeled as core states in the calculation of the paramagnetic phase but will be included for the calculation of magnetically ordered phases later in the manuscript. Here, the experimental observation of 4f states serves as a guide to match the DFT calculations to the experimental observations. The energy of the 4f band agrees well with the photoemission spectra of CeTe or CeBi (30). The localization of the 4f states is further strengthened by our magnetic susceptibility data that clearly indicate that CeSbTe contains one localized 4f electron per Ce atom. The magnetization data will be described in the following paragraph. Thus, we can conclude that, although the 4f states are responsible for the magnetism in CeSbTe, they do not interfere severely with the electronic structure beyond providing an effective exchange field in the polarized phase.

Temperature-dependent measurements of the magnetic susceptibility of a single crystal of CeSbTe are shown in Fig. 3A. The field was applied along the c axis (see the Supplementary Materials for the other field orientation). For data with low field strengths, the susceptibility shows a sharp cusp at the Néel temperature $T_N = 2.7$ K, indicative of the emergence of AFM order below this temperature [the exact transition temperature was derived from plotting $d(\chi T)/dT$ versus $T$]. For field strengths larger than 0.25 T, the cusp disappears and the susceptibility continues to increase with decreasing temperature, saturating at very low temperatures, reminiscent of FM behavior (reaching the fully polarized state). Curie-Weiss fits (see the Supplementary Materials) reveal an effective moment of 2.50 $\mu_B$ per formula unit, which matches the expected free ion value of 2.54 $\mu_B$ for a Ce3+ ion well. Deviations from the Curie-Weiss law at low temperatures are due to the crystal electric field (CEF) splitting of the sixfold degenerate ground state of Ce3+.

Deviations from the Curie-Weiss law at low temperatures are due to the crystal electric field (CEF) splitting of the sixfold degenerate ground state of Ce3+. Fits of the susceptibilities indicate a separation of the first excited CEF doublet of $\approx 150$ K (see Fig. S6B). Because we observe the expected Curie-Weiss moment of 2.50 $\mu_B$ per formula unit, the magnetic order is most likely a result of a Ruderman-Kittel-Kasuya-Yosida interaction, where the conduction electrons mediate the exchange between localized spins. The observed moment also indicates that the Ce 4f states are localized and away from the Fermi level. The field-dependent data (Fig. 3B) elucidate the transition from an AFM to an FM (fully polarized) phase; at a field of $\mu_0H_c = 0.224$ T, the field-dependent susceptibility shows a sudden increase. As shown in Fig. 3B, the required field is higher (1.75 T) if the field is applied perpendicular to the $c$ axis, which is the usual observation for spin-flop transitions. This indicates that the moments prefer to align along the $c$ axis (that is, the easy axis). The expected saturation moment of a Ce3+ ion (1 $\mu_B$ per Ce) is reached faster if the field is aligned perpendicular to the $c$ axis. A possible explanation for this behavior is a strong magnetic anisotropy of the Ce moments. Similar field-dependent magnetic transitions have also been observed in different square lattice Ce compounds, such as CeTe2 or CeSbSe (31, 32). Moreover, other magnetic square lattice compounds, such as CsCo2Se2, can show a field-induced magnetic transition (33).

The magnetic properties were additionally investigated with specific heat measurements (see Fig. 3C). At zero field, a magnetic transition is clearly visible at 2.7 K (derived from the $C/T$ plot shown in the inset), agreeing well with the susceptibility data. Although the AFM phase transition (sharp peak in $C/T$) is shifted to slightly lower temperatures with a small applied field, the field is aligned along the $c$ axis, which is typical for AFM order, the crossover seen as a broad peak in $C/T$ shifts to higher temperatures when the applied field is larger than 1 T, reminiscent of behavior seen in ferromagnets. The crossover between the two different types of magnetic order is therefore also reflected in the specific heat. For information about magnetic entropy, see the Supplementary Materials.

