Abstract

MAISE is an open-source package for materials modeling and prediction. The code’s main feature is an automated generation of neural network (NN) interatomic potentials for use in global structure searches. The systematic construction of Behler-Parrinello-type NN models approximating \textit{ab initio} energy and forces relies on two approaches introduced in our recent studies. An evolutionary sampling scheme for generating reference structures improves the NNs’ mapping of regions visited in unconstrained searches, while a stratified training approach enables the creation of standardized NN models for multiple elements. A more flexible NN architecture proposed here expands the applicability of the stratified scheme for an arbitrary number of elements. The full workflow in the NN development is managed with a customizable ‘MAISE-NET’ wrapper written in Python. The global structure optimization capability in MAISE is based on an evolutionary algorithm applicable for nanoparticles, films, and bulk crystals. A multitrue extension of the algorithm allows for an efficient simultaneous optimization of nanoparticles in a given size range. Implemented structure analysis functions include fingerprinting with radial distribution functions and finding space groups with the SPGLIB tool. This work overviews MAISE’s available features, constructed models, and confirmed predictions.

1 Introduction

Module for \textit{ab initio} structure evolution (MAISE) was first written as a standalone C code in 2009 \cite{1}. It was originally designed as an evolutionary optimization engine interfaced with external density functional theory (DFT) packages to enable unconstrained ground state structure searches. The implemented evolutionary algorithm followed a general principle of using natural selection to evolve populations of structures with crossover and mutation operations \cite{2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16}. MAISE-specific features include radial distribution function (RDF)-based structure fingerprinting for detecting and eliminating similar population members \cite{1, 17, 18} and an efficient co-evolutionary optimization of nanoparticles (NP) in a given size range via sharing of best motifs among multiple tribes \cite{19, 20}. \textit{Ab initio} predictions made with MAISE and confirmed in experimental studies are overviewed in Section 2.

The primary function of the present MAISE package is the construction of NN interatomic models for accurate mapping of \textit{ab initio} potential energy surfaces. The significant advances in the application of machine learning methodology to the description of interatomic interactions \cite{21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54} opened up the possibility of accelerating \textit{ab initio} structure
prediction. Our examinations of NN performance in prediction of stable compounds have revealed limitations of the traditional approaches used to sample configuration spaces and train NNs for multiple elements [34]. An evolutionary sampling and a stratified training schemes introduced in Ref. [34] and discussed in Section 8 have allowed us to build reliable NN models for extended sets of metals. Our developed MAISE-NET Python script streamlines all stages of the process, from generating reference structures and handling external \textit{ab initio} calculations to performing NN training and testing. With the machine learning module and relevant utility functions comprising about 9,130 out of 14,364 lines of the full code, a more descriptive reading of the MAISE acronym at this point is 'module for artificial intelligence and structure evolution'.

MAISE can perform local/global optimizations, molecular dynamics (MD), and basic phonon calculations by evaluating the total energy, atomic forces, and unit cell stresses for given structures at the NN or empirical potential levels. The main input/output files have a general VASP [55, 56] format to simplify interfacing MAISE with other structure prediction and property analysis engines (PyChemia [57], PHON [58], etc.). The NN training and structure simulation modules are parallelized with OpenMP [59]. Command-line structure analysis and manipulation operations, such as structure comparison or space group determination, are listed in Section 4.

2 Confirmed predictions

The reliability of \textit{ab initio} predictions for finding new materials depends on the accuracy of the theoretical method for computing the structure stability (Gibbs free energy) and the exhaustive sampling of large configuration spaces (structures and compositions). A common approach to evaluating Gibbs free energy with continually improving DFT approximations [60, 61, 62, 63, 64, 65, 66] is to determine the enthalpy at $T = 0$ K and then include the temperature-dependent vibrational/configurational entropy terms for viable candidates. Explorations of configurational spaces can be done with a variety of advanced structure prediction methods introduced in the past two decades [7, 8, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79]. The search strategy employed in our predictive work has involved (i) high-throughput (HT) screening of known relevant prototypes to establish a baseline for compound stability; (ii) unconstrained evolutionary search (ES) to identify new stable motifs; and (iii) stability analysis to explain or improve the stability of identified materials.

Here, we recount notable factors leading to successful predictions and provide context on the discovered materials’ significance (Figure 1 and Table 1). In terms of novelty, (i) FeB$_4$ [1, 80, 81], LiB [82, 83, 84], and NaSn$_2$ [85, 86] are new phases predicted before their experimental realization; (ii) CaB$_6$ [17] and Na$_3$Ir$_3$O$_8$ [87] are solutions of complex phases synthesized and characterized in joint studies; and (iii) Na$_2$IrO$_5$ [88], CrB$_4$ [80, 89], and MnB$_4$ [90, 91, 92] are confirmed revisions of previously misidentified crystal structures. All cases except for Na$_2$IrO$_3$ involved extensive evolutionary searches and resulted in brand-new crystal structures for FeB$_4$, CrB$_4$, MnB$_4$, CaB$_6$, and Na$_3$Ir$_3$O$_8$. All phases except for Na$_3$Ir$_3$O$_8$ have been either synthesized at or successfully quenched down to the ambient pressure.

FeB$_4$ [1, 80, 81] is an early example of a superconductor predicted fully ‘\textit{in silico}’. With a combination of HT screening, ESs, and electron-phonon calculations, we demonstrated that an FeB$_4$ compound should become thermodynamically stable under moderate pressures around 10 GPa in a brand-new oP10 crystal structure (SG#58), remain metastable under normal conditions, and exhibit phonon-mediated superconductivity unusual for an Fe-containing material. The subsequent discovery of the superconductor [81] has motivated further studies [93, 94]. LiB was proposed to be a new synthesizable layered phase [82, 83] with electronic features
Figure 1: Structures of select MAISE confirmed predictions detailed in Table I. The small (large) spheres show boron (metal) atoms.

 desirable for MgB$_2$-type superconductivity [95]. The set of ‘metal sandwich’ configurations was constructed by analyzing stability trends in our HT data. In order to determine suitable synthesis conditions, we explained the off-stoichiometric LiB$_x$ material and modeled the complex behavior of the two competing phases under high pressures. Our synthesis and XRD analysis confirmed the predicted shifts in the LiB$_x$ composition and the existence of the LiB phase with random stacking [84]. The demonstration of the LiB metastability under ambient pressure should simplify future study of the material’s superconductivity.

NaSn$_2$ [85] was predicted to be an overlooked phase synthesizable under ambient pressure. With the primary focus on finding new bulk Sn materials that could be exfoliated into stanene, we examined a set of layered Sn alloys and showed that Na stabilizes a rigid 3D framework with flat Sn layers. Our electronic structure analysis indicated that the compound should have non-trivial topological properties. The predicted hP3-NaSn$_2$ phase (SG#191) was observed later in an independent experiment [86].

CaB$_6$ proved to be the most challenging case in our structure prediction work. A preliminary ground state search uncovered several CaB$_6$ polymorphs stabilized by high pressure but none of them matched the high-pressure XRD patterns obtained in our concurrent experiments [17]. An ES for a larger 28-atom unit cell eventually converged to a new tI56 structure (SG#139) with unique boron building blocks that explained the convoluted XRD data. In contrast to studies that determined ground states of similar size, the ES for CaB$_6$ did not use any structural input from experiment, which makes tI56 one of the largest confirmed crystal structures found truly ‘from scratch’. Our follow-up tests for tI56-CaB$_6$, oC88-Li, and γ-B$_{28}$ showed that the use of unit cell dimensions extracted from XRD makes it possible to find the ground state one-two orders of magnitude faster [17].

