**Abstract**

**Background:** *Toxoplasma gondii* is an obligate, intracellular, apicomplexan parasite that causes toxoplasmosis. Although the global prevalence of toxoplasmosis has been estimated to be approximately 30%, there is limited seroprevalence data in Ghana, with a dearth of information on the impact of *T. gondii* on haematological parameters in exposed persons.

**Methods:** Questionnaires were administered to 300 consenting individuals to obtain demographic information and assessment of their risk of exposure to *T. gondii*. Using anti- *T. gondii* IgG/IgM combo test kits, seropositivity to *T. gondii* parasite-specific IgG and/or IgM was determined. A haematological analyser was used to measure haematological parameters.

**Results:** There was an overall seroprevalence of 50.3% (n=151), with 49.7% (n=149) of the study participants seropositive for IgG and 1% (n=3) testing positive for IgM. Furthermore, the observed seroprevalence among pregnant women was 56.4% (n=62). With regard to settlement type, a seroprevalence of 55.6% was observed in the rural community, 50.6% in the peri-urban community and 47.1% in the urban community. The study identified cat ownership, contact with cat litter, contact with raw meat [RR (95% CI: 1.76 (1.23-2.53), 1.66 (1.03-2.67), 1.25(1.00-1.57)] and age (p<0.001) as risk factors for infection. Analyses of haematological data revealed significant reduction in the white blood cell, lymphocytes and mean corpuscular volume levels in seropositive males (p=0.0223, 0.0275, and 0.0271) respectively. Only the mean corpuscular volume of seropositive females reduced significantly as compared to the seronegative counterparts (p=0.0035).

**Conclusions:** About half of the study population, including women of reproductive age carried antibodies against *T. gondii*, raising concerns...
about the risk of congenital toxoplasmosis and anaemia. We, therefore, recommend that screening for *Toxoplasma gondii* be included in the routine screening of pregnant women seeking antenatal care and further investigation should be conducted on the haematological implications of infection in humans.

Amendments

1. We introduced Figure 1, which describes the seroprevalence of anti-T. gondii IgG, IgM and both IgG and IgM among children and pregnant women. Accordingly, the results section has been updated.

2. Table 2b gives a bit more information on the seropositivity for specific immunoglobulins per the settlement (rural, peri-urban and urban).

3. Information was also provided on the seroprevalence of the T. gondii specific immunoglobulins G and M in the trimesters of pregnancy. This can be found in Table 3b.

4. We also included the information on the risk factors (Table 4)

5. An update was made on the hematological analysis. These can be seen in (Tables 6 a-c) The summary on the results and discussion have also been updated.

Any further responses from the reviewers can be found at the end of the article

Introduction

Toxoplasma gondii — the causative organism for toxoplasmosis — is an obligate, intracellular, apicomplexan parasite with a wide geographic distribution and the ability to infect virtually any cell type across a broad host range, including humans, companion animals, livestock and wildlife. About a third of the world’s population is infected with T. gondii but the parasite does not usually cause clinically significant disease. Until recently, latent infections in humans were assumed to be asymptomatic; however, results from animal studies, personality and behavioural profiles, as well as psychomotor performance tests have led to a reconsideration of this assumption.

Certain individuals, including foetuses, neonates, and the immune-compromised are at high risk for life-threatening complications from toxoplasmosis. Congenital transmission of T. gondii carries the risk of miscarriage or stillbirth, and children born with toxoplasmosis are likely to suffer from severe symptoms, such as hydrocephalus, calcifications of the brain or retinochoroiditis later in life if not treated.

People are typically infected by either accidentally ingesting infectious oocysts or eating undercooked meat containing tissue cysts (bradyzoites). Toxoplasma oocysts can be found in soil or water contaminated with cat faeces, making the consumption of raw vegetables and water from unsafe drinking sources important risk factors for infection. The consumption of raw or undercooked meat is also a risk factor as livestock and game often harbour bradyzoites. The parasite can also be transmitted in utero to a developing foetus if a woman is infected for the first time while pregnant. Solid-organ transplantation such as the heart, liver and kidney transplants are another means by which T. gondii infection can occur, although this is very rare.