To analyze the low-field magnetic structure of CeSbTe, neutron powder diffraction measurements were performed. Some refinements are shown in Fig. 3D, and more detailed figures and tables with refined parameters can be found in the Supplementary Materials. As mentioned before, at 5 K, above the Néel temperature, the refinement yields the tetragonal space group $P4/nmm$, in agreement with the results from SXRD and PED. Upon cooling, additional Bragg peaks appear owing to magnetic order. These extra reflections can be indexed with a propagation vector $k = (0, 0, 1/2)$, and the absence of the $(00l \pm 1/2)$ reflections clearly indicates that the spins are oriented along the $c$ direction, matching the indications from the susceptibility data (see the Supplementary Materials for details). The magnetic structure was solved at 1.5 K with a doubling of the unit cell along $c$ in the magnetic space group $P4/ncc$ (no. 130.432, type IV) corresponding to the $m2\Gamma_z$ irreducible representation (see Fig. 3D for a fit of the nuclear and magnetic
contributions and the pure magnetic diffraction pattern). A drawing of the magnetic structure can be found in Fig. 4. In each Ce single layer, the spins are ferromagnetically arranged and coupled antiferromagnetically with the following layer, forming an AFM bilayer. The bilayers are then coupled antiferromagnetically with each other, which causes the doubling of the unit cell along c. Further information regarding the magnetic structure solution is given in the Supplementary Materials.

The magnetic phase diagram of CeSbTe is summarized in Fig. 4, which includes the results of the susceptibility, specific heat, and neutron diffraction measurements, measured on multiple and distinct single crystals. The transition temperatures in the susceptibility data were inferred from the derivative \(d\chi(T)/dT\). There are three regions in the phase diagram: at temperatures below \(T_N = 2.7K\) and \(\mu_0H_c = 0.224T\), the spins order antiferromagnetically; above the critical field, they switch to an FM-type, fully polarized order; above \(T_N\) and low field, the material is paramagnetic. Note that the spin-flop transition to the FM phase happens at higher field strengths if the field is aligned perpendicular to the c axis. Depending on the field alignment, the spins can be adjusted to point in different crystallographic directions.

**DISCUSSION**

The different possibilities of magnetic order are expected to have a significant effect on the electronic structure of CeSbTe. In the paramagnetic case, TRS is preserved, conserving the fourfold degeneracies at the nonsymmorphically protected high-symmetry points. In the AFM and FM phases, it is broken, which usually leads to a lifting of degeneracies. In addition, in the AFM structure, there is now an antitranslation \(\{111\langle 0\ 0\ 0\ \frac{1}{2}\rangle\}\) acting on the Ce atoms; thus, this phase has an additional nonsymmorphic symmetry element. Figure 5A shows the calculated band structure of the paramagnetic phase of CeSbTe. Without consideration of f-electrons and spin polarization, fourfold degenerate lines, protected by joint IS, TRS, and nonsymmorphic symmetries, exist on the boundary of the BZ, such as that along RX, similar to ZrSiS and related compounds (21, 29). These fourfold protected crossings are guaranteed by group theory to be present in the space group \(P4/nmm\) (34), and their appearance in the DFT calculation confirms the accuracy of the latter in this case. At the X point, one of these crossings appears very close to the Fermi level (see the green highlight in Fig. 5C). Further fourfold degeneracies appear at M and A, but those are much further away from the Fermi level. Along FZ, there is a slightly tilted Dirac crossing that is protected by the fourfold rotation symmetry in the tetragonal space group \(P4/nmm\).