Na$_3$I$_3$O$_8$ was experimentally observed to transform into a lower-symmetry phase under pressure. Given the considerable size of the 56-atom ambient-pressure ground state, we used it to initialize our ES but did not rely on any high-P experimental data. An independently obtained mP56 solution (SG#4) with a dimerized Ir-Ir network turned out to be in excellent agreement with the collected XRD patterns [87].
| Phase structure | Prediction confirmation | Synthesis P | Quenched P | Properties | Remarks |
|-----------------|-------------------------|-------------|------------|------------|---------|
| FeB$_4$ oP10    | 2010 [1, 80]            | 10 GPa      |            | Fe-based BCS superconductor | predicted fully 'from scratch' |
| LiB hP4-8       | 2006 [82, 83]           | 21 GPa      |            | proposed MgB$_2$-type superconductor | cold compression synthesis |
| NaSn$_2$ hP3 ($\text{AlB}_2$) | 2016 [85]               | 1 bar       |            | 3D Sn framework with flat Sn layers | non-trivial topological properties |
| CaB$_6$ tI56    | 2012 [17]               | 31 GPa      | 1 bar      | unique boron building blocks | found w/o any structural input |
| Na$_3$Ir$_3$O$_8$ mP56 | 2018 [87]               | 11 GPa      | 1 bar      | dimerized Ir framework | found w/o any high-P structural input |
| Na$_2$IrO$_3$ mS24 | 2012 [88]               | 1 bar       |            | candidate for the Kitaev model | revised structure |
| CrB$_4$ oP10    | 2011 [80]               | 1 bar       |            | distorted 3D boron framework | misidentified for over 40 years |
| MnB$_4$ mP20    | 2014 [90, 91, 92]       | 1 bar       |            | distorted 3D boron framework | unsolved for over 40 years |

Table 1: MAISE confirmed predictions with listed ground state structures, synthesis pressure, established metastability under normal conditions (for phases synthesized at high pressures), key features, and general observations.

Na$_2$IrO$_3$ structure was originally assigned SG#15 ($C2/c$) [96]. A simple local optimization revealed the ground state to have SG#12 ($C2/m$) in agreement with the experimental solution established by our colleagues in a joint study [88]. Our RDF analysis helped rationalize the bond rearrangement resulting in the more stable configuration. The compound has received considerable attention as a candidate for the realization of the Kitaev model.

CrB$_4$ [80] was first synthesized over 50 years ago and represented as an oI10 structure (SG#71). Having determined that FeB$_4$ is significantly more stable in the related distorted oP10 configuration (SG#58) [1, 80], we re-examined CrB$_4$ and showed oP10 to be the ground state for this compound as well. The significant distortion of the 3D boron framework was shown to have little effect on the powder XRD patterns which explained the mischaracterization of the CrB$_4$ structure. Following electron diffraction [89] and single-crystal XRD [97] measurements confirmed the revised oP10 solution for CrB$_4$.

MnB$_4$ [90] was also synthesized over 50 years ago and tentatively assigned an mS10 (SG#12) structure. Our ES found a more stable mP20 (SG#14) derivative in early 2013. Matching solutions were obtained independently by several groups around the same time [91, 92].

Our predictive work has shown that crystalline ground states can be found rather routinely without the need of advanced structure prediction algorithms if (i) the unit cells have fewer than
about 10 atoms; (ii) the search is initialized with related configurations; or (iii) the search is constrained with unit cell dimensions extracted from experiment. The ES becomes essential for larger systems, especially when no prior information is available.

3 Installation

**Download** The full MAISE package, currently MAISE version 2.5 and MAISE-NET version 1.0, can be obtained from the Github repository [98, 99]. It contains MAISE C-language source code, MAISE-NET Python script (Section 8), available NN and empirical potential models (Section 9), and basic examples.

**Compilation** The source code for MAISE can be compiled with: $ make --jobs. During MAISE compilation, the makefile script checks if two required external libraries, GSL [100] and SPGLIB (v1.11.2.1, Feb 2019) [101], are present. If not, they will be automatically downloaded to ./ext-dep and installed in ./lib on most systems. If the GSL or SPGLIB installation is not completed automatically the user should compile them manually and copy (i) libgsl.a, libgslcblas.a and libsymspg.a into the './lib' subdirectory; (ii ) the 'spglib.h' header into './lib/include' subdirectory; and (iii) all gsl headers into the './lib/include/gsl' subdirectory.

**Post-compilation test** A 'check' script is available in the './examples/' directory which can be run after compiling the MAISE executable to ensure the proper function of the code. The script parses a small dataset, trains a basic NN, and optimizes a crystal structure. Error logs are generated in case any issues are detected.

4 Unit cell analysis and manipulation

A variety of structure analysis and manipulation tools are implemented in MAISE package which can be used in the command-line with the corresponding task-specifier flag. Working primarily with the VASP structure format (POSCAR file) as input, MAISE can determine the space group, calculate the radial distribution function (RDF) [1, 17], measure the similarity of two structures via RDF pattern comparison, calculate volume per atom for bulk and cluster geometries [102], align the cluster in the simulation box along the high symmetry axes, etc. The code expects a 'POSCAR' file in the running directory for operations involving a single structure or two 'POSCAR0' and 'POSCAR1' files for structure comparison. The tasks listed in Table 2 can be performed in the command line by running: $ maise -[flag].

The similarity, or dot product, between two structures $k = 1, 2$ with species $N_{spc}$ has been defined in MAISE as

$$C_1 \cdot C_2 = \sum_{n} \sum_{s_1} \sum_{s_2} \frac{RDF_{1,s_1,s_2}(R_n)RDF_{2,s_1,s_2}(R_n)}{(\text{norm}_1 \text{norm}_2)},$$

$$\text{norm}_k = \left[ \sum_{n} \sum_{s_1} \sum_{s_2} RDF_{1,s_1,s_2}(R_n)RDF_{2,s_1,s_2}(R_n) \right]^{1/2}.$$

The RDFs are defined for each structure $k$ at each bin $R_n = n/N_{\text{bin}}R_{\text{hard}}$ ($N_{\text{bin}} = 3,000$) as

$$RDF_{k,s_1,s_2}(R_n) = \sum_{i,s_i=s_1}^{N_{\text{atom}}} \sum_{j \neq i,s_j=s_2}^{N_{\text{atom}}} e^{-\frac{(R_{ij}-R_n)^2}{2\sigma}} f_{\text{cut}}(R_n),$$
where $s_i$ and $s_j$ denote the species of atoms $i$ and $j$, respectively. $f_{\text{cut}}(R_n) = 1$ for $R_n < R_{\text{soft}}$ and $f_{\text{cut}}(R_n) = \cos \left( \frac{\pi}{2} \frac{R_n - R_{\text{soft}}}{R_{\text{hard}} - R_{\text{soft}}} \right)$ for $R_{\text{soft}} < R_n < R_{\text{hard}}$. For efficiency purposes, only $R_n - 3\sigma < R_{ij} < R_n + 3\sigma$ are included in the sum.

The dot product is sensitive to the choice of $R_{\text{soft}}$, $R_{\text{hard}}$, and $\sigma$. It is good practice to include at least two shells of nearest neighbors ($R_{\text{hard}} \gtrsim 5$ Å) and use sharper Gaussians ($\sigma \approx 0.008$ Å) for disordered or cluster structures and wider ones for high-symmetry structures ($\sigma \approx 0.02$ Å).

| flag | description |
|------|-------------|
| man  | output the list of available flags |
| rdf  | compute the RDF for POSCAR |
| cxc  | compute dot product for POSCAR0 and POSCAR1 using RDF |
| cmp  | compare RDF, space group, and volume of POSCAR0 and POSCAR1 |
| spg  | convert POSCAR into str.cif, CONV, PRIM |
| cif  | convert str.cif into CONV |
| rot  | rotate a cluster along eigenvectors of moments of inertia |
| dim  | find whether POSCAR is periodic (3) or non-periodic (0) |
| box  | reset the box size for clusters |
| sup  | make a $N_a \times N_b \times N_c$ supercell |
| vol  | compute volume per atom for crystals or clusters |

Table 2: List of the available command-line flags in MAISE package for structure analysis and manipulation.