During acute primary infection with T. gondii, anti- T. gondii immunoglobulin M (IgM) is initially produced. However, IgM titres decline over the next few months, becoming undetectable within a year. The immune system also produces anti- T. gondii IgG a few weeks after the initial infection. IgG antibody levels usually peak within one or two months after the infection but are still detectable throughout the lifetime of the infected individual. The seroprevalence of antibodies against T. gondii has been reported across the globe, and ranges from 51% to 72% in several countries in Latin America and the Caribbean, including Argentina, Brazil, Cuba, Jamaica, and Venezuela. In Scandinavia, the seroprevalence of antibodies specific to T. gondii is reported to vary between 11% and 28%, while in Southeast Asia, China and Korea, seropositivity to T. gondii exposure has been estimated to range from 4% to 39% in women of reproductive age. Furthermore, both active and latent infections of T. gondii have been reported in many African countries, particularly in individuals suffering from HIV/AIDS. For example, 88.2% of HIV-positive individuals seeking healthcare at Arba Minch Hospital in Ethiopia were also seropositive for T. gondii infection, and a study conducted in Burkina Faso among pregnant women revealed an overall seroprevalence of 31.1%.

In Ghana, Sefa-Boakye et al. and Ayi et al. reported seroprevalence rates of 83.6% and 92.5% among pregnant women in Kumasi and Accra, respectively. In the Central region of Ghana, Abu et al. reported an overall seroprevalence of 85% in a population-based study that investigated risk factors for T. gondii infection. A follow-up study later revealed that 2.6% of the study participants showed signs of ocular toxoplasmosis. In the Greater Accra region, Kwofie et al. analysed placental tissue samples from IgG-seropositive women post-delivery and estimated the risk of congenital transmission of the infection to be 39.8% based on the presence of T. gondii DNA in the placental samples.

Methods

Ethical consideration

Prior to the commencement of the study, approval was obtained from all three hospitals. Ethical approval for the study was also given by the Committee on Human Research Publications and Ethics at the Kwame Nkrumah University of Science and Technology and Komfo Anokye Teaching Hospital in Kumasi, Ghana (reference number: CHRPE/AP/018/18). Written informed consent was obtained from all the study participants.

Study design

A cross-sectional study design was employed. Study participants were recruited during hospital visits that occurred between 30th January and 28th February 2018. Questionnaires were administered to obtain data on demographics and risk factors.
Study site
The study was conducted at three hospitals; namely, Kumasi South Hospital (KSH), Agona Government Hospital (AGH) and Kuntanase Government Hospital (KGH), all in the Ashanti region of Ghana. KSH is located in Atousu, a community within the Asokwa Sub-metropolitan Assembly of the Kumasi Metropolis which has a population size of 1,730,249. Recruitment and sample collection were conducted from 31st January to 8th of February 2018 at KSH. At KGH, recruitment and data collection were carried out from 15th–16th and 27th–28th February 2018. KGH is situated in Kuntanase, the capital of the Bosumtwi district of the Ashanti Region with a population of 93,910 and located at about 28km from the capital city, Kumasi. AGH is located at about 37 km from Kumasi and is situated in the Sekyere South District, which has a population of 94,009. Recruitment and selection of participants took place from 19th–21st February 2018 at the Agona Government Hospital.

Participant selection
To be included in the study, individuals had to be at least six months of age and had to have been referred to the laboratories of one of the study hospitals (KSH, KGH and AGH). Pregnant women were preferentially recruited into the study due to our interest in congenital toxoplasmosis. The selection of study subjects was based on their willingness to participate after being briefed about the study, and confirmed by signing or thumb-printing an informed consent form. In the case of minors, consent was obtained from parents or legal guardians. Critically ill patients (individuals in need of urgent medical attention) and children below 6 months were excluded from the study. We provided a written questionnaire to each of the participants as they waited for their turn at the laboratory of the various hospitals. The questionnaires were administered in the form of an interview to all participants by the investigators.

Variables
Data obtained from the questionnaires on factors that predispose respondents to infection (cat ownership, contact with cat litter, eating raw meat, consumption of raw or undercooked vegetables and sources of drinking water) were analysed. As part of the demographic data, age, sex, location (rural, urban or peri-urban), education and employment were also analysed. These variables were treated as predictor variables and compared with the anti-\textit{T. gondii} serological results (endpoint variables).

Bias
The female to male ratio was identified to be biased. This was due to priority being given to the enrolment of pregnant women.