If magnetism is included in the calculation, then the electronic structure is affected rather severely depending on the type of magnetic order and the orientation of the spins. As long as spin polarization is taken into consideration, the symmetry is reduced by breaking TRS, leading to splitting of the fourfold degenerate lines. Figure 5C shows the region around the X point, when different types of spin polarizations are included in the calculation. For complete plots of the electronic structure including spin polarization, see the Supplementary Materials. Without SOC, the nonsymmorphic symmetry \(C_{2x} = \{C_{2x}\langle \frac{1}{2}, 0, 0\rangle\}\) guarantees the
double degeneracy at the X point. With SOC, each band remains twofold degenerate because $(TT)^2 = -1$, where $T$ is TRS and $I$ is the spatial IS. The screw $C_{2x}$ anticommutes with $I$ at the X point, leading to a fourfold degeneracy (35). When an FM spin polarization is taken into account, TRS is broken and the Dirac point at X splits correspondingly. The details of the band structure are strongly dependent on the orientation of the magnetization. If the spins are aligned along [001], only TRS is broken, whereas the anti-unitary combination of the nonsymmorphic symmetry $C_{2x}$ and time-reversal $C_{2x} \tau$ is preserved. Therefore, the fourfold degeneracy is reduced to a double degeneracy at X and doubly degenerate bands for all $k = (\pi, \pi, k_z)$. Note that this scenario appears below 2.7 K and $\mu_B H_c > 0.224$ T if the field is aligned along the crystallographic $c$ axis. If the spins are aligned along [100], which is analogous to [010] in a tetragonal system, only the unitary nonsymmorphic symmetry $C_{2x}$ remains. A new anti-unitary symmetry $m_z T$ (where $m_z$ is a mirror operation) is present additionally, protecting a double degeneracy along the line XR. The same symmetry appears for an FM spin orientation along the [110] direction. In the AFM phase, even if TRS is no longer a symmetry of the Schrödinger Hamiltonian, the symmetry element $\{1\} (0, 0, \frac{1}{2})$ squares to $-1$ and maps $k$ to $-k$, such as what TRS would do in space group no. 130. This is a result from the doubled $c$ axis in this phase. Therefore, although CeSbTe crystallizes in space group no. 129, its AFM phase behaves like a material in space group no. 130 with TRS. This causes the bands to be fourfold degenerate at X, R, and M and eightfold degenerate at A at $E_i = -4.6$ eV (see Fig. 6). We can conclude that AFM order is a possibility to create higher-order degeneracies that are associated with new types of topological phases in space groups that have previously not been considered. This considerably extends the amount of materials that can exhibit such unconventional quasi-particles. For example, we can extend this scenario to further materials crystallizing in the space group $P4/nmm$, where AFM order creates additional nonsymmorphic symmetries. Examples of further materials where eightfold band degeneracies might be realistic are LiMnAs (36), CeTe$_2$ (31), and LaMnGe (37). All these materials are known to crystallize in the space group $P4/nmm$.

sensitive spectroscopic techniques, despite the convolution with other
terference. STM experiments should be very sensitive to the changes in
electronic structure can be investigated by measuring quasi-particle in-
in scanning tunneling microscopy (STM) experiments, where the
representations of the Bilbao Crystallographic Server (http://cslab.
lk.ehu.es) are summarized in table S3. The tabulated values can be found in table S3.

In conclusion, we showed that the tetragonal compound CeSbTe can
to highlight the degeneracies at the A point. Two crossing points are
highlighted, with the lower one showing a true eightfold degeneracy.
and double their c axis by adding an antitranslation symmetry operation
({{1|0, 0, 1/2}}) in their AFM structure.
The changes in symmetry also affect the electronic structure away
from high-symmetry points. For example, twofold degenerate Weyl
points appear close to the X point if the spins are aligned along [110].
In addition, there is an effect on the tilted fourfold degenerate Dirac
crossing along the GZ direction (Fig. 5D). In the FM phase, with spins
aligned along [001], one of these bands splits, whereas the other one
remains degenerate, resulting in a triply degenerate point close to the
Fermi level that is composed of two different irreducible representations
of 2 + 1 dimensions along the line A connecting G and Z. Triply
degenerate band crossings have also been associated with the possibility
of creating double Fermi arcs at the surface (16).

CeSbTe is thus a unique material that allows access to many different
group and how the system can be transformed to exhibit each symmetry.
Drawings of the crystal structure of CeSbTe in each magnetic group
are also shown in the same figure. The magnetic groups that are acces-
sible in CeSbTe can be either symmorphic or nonsymmorphic, which
adds to the richness of the different irreducible representations that are accessible.

To have a wider view of the rich diversity of quasi-particles that ap-
pear at the time-reversal inversion momenta (TRIMs) of the different
phases of CeSbTe, we have tabulated all the dimensions of the ir-
reducible matrix representations at these points, using the double group
representations of the Bilbao Crystallographic Server (23–26), including
and excluding TRS. The tabulated values can be found in table S3.

The multitude of exotic quasi-particles that can be accessed by
changing the temperature or applied magnetic field should be visible
in scanning tunneling microscopy (STM) experiments, where the
electronic structure can be investigated by measuring quasi-particle in-
terference. STM experiments should be very sensitive to the changes in
the necessarily occurring surface electronic structure when a magnetic
field is applied. Surface states related to Weyl nodes that can be con-
trolled by a magnetic field should be identifiable by careful surface-
sensitive spectroscopic techniques, despite the convolution with other bulk states.