5 Structure simulation

Available structure simulation functions include unit cell relaxation, MD, and phonon property analysis. The structure, the interaction model, and the job settings are specified in 'POSCAR', 'model', and 'setup' files, respectively.

5.1 Local structure optimization

Structure optimization with analytic derivative-based BFGS \[103\] or CG \[104\] algorithms can be performed by using NN or other classical interatomic interaction models available in MAISE. The local optimization is carried out until the maximum number of iterations (MITR) or the targeted enthalpy difference between successive steps (ETOL) is reached. The full list of relevant 'setup' parameters for the local optimization task is provided in Table A3.

The unit cell parameters, total/atomic energies, and force/stress components can be outputted at each relaxation step in an 'OUTCAR' file, while the final structure is saved in a 'CONTCAR' file. This information saved in the VASP-style format can be utilized by external codes to perform vibrational property analysis, global structure optimization, etc.

5.2 Molecular dynamics simulations

MD simulations can be run in the microcanonical ensemble (NVE) with the Verlet algorithm \[105\], the canonical ensemble (NVT) with the Nosé-Hoover thermostat \[106\] \[107\], and isobaric-isothermal ensemble (NPT) with a combination of the Nosé-Hoover thermostat and the Berendsen barostat \[108\]. The velocities are initialized either according to the Maxwell distribution at a given
starting temperature or with the values specified in the ‘POSCAR’ file. Table A4 lists ‘setup’ parameters relevant for MD simulations. MAISE outputs energies, lattice parameters, Lindemann index, average RDF, etc. for each temperature. In the current version of MAISE, Lindemann index value is well-defined only for NPs and the barostat is implemented for unit cells with orthogonal lattice vectors.

Figure 2 illustrates the use of the NPT ensemble and our latest NN model for evaluating the linear thermal expansion coefficient $\alpha = \frac{1}{L} \left( \frac{\partial L}{\partial T} \right)_P$ in Ag near room temperature. A 108-atom $3 \times 3 \times 3$ supercell of FCC-Ag was simulated at $T = 300 \pm 10$ K for 0.5 ns with a 1 fs time step (500,000 integration steps in total) to find the numerical temperature derivative of the lattice constants. Allowing the first 0.025 ns for equilibration, we observed convergence of $\alpha$ to within 0.5% in the following 0.25 ns. Simulations of FCC-Cu and BCC-Na showed similar convergence rates. The resulting linear thermal expansion coefficients of $21.0 \times 10^{-6}$ K$^{-1}$ for Ag, $14.9 \times 10^{-6}$ K$^{-1}$ for Cu, and $51.7 \times 10^{-6}$ K$^{-1}$ for Na are within 10-30% relative to the corresponding experimental values of $19.0 \times 10^{-6}$ K$^{-1}$, $16.7 \times 10^{-6}$ K$^{-1}$, and $69 \times 10^{-6}$ K$^{-1}$ [109]. Simulations with a smaller temperature difference $T = 300 \pm 5$ K and a larger structure (256-atom $4 \times 4 \times 4$ supercell of FCC-Ag) showed similar results for the expansion coefficient.

![Figure 2: (Top panel) Fluctuations of the lattice parameter for a 108-atom supercell of FCC-Ag at $T = 290$ K (grey), $T = 300$ K (blue), and $T = 310$ K (green) along with the corresponding average lattice parameters (red) as a function of the number of MD steps. (Bottom panel) Linear thermal expansion coefficient ($\alpha$) at $T = 300$ K as a function of the number of MD steps. The calculated linear expansion coefficient for Ag is in 10% agreement with the measured value [109].](image)

5.3 Phonon calculations

Our studies of vibrational properties [20] have been performed with an external PHON package [58] because it readily links with VASP or MAISE for a consistent comparison of the NN models against the DFT. Presently, MAISE has an internal option to calculate Γ-point phonons with the frozen phonon method in the quasi-harmonic approximation. The dynamical matrix is constructed
by numerical differentiation of the atomic forces. The magnitude of atomic displacements of each atom is defined by the 'DISP' parameter. Due to the negligible numerical noise of the NN analytic forces, the displacement values can be kept small to reduce the anharmonic effects and satisfy the acoustic sum rule (a list of setup parameters for phonon calculations in MAISE code is presented in Table A5).

The main application of this basic feature is to determine the presence of soft frequencies in the analysis of structures' dynamical stability. The code marks trivial zero-frequency translational (and rotational) modes by checking whether the eigenvectors generate net linear (and angular) momenta in crystals (and clusters). Ordered frequencies and the corresponding eigenvectors are printed in the 'OUTCAR' file and can be used for introducing soft-mode mutations in global evolutionary searches [110] or monitoring nudged elastic band method convergence in transition state searches.

6 Evolutionary search

Overview Evolutionary algorithms rely on Nature’s heredity and ‘survival of the fittest’ principles for optimizing complex systems. MAISE enables the search for lowest-enthalpy bulk crystals, flat films, or NPs at a fixed chemical composition. The majority of the algorithm’s numerous internal parameters related to the generation, evolution, and selection of structures have been tuned for typical crystalline unit cells with up to about 50 atoms and NPs with a few hundred atoms. Below we briefly overview the key settings adjustable by the user for the algorithm’s optimal performance.

Interaction description method The evolutionary optimization module expects local relaxations of structures to be performed by an external code (flag CODE) through a queueing system (flag QUET). The current version is linked with VASP for DFT calculations and with MAISE for NN calculations. In case of fast Lennard-Jones, Gupta, or Sutton-Chen potentials, local optimization calls can be made directly from the evolutionary engine in MAISE. Input files and submission scripts for DFT/NN relaxations should be specified in the INI directory.

Population initialization Bulk ground state searches can be initialized via (i) randomization of given structures to bias the search toward nearby stable configurations; (ii) randomization of atoms in a constrained unit cell to make use of available information from XRD; and (iii) unbiased generation of random unit cells and atomic positions. In case the structures have interatomic distances shorter than a tabulated species- and pressure-dependent value, they are adjusted using a simple repulsive interatomic potential or re-generated. NPs can be created with a TETRIS-like function introduced in our recent study [19] that ensures good packing and customizable radial/angular distributions of species. 2D films are constrained to the \( x-y \) plane at the beginning and duration of the ES [111].

Evolution operations Offspring bulk structures are obtained with mutation or crossover operations. The former acts on a randomly chosen parent structure to distort lattice vectors, displace atomic positions, and/or swap atoms of different species. The latter randomly picks two parent structures, rotates the lattice vectors to ensure the best matching of unit cell dimensions, slices the unit cells approximately in half, and combines the pieces with small adjustments at the boundary to avoid short interatomic distances. Offspring NPs can also be created with alternative “Rubik’s Cube” and “spherical cut crossover” operations, described in our previous study and used to quantify the effectiveness of the traditional crossover [19].

Structure selection Once a new generation is locally optimized, the joint population of parent and child structures is ranked according to their enthalpy and each structure \( n \) is assigned the survival probability proportional to \( 1/2(1 - \tanh[2(H_n - H_{min})/(H_{max} - H_{min}) - 1]) \) where \( H_{min} \) and \( H_{max} \) are lowest and highest enthalpies in the population, respectively [112]. Duplicate structures
determined to have similar RDFs, energies, and volumes are assigned zero chance of survival. Structures are eliminated one by one until the merged population is reduced to its original size. Ground states with 10-16 atoms per primitive unit cells are usually found in 1,000-3,000 local optimizations. Configurations with large lattice constant differences (e.g., long stacking sequences) and low atomic densities (e.g., the low-coordination diamond structure) tend to take longer to appear.