Sample size determination
A minimum sample size of 207 was determined using the binomial model. This was calculated with a 95% CI and precision level of 5%: \( N = \frac{Z^2 \cdot (P) \cdot (1-P)}{d^2} \) using overall seroprevalence of 83.4% observed by Sefah-Boakye et al.\textsuperscript{3} in the Ashanti region. In this equation, \( N \) is the sample size, \( Z \) is the critical value of the binomial distribution at the 5% level (1.96), \( P \) is the overall seroprevalence (0.84), \( q = 1 - p \), and \( d \) (error) is the precision level (5%).

Quantitative variables
Participants who tested positive for parasite-specific IgG, IgM or both were classified as seropositive, while those with negative tests were described as seronegative. We compared the median haematological parameter values of the seropositive and seronegative categories to investigate the effects of infection on the different haematological indices.

Haematological analyses
Using sterile needles and syringes, qualified phlebotomists obtained 3 mL of venous blood from each participant. The blood samples were dispensed into labelled EDTA tubes to prevent clotting and were later used for haematological analyses. Complete blood counts were run on the blood using the Sysmex XP-300 Automated Haematology Analyzer. The analyser provided cell count data on red blood cells (RBC), white blood cells (WBC), lymphocytes, neutrophils and platelets. Other parameters measured included haemoglobin (Hb), mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), mean platelet volume (MPV), plateletcrit and red blood cell distribution width (RDW).

Serological analyses
The blood samples were tested for the presence of anti-\textit{T. gondii} IgG/IgM using the commercially available OnSite Toxo IgG/IgM rapid combo test kit manufactured by CTK Biotech, USA. This test kit works with either whole blood or serum. Following the manufacturer’s protocol, a 10 µL sample of blood was dropped into the sample/buffer well on the kit. Two drops of buffer were then added and allowed to stand for 10–15 min. Results were recorded as positive if both the test control line and M and/or G line(s) developed. Test results were seropositive for IgG if the G line developed in addition to the control (C) while blood samples were seropositive for IgM if the M line appeared in addition to the control. Seropositive results to IgG and IgM were obtained when both the M and G lines developed in addition to the control (C) band.

Data analysis
Data obtained from serological examination and questionnaires were keyed into Microsoft Excel (2016). Seroprevalence was calculated by expressing the number of seropositive individuals as a percentage of the total number tested. The chi-square and Mann-Whitney U tests were carried out in GraphPad Prism 6 (GraphPad Software, Inc., San Diego, CA, USA) to investigate the association between demographics and seropositivity, as well as to compare the differences in the median haematological values of seropositive and seronegative individuals respectively. STATA 14 was also used to determine the relative risk of seropositivity for each risk factor. Analysed results were considered statistically significant if \( p \leq 0.05 \).

Results
In total, 300 participants were recruited for the study. Out of this number, 80.6% (n=242) were female, of which 45.5%
A total of 110 pregnant women were recruited into the study, including 37 in their first trimester, 41 in the second trimester and 32 in the third trimester. The women ranged in age from 16 to 45 years, with a mean age of 28.6 years. Out of the 110 pregnant women, sixty-two were seropositive, indicating a general seroprevalence of 54.6%. Seropositivity for *T. gondii* was observed in 18 (48.6%) of the pregnant women in their first trimester, 22 (53.7%) in their second trimester and another 22 (68.8%) in their third trimester (Table 3a). Almost all seropositive pregnant women within the first 16.4% (n=18), second 20% (n=22) and third 20% (n=22) trimesters were seropositive for only anti-*T. gondii* IgG. (Table 3b).

To identify risk factors for *T. gondii* infection, the risk-ratio and chi-square tests were conducted to investigate the association between a few predisposing factors and seropositivity. Cat ownership (p=0.002) and contact with cat litter (p=0.003) were strongly associated with seropositivity for *T. gondii*. Handling of raw meat was also identified as a risk factor for exposure (p=0.05) (Table 4).

Certain demographic factors were also investigated to ascertain their association with seropositivity. The results revealed that...
In this study, an overall seroprevalence of 50.3% was observed, which is similar to a study from Accra that reported a seroprevalence rate of 49.7%17, in contrast to another Accra-based study that reported 92.5% seroprevalence12. The study also found a seroprevalence rate of 1.0% for parasite-specific IgM, suggesting active infections in these study participants. Other studies have previously reported fairly low seroprevalence rates of IgM, including 6.0% in the Central region of Ghana and 2.5% in Southwestern Ethiopia13,14. However, anti-T. gondii IgM seroprevalence rates as high as 29.7%, 39.1% and, even, 76.1% have been reported in Accra and Kumasi14,12,17. Variations in the seroprevalence of anti-T. gondii antibodies from different studies may be due to methodological differences, including the choice of commercial ELISA kits.