**MATERIALS AND METHODS**

Single crystals were grown with iodine vapor transport. The crystal
structure was solved with SXRD, neutron diffraction, and electron dif-
fraction (see the Supplementary Materials for details). Magnetic mea-
surements were performed on a magnetic property measurement
system (XL and a physical property measurement system (PPMS)
equipped with a vibrating sample magnetometer option from Quantum
Design. Specific heat measurements were performed on a PPMS from
Quantum Design. Powder neutron diffraction data were collected on
the WISH instrument at ISIS, Harwell Oxford (see the Supplementary
Materials for details) (38). For ARPES measurements, crystals were
cleaved and measured in ultrahigh vacuum (low 10^{-10} mbar range).
Spectra were recorded with the 12-ARPES experiment installed at the
UE112-PGM2a beamline at BESSY-II in Berlin. The spectra were taken
at room temperature. DFT calculations were performed using the
augmented plane-wave method, as implemented in the Vienna ab initio
Simulation Package (39). Because of the presence of Ce-f electrons, we
have considered the exchange–correlation energy by the DFT + U
method, with U = 6 eV (or U = 5 eV) added to the Ce atoms (40),
reproducing the experimentally measured magnetic moment and the
experimental energy of the Ce 4f states. To model the paramagnetic
phase, we used a Ce-pseudopotential in which the 4f states were
used at room temperature. DFT + U method.

**CONCLUSION**

In conclusion, we showed that the tetragonal compound CeSbTe can
host many different topological features in its electronic structure,
-ranging from fourfold and twofold Dirac and Weyl crossings to more
exotic eightfold and threefold degeneracies. Because of the easy access to
several different magnetic phases, this system is a rich playground to
study the effects of symmetry breaking due to magnetic order on differ-
ent types of Dirac crossings, as well as on higher-order degeneracies
that result from nonsymmorphic symmetry. In particular, the AFM
phase is represented by a space group of higher symmetry order, the
nonsymmorphic group P4/nmc. Because of the added symmetry
elements, the material shows the same irreducible representations
as materials that crystallize in space group no. 130 with TRS. As a
consequence, CeSbTe displays exotic states such as eightfold degenerate
new fermions. This concept can also be extended to further materials
crystallizing in space group no. 129 (a much more abundant space
group compared to no. 130), significantly increasing the available
materials that could host new fermions. Because of the difficulty of
taking ARPES spectra in the presence of a magnetic field, future in-
vestigations of CeSbTe with STM are of high interest.

Acknowledgments: We thank R. Eger for the single-crystal diffraction measurements. Funding: We acknowledge the financial support from the Max Planck Society, the Nanosystems Initiative Munich, and the Center for Nanosciences. L.M.S. acknowledges the financial support from the Minerva Fast Track Fellowship. M.G.V. was supported by the FIS2016-75862-P national projects of the Ministry of Economy and Competitiveness, Spain. This work was partially supported by the Deutsche Forschungsgemeinschaft within the proposal D16 in materials science in condensed matter under proposal SCHO 1730/1-1. The authors acknowledge the Science and Technology Facility Council for the provision of neutron beamtime at the ISIS facility (UK). Author contributions: L.M.S. initiated the project and performed initial calculations of the bulk electronic structure, thus identifying CeSbTe as a compound that could combine topology and magnetism. L.M.S. and J.L. grew the crystals and performed the magnetic susceptibility measurements together with A.W.R. A.T., S.S., A.V., and M.K. measured and analyzed ARPES spectra at BESSY, A.T., F.O., and P.M. performed neutron measurements at WISH. F.O. and P.M. analyzed the neutron data and solved the magnetic structure. L.M., B.Y., Y.S., and M.G.V. performed the DFT calculations and wrote the theoretical part of the manuscript. M.G.V. performed the group theory calculations.
analysis with input from F.O. V.D. investigated the samples using transmission electron microscopy. R.K.K. performed the specific heat measurements, repeated some of the susceptibility measurements, and fitted the CEF. A.W.R., L.M.S., and R.K.K. interpreted the magnetic properties. L.M.S., A.W.R., and C.R.A. helped interpret the ARPES data. C.R.A. and B.V.L. supervised the research. All authors discussed the results of the paper and contributed to the writing of the manuscript. Competing interests: The authors declare that they have no competing interests. Data and materials availability: All data needed to evaluate the conclusions of the paper are present in the paper and/or the Supplementary Materials. Additional data related to this paper may be requested from the authors.