**Job execution** The evolutionary optimization is executed by running MAISE in the background. The search (re)starts from a given generation and proceeds for a specified number of iterations (flag NITR). In each cycle, the code generates a new population, submits a job for each structure to a specified queue, checks if the jobs finished successfully, processes the results, and outputs enthalpy/volume for each structure.

**Multitribe optimization** The efficient co-evolutionary simultaneous optimization of NPs introduced and tested in our recent study [20] requires a separate bash script. The wrapper manages the submission of ESs and the exchange of seeds among tribes at the end of each cycle of isolated evolution.

**ES output** The ES progress can be monitored by visualizing the enthalpy profile and heredity of population members saved in 'ebest.dat', 'erank.dat', and 'elink.dat' files (see Figure 3). The connections between points in consequent generations illustrate which parent structures were used to generate the offspring: one for mutations and two for crossovers. After an ES is completed, one can select distinct low-enthalpy structures in the entire pool of locally optimized members by running a post-search analysis with JOBT=13. Configurations with dissimilar RDF dot products by at most SCUT (e.g., 0.95) and with enthalpies at most DENE (e.g., 20 meV/atom) above the lowest-enthalpy structure will be saved and optionally relaxed at the DFT level.

**ES example** Figure 3 illustrates the performance of a typical ES. Structures with Mg$_8$Ca$_4$ unit cells were modeled with our latest NN interatomic potential. A population of 32 members was evolved for 40 generations and converged to the known C14 Laves phase ground state, producing the metastable C15 along the way. Our previous study revealed that C15/C36-Mg$_2$Ca and cS36/mS18-Mg$_7$Ca$_2$ could be overlooked phases synthesizable under high temperatures while B2-MgCa and cF16-Mg$_3$Ca are thermodynamically stable under high pressures [40]. To the best of our knowledge, they are the first examples of new synthesizable compounds predicted with global structure searches based on NN interatomic potentials.

Figure 3: Typical results of ES runs performed with MAISE. This global structure search at the Mg$_8$Ca$_4$ composition identified both the metastable C15 Laves phase and the C14 ground state. The interactions were modeled with the latest Mg-Ca NN interatomic potential. (a) Energy distribution and structure heredity for an ES with 40 generations and 32 members in the population. (b) Collection of all local/global minima at the end of the ES.
7 Neural network model construction

In contrast to traditional classical potentials crafted to describe particular interaction types \[113, 114, 115, 116, 117, 118, 119, 120, 121, 122\], common NN models are intentionally kept devoid of any embedded physics to achieve better transferability \[31\]. The NNs’ great interpolation power comes with users’ great responsibility to generate proper reference datasets and perform careful fitting. This section describes key steps for building general NN interatomic potentials and overviews guidelines for constructing practical NNs applicable to compound prediction.

7.1 Reference data generation

The starting point in NN construction involves choosing a suitable reference interaction description method and selecting particular parts of the potential energy surface (PES) to approximate. Both choices are essential because NNs inherit the method’s systematic/numerical errors and represent the PES well only in or near the sampled regions. While there are well-established comparable DFT approximations that can be picked to describe targeted materials properties \[60, 61, 62, 63, 64, 65, 66\], automated protocols for generating reference dataset are still being developed and tested \[26, 34, 41, 123, 124, 125, 126, 127\].

As a general principle, it is natural to expose NNs to typical configurations that will be encountered in intended applications, such as ground/transition state searches, MD, Monte-Carlo simulations, vibrational property calculations, etc. In our previous study dedicated to unconstrained searches \[34\], we departed from the popular MD-based scheme and introduced an evolutionary sampling approach reviewed and generalized further in Section 8. With the bulk of the diverse dataset created in an unsupervised fashion, we keep an option open for customized input.

One important recourse discussed in Ref. \[34\] is the incorporation of equation of state (EOS) data for select structures, e.g., the dimer, FCC, BCC, HCP, etc., which helps reduce the number of NN artifacts. We demonstrated \[34\] that inclusion of such structures with very short and very long interatomic distances has little effect on the NN description of low-energy structures but teaches the NN to disfavor unphysical configurations that can be inadvertently probed in global searches or MD runs. We found this approach to work better than the common introduction of a repulsive potential. Another beneficial option is the elimination of structures that are either too similar to each other or clearly irrelevant. The reduction of similar structures is performed naturally in our short evolutionary runs during data generation. The exclusion of structures with high energy or forces is done during data filtering as detailed in the next Section. Our typical datasets consist of 86% of evolutionary data with 1-8 atoms per unit cell, 12% of EOS data, and 2% of structures obtained during evolutionary testing of NN models (more details in Section 8).

Standard target values taken from DFT calculations are total energies, atomic forces, and unit cell stresses. In energy training, the outputs of an atomistic NN model need to be summed up for an entire unit cell before they can be compared against the corresponding DFT value. In energy-force training, implemented and examined in our studies in early 2000’s \[128\], the dataset is expanded dramatically with more direct information about local environments. Due to the correlation of forces on nearby atoms according to Newton’s 3\textsuperscript{rd} law, we randomly pick only 25-50% of atoms with non-zero forces in a structure. The resulting ratios of force to energy data in our studies are at least 7:1.

7.2 Data filtering and parsing

The data processing step allows the user to filter out irrelevant configurations, earmark structures for training and testing, and parse atomic environments into NN inputs. These operations can be
customized by choosing flags in the 'setup' file, arranging the data by type into subdirectories, and specifying Behler-Parrinello (BP) symmetry functions [21] in the 'basis' file.

In data filtering, the ECUT, EMAX, and FMAX flags described in Table A8 control the maximum values of energy (enthalpy) and forces allowed in the database. A single energy cutoff is ill-defined or not helpful if the database contains entries with different structure types (clusters or crystal structures), compositions (in multielement systems), or simulation conditions (pressure values). Provided that the data is sorted in subdirectories by type, ECUT and EMAX are applied to the energy per atom within each subset. These values can be overwritten for a specific subset by placing a 'tag' file in the corresponding subdirectory. This 'tag' file can also be used to promote the inclusion of the subset, e.g., EOS data, into the training set.

The energy and force cutoff parameters are critical for striking a balance between the accuracy and the reliability of a NN. It may be tempting to keep EMAX and FMAX below about 0.5 meV/atom and 1 eV/Å, respectively, for exploration of (nearly) stable phases. However, our tests have shown that such NNs develop numerous artificial minima easily accessible in MD or structure optimization runs, a problem known not only for NNs but also for traditional potentials. We have found that when the cutoff values are raised to 5 eV/atom and 10 eV/Å, and even higher for EOS data, the NNs lose 1-2 meV/atom in accuracy but become robust enough to be used in unconstrained searches.

In data parsing, the idea is to precompute and store NN inputs for each structure only once to avoid performing this costly operation at each NN fitting step. The BP symmetry functions used for the conversion can be easily customized by adjusting the parameters in the 'basis' file. We typically use the set with 51 functions per element with the cutoff expanded from 6.0 Å to 7.5 Å and the corresponding η parameters rescaled by a factor of 1.25 (as described in our previous study [40]).

The filtering, earmarking, and parsing operations are done in a single JOBT=30 run. It produces a file for each structure with parsed energy/force NN inputs and collects statistics on the energy, force, volume, and RDF distributions in the full dataset.

7.3 Neural network training

The default NN implemented in MAISE has a standard feed-forward architecture with one bias per input or hidden layer. Signals are processed with hyperbolic activation functions in hidden layers and with the linear function in the output neuron. Our tests on metallic alloys have shown comparable performances of one- or two-layer NNs with the same total number of neurons and insignificant NN accuracy improvements beyond 20 neurons [34]. Based on these observations, we have adopted the 51-10-10-1 architecture with \((51+1) \times 10 + (10+1) \times 10 + (10+1) = 641\) adjustable parameters per chemical element.

The filtered and parsed data is split into training and testing sets with the NTRN and NTST flags, usually at the 9:1 ratio. Data earmarked for training with 'tag' files in the corresponding subdirectories (see Section 7.2) has a higher priority to be placed into the training set.

NN fitting via backpropagation can be performed with BFGS or CG algorithm as implemented in the GSL. Analytic derivatives of the weights are used in both energy and force training, with the latter procedure being slower by a factor of \(\sim 3\) per data point. In order to balance the significance of the energy and force data, the contributions to the full error function from the mismatches between the NN and target force component values are multiplied by 0.1 Å (throughout the present work, 'error' represents the root-mean-square error). The NN weights are initialized randomly or read in from a previous 'model' file.

The optimization is usually carried out for \(1 - 5 \times 10^5\) epochs. We have observed that initial
Figure 4: Error convergence in optimizations of a Cu-Ag NN model with 1,880 adjustable parameters for the same binary structure set with 5,352 energy-only training data (black lines) or 5,352-37,803 energy-force training data (red lines). The ratio of the training to testing data is 9:1. The training errors (dashed lines) are higher than the testing errors (solid lines) for the first 20,000 steps because the training set includes high-energy EOS data. The NN trained only on energies displays a sign of overfitting after about 50,000 steps, while the one trained on energy-force data shows comparable training and testing errors (with or without EOS data) until the end of the 420,000 optimization run.

weight values have little effect on the resulting NN accuracy and that NN snapshots saved during an optimization run provide similar description of EOS, defect energy, and phonons (Figure S4 in Ref. [34]). Overfitting is avoided by keeping the data to parameter ratio above 10:1 and using $L_2$ regularization with $10^{-8} - 10^{-6}$ values. Figure 4 shows typical rates of convergence in energy and energy-force training runs.

7.4 Stratified training

The construction of NNs for multielement systems in MAISE follows a stratified scheme introduced and examined in our previous study [34]. It differs from the traditional approach in that we fit NN weights in a hierarchical fashion from the bottom up, first for elements, then for binaries, and so on. The intact description of the subsystems, as the NN is expanded to more elements, is achieved via the use of a constrained NN architecture. The concept of stratification has been used in the development of classical and tight-binding models [129, 130, 131] but has not received much attention yet in the development of machine learning potentials.

Under ideal conditions - given a complete basis for representing atomic environments within a large cutoff sphere, unlimited number of adjustable parameters and reference data, and a powerful fitting algorithm - a multielement NN with fully optimized elemental and interspecies weights is expected to accurately map the PES for all subsystems. In practice, the use of approximations leads to the following problem. Suppose one wishes to fit a model describing A, B, and AB phases given three datasets of A, B, and AB structures. Let’s say that the PES of element A happens to be trivial and can be approximated with negligible error in the region spanned by the A data. If one now fits all parameters simultaneously to the full A, B, and AB dataset the larger error will be distributed across all elemental and binary systems. In other words, the addition of B and AB data unphysically alters the description of the elemental A phases. It should be noted that the constrained NN architecture does account for the change in the interaction strength between
A atoms induced by the presence of B atoms because the AA/AAA inputs are mixed in with the AB/AAB/ABB inputs via neurons’ non-linear activation functions.

In a study of a particular composition, e.g., MgO, it would not make much sense to start the parameterization with the elements because they will not be encountered in charge-neutral forms or relevant coordinations in MgO structures. With our primary interest in the exploration of full compositions in multiple binary/ternary metal alloys, we have relied on the stratified scheme to build sets of reusable NN models. Our extensive tests have shown that the constraints in the adopted NN architectures do not introduce any appreciable errors for the considered chemical systems [34].

In addition to having a more sound foundation, the stratification procedure significantly accelerates the creation of NN libraries. For example, the full training of a binary AB model on all A, B, and AB data takes about the same time as the sequential training of A, B, and AB models on the corresponding data subsets. However, for an extended block of A, B, and C elements, the standard approach involves the fitting of AC and BC NNs from scratch, while the inheritance of A and B weights in the stratified scheme reduces the total fitting time by at least a factor of two. The speed-up increases dramatically as more elements are added and ternary models are built.

Users can choose the full or stratified scheme with the JOBT flag in the ‘setup’ file. In the latter case, substituent models should be placed in the working directory, e.g., ‘Cu.dat’ and ‘Pd.dat’ for fitting the Cu-Pd binary NN, or ‘CuPd.dat’, ‘CuAg.dat’, and ‘PdAg.dat’ for fitting the Cu-Pd-Ag ternary NN. Presently, MAISE allows for training NN models with up to three elements. While the treatment of systems with more elements is possible conceptually, the practical cost of data generation and parameter optimization becomes expensive.

7.5 Generalized stratified training

In order to extend the stratified procedure to materials with more complex interactions and an arbitrary number of elements, we have considered more flexible NN architectures that still preserve the intact description of the subsystems. Compared to the original stratified NN layout [34], it involves addition of new neurons, shown as green units in Figure 5, with different connection patterns and conditions.

The schematic of a ‘stratified+’ binary NN (top row in Figure 5) illustrates that as long as there are no connections from the inputs or neurons in the elemental subnets to the inserted neurons, the new adjustable weights do not alter the signal processing for pure elemental structures. Despite the added flexibility, the NN still does not allow the proper fitting of interactions in compounds with more than three chemical elements. Indeed, the adjustable parts of such NNs involve 60% of inputs in binaries (top right box in Figure 5), 11% of inputs in ternaries (caption of Figure 5) and none for systems with more elements. In our previous discussion [34], we incorrectly attributed this limitation to the use of pair and triplet symmetry functions. This restriction is actually imposed not by the particular geometric representation of the atomic environments [21, 132, 133] but rather by the NN architecture, and can be lifted as follows.

The ‘stratified±’ expansion (bottom row in Figure 5) introduces semi-adjustable links even in the inherited parts of the merged NN. We add neurons in pairs, coupling the two weights incoming from each subsystem input to have opposite values while coupling the two outgoing weights to be the same. For a purely elemental structure, the interspecies input values are zero and the net signal (at neuron 5) from each elemental input (1) passed through the paired neurons (3&4) will be zero as well regardless of the coupled weight magnitudes. For a binary structure, the non-zero binary inputs multiplied by fully unconstrained weights will unbalance the elemental signals because of the non-linear nature of the activation function resulting in a non-zero contribution at neuron 5.
that depends on both elemental and binary (semi)adjustable weights.

The set of new partially constrained weights shown in yellow in Figure 5 enables the stratified± NN to better capture the screening and charge transfer effects as well as describe interactions in systems with an unlimited number of species. In a trial implementation, we imposed the constraint by penalizing the mismatch between the coupled weights as $\sum_{N} \sigma (w_{1,N} \pm w_{2,N})^2$. We have observed no need to adjust the $\sigma$ penalty factor during the NN optimization, as the differences between coupled weight magnitudes become negligible after a few dozen training steps; near the end of optimization, we set the magnitudes to their average and keep them fixed without any appreciable effect on the error. To the best of our knowledge, this semi-constrained solution for systematically expanding NN features has not been considered in the field of materials modeling. It adds to the collection of alternative NN architectures proposed in recent years for more general applications, such as progressive [134], dynamically expandable [135], and implanted [136] NNs.

One way to determine whether the use of the expanded NN architectures is warranted is to reoptimize the standard stratified NN without any constraints on the full dataset. A significant reduction in the training and testing errors would indicate the need for additional NN flexibility. In our studies of metal alloys, the error reductions are usually in the 0-15% range (e.g., see Figure 4 in Ref. [34]). Our preliminary tests have shown that both stratified+ and ± architectures end up with errors about midway between those in the stratified and full NNs. In order to quantify the improvements arising from the additional degrees of freedom in each scheme, we plan to investigate more challenging systems comprised of different element types in future studies.

Figure 5: Schematic illustration of stratified+ (top row) and stratified± (bottom row) NN architectures for a binary chemical system. The expansion of the original stratified architecture is done with the addition of new neurons shown in green. The weights of elemental NNs (middle row) are copied and kept fixed in all stratified variations. Free, coupled, and fixed weights are shown in green, yellow, and red, respectively. (a) Connections in a simplified NN with one hidden layer and only pair inputs. The partial constraints shown in yellow and explained in the main text ensure intact description of the elemental structures. (b) Color-coded degrees of weight constraints in NNs with pair and triplet inputs. The original and stratified+ schemes have 60% adjustable weights in the first layer in binaries, 11% in ternaries (e.g., only the last one among AA, AB, AC, AAA, AAB, AAC, ABB, ACC, ABC, see Ref. [34]), and none in quaternaries. The stratified± architecture can be used for an arbitrary number of chemical elements.
8 MAISE-NET: automated generator of neural networks

Generation of reference structures suitable for tuning machine learning models has been explored in numerous studies \[26, 27, 37, 43, 124, 137, 138, 139, 140, 141, 142, 123, 125, 126, 143, 127, 144\]. \textit{Ab initio} MD has been a particularly popular approach to sample physically meaningful configurations \[26, 27\]. In our previous work, we argued that datasets created with MD might not have the sufficient representation of diverse environments probed in global structure searches \[34\]. Our evolutionary sampling protocol proposed in 2017 served as a basis for an unsupervised creation of diverse datasets, and our NN models trained on such data have been successfully used in structure prediction \[40, 19, 20\]. A similar approach was developed by Dolgirev et al. \[145\]. Several strategies to improve the mapping of configuration spaces have been developed in recent years, e.g., normal mode sampling \[142\], active learning-based models \[125, 126\], enhanced sampling \[127\], \textit{ab initio} random structure searching \[123, 124\], and entropy-maximization approach \[143\]. A number of studies have shown the benefit of iterating the generation of data and the parameterization of models \[26, 34, 41, 123, 124, 125, 126, 144\].

The generalized sampling protocol implemented in the MAISE-NET wrapper \[99\] relies on the evolutionary search, structure analysis, and NN fitting features in MAISE to construct training datasets in an automated iterative fashion. It has been developed over several studies to deal with systems of increasing complexity. In our early investigation of crystal structure phases of relatively simple Cu-Pd-Ag metals, it was sufficient to generate each of the unary, binary, and ternary datasets in a single cycle, as the NNs trained on this data showed robust performance \[34\]. An accurate description of Cu-Pd-Ag and Au NPs required an iteration to sample cluster geometries with pretrained NNs \[19, 20\]. Our ongoing studies have been dedicated to predicting high-pressure alloy phases and involve several cycles to include unusual motifs stabilized under compression.

An overview of the MAISE-NET operation is presented in Figure 6. A database construction run starts with building a precursive dataset followed by cycles of data generation and NN model training. The complete data generation process is carried out in multiple steps as follows:

(a) \textit{Basic data generation (optional):} If instructed by the user, the script generates a single atom reference and sets of EOS data for small clusters with 2-4 atoms and select high-symmetry prototypes preoptimized for the considered element(s). While being optional, these reference sets, called collectively as EOS0, are essential for teaching the NN to disfavor configurations with unphysically short or long interatomic distances.

(b) \textit{Preliminary DFT-level evolutionary sampling:} MAISE-NET sets up short evolutionary MAISE runs initialized with random structures. As described in Ref. \[34\], the local DFT optimization of each population member for a few ionic steps is followed by an accurate static evaluation of the energy and forces of the resulting configuration. The small set of structures in this cycle 0 samples the walls of multiple basins and is sufficient for a rough approximation of the PES.

(c) \textit{NN model training:} The collection of all available high-accuracy DFT data is parsed and a NN model is built. Various system- and cycle-dependent fitting specifications can be defined in the setup file, e.g., the energy or energy-force training type, the number of steps for each training type, etc.

(d) \textit{NN-driven generation of DFT data:} MAISE-NET launches MAISE evolutionary runs to randomly generate and locally optimize new structures using the latest NN model. Compared to step (b), it proved to be unnecessary to proceed beyond the first ES generation because small unit cells with 1-8 atoms have a chance to converge to the global minimum with full local optimization affordable at the NN level. After the uniqueness of the obtained minima is verified through the structure comparison feature in MAISE and they are accepted in the pool based on a weighting
factor favoring low-enthalpy structures, the corresponding relaxation paths are examined to extract several intermediate structures per minimum. The target total number of generated structures per cycle, referred to as 'EVOS' data, is specified in the setup file.

(e) **NN model test and TEST data (optional):** If instructed by the user, MAISE-NET launches a proper evolutionary ground state search using the NN model trained in step (c). The resulting NN-based minima are then optimized at the DFT level. A detailed report is compiled on the symmetry and enthalpy of the resulting minima at the NN and DFT levels. The user has an option to include the DFT energies and forces of the NN- and DFT-based minima into the dataset for the NN training in subsequent cycles. The data will be added to the collection of training data as 'TEST' data. Although generation of the TEST data during the model construction run is optional, the script has the feature to perform this evolutionary search test for an existing NN model as an independent functionality.

(f) **DFT EOSN data generation (optional):** If instructed by the user, a small set of EOS data is generated for unique DFT-optimized minima obtained in each cycle and added to the pool of training data for the next cycles as 'EOSN' data.

Steps (c) through (f) are repeated for a user-specified number of cycles, with a NN model trained from scratch on all collected DFT data at the end of each iteration. The run can be terminated or extended by the user at each iteration depending on whether a satisfactory accuracy for the NN model is achieved. While steps (a), (e), and (f) are optional, our tests for elemental, binary, and ternary metal systems have indicated that addition of these datasets significantly improves the NN
model suitability for ground state searches in terms of accuracy and reliability. Generation of a typical training dataset of $\sim 5,000$ structures with the MAISE-NET script required roughly 20, 30, and 40 thousand CPU hours of DFT calculations for elemental, binary, and ternary metallic compounds, respectively. The higher DFT calculation cost for each binary and ternary systems is primarily due to the increased number of DFT calculations for structures with larger unit cells. Figure 7 illustrates the distribution of data and NN accuracy for Cu-Ag.

The end-to-end NN construction depends on a large number of parameters and can be a daunting task for new users. With this in mind, we have developed MAISE-NET to have the following features.

*Easy customization* MAISE-NET can be run with both Python 2 and 3 version families out-of-the-box without requiring any external modules to be installed. It includes well-tested ‘setup’ templates for developing elemental, binary, and ternary NN models. All key functionalities can be tuned by adjusting ‘setup’ parameters listed in Table A9. Upon detection of user-provided NN models for the relevant subsystems, the script performs the NN fitting in the stratified fashion.

*Complete automation* Once the run is configured, the data generation and NN construction can proceed without any further user input or supervision. In particular, the script makes sure that DFT data is collected only from successfully finished VASP calculations.

*Full transparency* An extensive set of messages is produced and sent into standard output/screen to notify the user about the progress of the run. The most important messages are saved in the ‘output.dat’ file. A comprehensive summary is generated to give the user a detailed account about the generated dataset.

![Figure 7: Characteristics of the generated dataset and accuracy of the constructed NN model for the Cu-Ag binary.](image)

(a) Distribution of the generated dataset for various data types: EVOS (evolutionary data), TEST (NN model testing results), EOS0 (basic data generated before zeroth cycle), and EOSN (EOS data generated during the evolutionary run). (b) Histogram of energy errors the testing set. (c) Distribution of testing errors as a function of the enthalpy difference relative to the lowest-enthalpy phase at each pressure.
9 Library of neural network models

A library of select NN and empirical potentials is provided with the distribution in the 'models/' directory. Model file names specify the interaction type (a NN or a traditional potential), dimensionality of the data used to parameterize the model (0 for crystals and clusters or 3 for crystals only), and the generation/version number. Model file headers list information about models' authorship, architecture, performance, etc. The body of the NN files contain bias and weight values. Finally, the end of the files specifies the symmetry function basis chosen for the model.

We have recently started building a new generation of NN models (gen2) for a large set of metals to allow the prediction of stable alloys under ambient and high pressures. The use of MAISE-NET with standardized settings ensures that we can create a library of models in the stratified fashion. Figure 8 shows the accuracy of the new generation of NNs tested to perform well in structure searches up to 30 GPa pressure.

Figure 8: Testing error for available second-generation NN interatomic potentials constructed with the MAISE-NET script.

10 Performance and efficiency

Benchmarking results reported in our previous studies [34, 40, 19, 20] have demonstrated the levels of speed and accuracy generally expected from the constructed NN models. For systems with 50-100 atoms, calculations performed with the order-\(N\) NNs were found to be \(10^4 - 10^5\) times faster than with the order-\(N^3\) DFT and about \(10^2\) times slower than the order-\(N\) empirical potentials [146, 35, 147, 148]. The two most demanding computational tasks, the NN training and the NN use in structure simulations, are parallelized with OpenMP over the total number of structures in the reference dataset in the former case and over the number of atoms in the latter one. Figure 9 illustrates that the parallelization efficiency is system-dependent and can be up 90% on 16 cores and 70% on 32 cores.

As overviewed in Section 9, the overall accuracy for most developed models ranges between 2 and 10 meV/atom in the considered systems with up to three metals. The DFT formation defect energies are typically reproduced within 0.1-0.2 eV/defect (see Figure 10), which is consistent with the NN errors per atom (see discussion in Ref. 34). The accurate description of forces with the NNs allows one to identify dynamically unstable structures and obtain accurate evaluations
of relative phase stability at elevated temperatures by including vibrational entropy corrections (Figure 5 in Ref. [20] and Figure 10 in the present work). It has been encouraging to observe practically the same accuracy of NNs trained in the full and stratified fashions.

Figure 9: MAISE performance in structure relaxation and NN model training. (a) Total CPU time for the relaxation of bulk (red circles) and NP (blue diamonds) Au structures performed on a 32-core Intel Xeon Gold 5218 @ 2.30 GHz compute node. (b) Parallelization efficiency of MAISE for local optimization of a 1024-atom Au crystal structure computed on a 16-core Intel Xeon E5-2650 @ 2.00 GHz (grey circles) and a 32-core Intel Xeon E5-4620 v2 @ 2.60 GHz (black diamonds). The dynamic allocation in OpenMP helps distribute the load for processing atoms with different numbers of neighbors. (c) Parallelization efficiency of training a NN model on energy-only (grey circles) and energy-force (black diamonds) data, performed on a 32-core Intel Xeon Gold 5218 @ 2.30 GHz compute node.

Figure 10: Accuracy of the NN models constructed with MAISE in the evaluation of different properties. (a) Vibrational entropy corrections to the relative stability between two low-energy NPs for two sizes, Au34 and Au55 [20]. (b) Substitutional defect formation energies for Cu-Ag binary structures evaluated with stratified (red circles) and full (blue diamonds) NN models and compared to the DFT values (black squares).
The most important quality measure of NNs developed in our studies has been their performance in structure prediction \[40, 19, 20\]. We carried out a systematic comparison of NN models and traditional potentials against the DFT, which appears to be the largest of the kind so far, to quantify their ability to resolve low-energy configurations in global structure searches \[20\]. By examining up to 60 lowest-energy candidates for each size in the Au\(_{30}\)-Au\(_{80}\) NP range, we established that NNs (6.5 meV/atom accuracy) are far better suited to guide \textit{ab initio} ground state search than the Gupta, Sutton-Chen, or embedded atom model (estimated 30 meV/atom accuracy). The large number of NP configurations with close energies makes it difficult to conclusively determine the DFT minimum with either approach but the use of the NNs instead of the traditional potentials reduces the number of structures needed to be re-evaluated at the DFT level by at least 1-2 orders of magnitude. Moreover, the good correspondence between the NN and DFT atomic forces allowed us to introduce a hybrid NN+DFT approach that significantly improves the search reliability. Application of NN models with 2-10 meV/atom accuracy to bulk crystals is expected to be far more effective for identifying the DFT ground states because of the simpler PES near the global minimum in systems without surfaces.

11 Summary

In this work, we have reviewed notable predictions and present capabilities of MAISE. The list of eight crystal structure predictions made at the DFT level and confirmed in concurrent or following experiments is presented in Section 2. The identification of possible synthesizable Mg-Ca phases with global structure searches at the NN level\[34\], which appears to be the first example of new thermodynamically stable crystalline compounds predicted in this fashion, is discussed in Section 2. Key aspects of the evolutionary optimization implemented in MAISE for crystals, films, and clusters are described in Section 6.

The main feature of the package is the construction of NN interaction models for use in structure prediction (Section 7). We outline our protocols for configuration space sampling and NN training that ensure the robustness of the DFT PES mapping. In particular, we introduce expanded stratified schemes that allow the construction of NN models in a hierarchical fashion for an arbitrary number of chemical elements. All stages of the iterative NN development are handled with an automated MAISE-NET wrapper (Section 8). The script has been used in our ongoing effort to build a new generation of NN models (Section 9). So far, NNs for 12 metals, 5 binary alloys, and 1 ternary alloy with an accuracy in the 2-9 meV/atom range have been tested in unconstrained structure searches at pressures up to 30 GPa. Section 5 illustrates MAISE and NN performance in local structure relaxations, MD simulations, and phonon calculations. MAISE, MAISE-NET, and developed NN models are available for download on Github \[98, 99\].

Appendix A  Setup parameters for various MAISE features

This section lists key setup parameters for evolutionary global structure optimization, local structure optimization, MD simulations, data parsing, and NN training with MAISE as well as key setup parameters for the automated NN model construction with MAISE-NET. The following tables include a minimal set of parameters, i.e., those which need to have a defined value for the code to operate properly.

| flag  | description                                      |
|-------|--------------------------------------------------|
| JOB T | job type: structure relaxation (20)              |
| NPAR  | number of cores for parallel run                 |
| NDIM  | dimensionality of unit cell: crystal (3); cluster (0) |
| MITR  | maximum number of cell optimization steps        |
| RLXT  | cell optimization type: force only (2); full cell (3); volume (7) |
| PGPA  | external pressure in GPa                         |
| ETOL  | error tolerance for cell optimization convergence|
| COUT  | output options E: final (00); first/final (01); all steps (02); EF: final (10); first/final (11); all steps (12) |
| MINT  | minimizer type: BFGS2 (0); CG-FR (1); CG-PR (2); steepest descent (3) |

Table A3: Setup parameters for local structure optimization.

| flag  | description                                                                 |
|-------|-----------------------------------------------------------------------------|
| JOB T | job type: molecular dynamics (21)                                           |
| MDTP  | MD run type: NVE (10); NVT (20); NPT (30); isobaric-isothermal (40)         |
| NPAR  | number of cores for parallel run                                           |
| TMIN  | starting temperature of the simulation                                      |
| TMAX  | final temperature of the simulation                                         |
| TSTP  | temperature increment during the simulation                                 |
| DELT  | integration time step in fs                                                |
| NSTP  | number of integration steps per temperature                                 |
| CPLTP | thermostat coupling constant                                               |
| CPLP  | barostat coupling constant                                                 |
| ICMP  | isothermal compressibility in 1/GPa                                        |

Table A4: Setup parameters for MD simulations.

| flag  | description                                                                 |
|-------|-----------------------------------------------------------------------------|
| JOB T | job type: phonon calculations (22)                                           |
| DISP  | size of the displacement made to each atom in angstroms                     |
| NPAR  | number of cores for parallel run                                           |
| NDIM  | dimensionality of the unit cell: crystal (3); cluster (0)                   |

Table A5: Setup parameters for phonon calculations.
| flag    | description                                                                 |
|---------|-----------------------------------------------------------------------------|
| JOBT    | evolutionary search: run (10); soft exit (11); hard exit (12); analysis (13) |
| NMAX    | maximum number of atoms                                                     |
| MMAX    | maximum number of neighbors within cutoff radius                           |
| NSPC    | number of species types                                                     |
| TSPC    | species types                                                               |
| ASPC    | atom number of each species in evolutionary searches                        |
| CODE    | MAISE-INT (0); VASP-EXT (1); MAISE-EXT (2)                                  |
| QUET    | queue type: torque (0); slurm (1)                                           |
| NDIM    | structure type: crystal (3); film (2); cluster (0)                          |
| LBOX    | box size for cluster calculations (ignored for crystals)                    |
| NPOP    | population size                                                             |
| SITR    | starting iteration                                                          |
| NITR    | number of iterations                                                        |
| TINI    | starting options if SITR=0                                                  |
| TIME    | max time per relaxation                                                     |
| PGPA    | pressure in GPa                                                             |
| DENE    | energy/atom window for selecting distinct structures                        |
| SCUT    | RDF difference for selecting distinct structures                            |
| TETR    | random using TETRIS                                                         |
| PLNT    | seeded                                                                      |
| PACK    | biased                                                                      |
| BLOB    | random using blob shape                                                     |
| MATE    | crossover using two halves                                                  |
| SWAP    | crossover using core-shell                                                  |
| RUBE    | Rubik’s cube operation                                                      |
| REFL    | symmetrization via reflection                                               |
| INVS    | symmetrization via inversion                                                |
| CHOP    | chop to make facets                                                         |
| MUTE    | distortion                                                                  |
| ELPS    | cluster ellipticity                                                         |
| MCRS    | crossover: mutation rate                                                    |
| SCRS    | crossover: swapping rate                                                    |
| LCRS    | crossover: mutation strength for lattice vectors                            |
| ACRS    | crossover: mutation strength for atomic positions                           |
| SDST    | distortion: swapping rate                                                   |
| LDST    | distortion: mutation strength for lattice vectors                           |
| ADST    | distortion: mutation strength for atomic positions                          |
| SEED    | starting seed for the random number generator (0 for system time)           |

Table A6: Setup parameters for evolutionary search.
| flag  | description                                                                 |
|-------|-----------------------------------------------------------------------------|
| JOBT  | job type: data parsing (30)                                                 |
| NPAR  | number of cores for parallel training or cell simulation                    |
| TEFS  | parsing for: E (0); EF (1)                                                   |
| FMRK  | fraction of atoms that will be parsed to use for EF training                |
| NSPC  | number of element types for dataset parsing and training                    |
| TSPC  | atomic number of the elements specified with NSPC tag                       |
| NSYM  | number of the BP symmetry functions for parsing data                        |
| NCMP  | the length of the input vector of the neural network                        |
| ECUT  | parse only this fraction of lowest-energy structures (from 0 to 1)           |
| EMAX  | maximum energy from the lowest-energy structure that is parsed              |
| FMAX  | will not parse data with forces larger than this value                      |
| RAND  | random seed for the parsing: time (0); seed value (+); no randomization (-) |
| DEPO  | path to the DFT datasets to be parsed                                       |
| DATA  | location of the parsed data to write the parsed data                        |

Table A7: Setup parameters for data parsing.

| flag  | description                                                                 |
|-------|-----------------------------------------------------------------------------|
| JOBT  | training type: full training (40); stratified training (41)                 |
| NPAR  | number of cores for parallel training                                        |
| MINT  | the optimizer algorithm for neural network training                           |
| MITR  | number of the optimization steps for training                                |
| ETOL  | error tolerance for training                                                 |
| TEFS  | training target value: E (0); EF (1)                                         |
| NSPC  | number of element types for dataset parsing and training                     |
| TSPC  | atomic number of the elements specified with NSPC tag                       |
| NSYM  | number of the BP symmetry functions for parsing data                        |
| NCMP  | the length of the input vector of the neural network                        |
| NTRN  | number of structures used for training (negative number means percentage)   |
| NTST  | number of structures used for testing (negative number means percentage)     |
| NNNN  | number of hidden layers (does not include input vector and output neuron)   |
| NNNU  | number of neurons in hidden layers                                          |
| NNGT  | activation function type for the hidden layers’ neurons: linear (0); tanh (1)|
| LREG  | regularization parameter                                                     |
| SEED  | rand seed for generating NN weights (0 for system time)                      |
| DATA  | location of the parsed data to read from for training                       |
| OTPT  | directory for storing model parameters in the training process               |
| EVAL  | directory for model testing data                                            |

Table A8: Setup parameters for training of NN models.
| flag    | description                                                                 |
|---------|-----------------------------------------------------------------------------|
| JOBT    | job type: basic data generation (80); evolutionary data generation (81); test run (87); pause (88); exit (89) |
| TSPC    | atomic number of the elements                                               |
| QUET    | queue type: torque (0); slurm (1); IBM-lsf (2)                              |
| LBOX    | unit cell size: should be non-zero for BASIC data                           |
| MAXJ    | maximum number of DFT jobs to be submitted at once                          |
| ECUT    | energy cut-off for DFT (0 = VASP default)                                   |
| PREC    | precision of the DFT run (e.g., norm,acc)                                   |
| KDNS    | K-mesh density for DFT runs                                                 |
| SMER    | VASP ISMEAR                                                                  |
| SIGM    | VASP SIGMA (for REFS and CLST data will be set to 0.01)                     |
| LREG    | regularization parameter                                                    |
| NNNU    | number of neurons in hidden layers                                          |
| NNGT    | activation function type for the hidden layers’ neurons: linear (0); tanh (1) |
| NPAR    | number of cores for parallel parsing                                        |
| NSYM    | number of the BP symmetry functions for parsing data                        |
| RCUT    | BP symmetry function cut-off radius: 6 Å (0); 7.5 Å (1)                      |
| FMRK    | ratio of atomic forces for training                                          |
| SITR    | starting cycle (0 for full run)                                             |
| NITR    | final cycle                                                                 |
| DATA    | desired number of structures per cycle (1+)                                 |
| aspc    | list of number of atoms/unit cell (for cycle 0)                             |
| npop    | list of population size for evolution runs (for cycle 0)                   |
| mitr    | number of training steps (for cycle 0)                                      |
| tefs    | type of training at each round                                              |
| ASPC    | list of number of atoms/unit cell (for cycles 1+)                           |
| NPOP    | population size for evolution runs (for cycles 1+)                          |
| ITER    | relaxation steps for NN-based search                                        |
| MITR    | number of training steps (for cycles 1+)                                    |
| TEFS    | type of training at each round (for cycles 1+)                              |
| EXTR    | extended force training factor when cycle = NITR                            |