As the three hospitals were located in different settlement types (urban, peri-urban and rural), we assumed that the patient population at each hospital primarily comprised individuals from the surrounding communities. We, therefore, compared seroprevalence rates among participants from the urban, peri-urban and rural communities. In many instances, rural inhabitants regularly come into contact with potentially oocyst-contaminated soil as part of their normal farming activities. However, we found no significant association between seropositivity and settlement type, which agrees with findings from Munoz-Zanzi et al.,19, who also found no obvious differences in seroprevalence between rural villages and urban slums. In contrast, Kawashima et al.20 showed that seropositivity was significantly higher in rural communities compared to urban communities.

Acute infection by T. gondii in pregnancy can be detrimental to the foetus, resulting in stillbirth, chorioretinitis, hydrocephalus or even death21. The ability of almost all subclasses of IgG — with the notable exception of IgG2 — to cross the placenta provides some form of protection to the foetus22. The period of pregnancy in which the expectant mother becomes infected greatly influences the incidence and severity of the disease. Infection within the first trimester of pregnancy carries an approximately 6% risk of transmission to the foetus, while in the second and third trimesters, the risk of congenital transmission is about 33–47% and 60–81%, respectively22. Contrary to the gestational risk of transmission, the risk of developing clinical symptoms of the disease (congenital toxoplasmosis) is highest when maternal infection occurs within the first trimester and gradually reduces through the second and third trimesters21. Our study estimated an overall anti-T. gondii seroprevalence of 56.4% among pregnant women. This observation is lower than the 83.6% reported by et al.19, who also found no significant association between seropositivity and settlement type, which agrees with findings from Munoz-Zanzi et al.,19, who also found no obvious differences in seroprevalence between rural villages and urban slums. In contrast, Kawashima et al.20 showed that seropositivity was significantly higher in rural communities compared to urban communities.

In this study, an overall seroprevalence of 50.3% was observed, which is similar to a study from Accra that reported a seroprevalence rate of 49.7%17, in contrast to another Accra-based study that reported 92.5% seroprevalence12. The study also found a seroprevalence rate of 1.0% for parasite-specific IgM, suggesting active infections in these study participants. Other studies have previously reported fairly low seroprevalence rates of IgM, including 6.0% in the Central region of Ghana and 2.5% in Southwestern Ethiopia13,14. However, anti-T. gondii IgM seroprevalence rates as high as 29.7%, 39.1% and, even, 76.1% have been reported in Accra and Kumasi14,12,17. Variations in the seroprevalence of anti-T. gondii antibodies from different studies may be due to methodological differences, including the choice of commercial ELISA kits.

In disease control, prevention and elimination, identification of the risk factors for infection are key. Horizontal transmission of T. gondii may occur via contact with cat litter,

Consumption of raw meat, eating of raw or undercooked vegetables, organ transplant and blood transfusion. We identified cat ownership, contact with cat litter and handling of raw meat as important risk factors for infection among our study population. Since T. gondii undergoes sexual reproduction in the gastrointestinal tract of domestic felines, individuals who owned cats or had regular contact with cat litter had 76% and 66% greater risk of T. gondii infection respectively compared to individuals who neither owned cats nor handled cat litter. Furthermore, since T. gondii is capable of encysting in the tissues of infected animals, people who regularly handle raw meat are also at greater risk of infection. We also investigated the association between certain demographic parameters and seropositivity. Consistent with findings from other studies in Ghana and Iran, seropositivity increased with age. This is due to the fact that infection has strongly been associated with contact...
with the soil where the oocyst prevails for years. The longer an individual survives, the greater the likelihood of coming into contact with contaminated soil hence the increase in seroprevalence with age.

*T. gondii* is capable of invading any nucleated cell, including immature red blood cells\textsuperscript{26}. As a mechanism of survival, intracellular parasites need to exit and re-infect other cells.

The mechanism by which *T. gondii* exits infected cells is still not clearly understood. Some *in vitro* studies have demonstrated that *T. gondii* exits the cell by exerting tension on the host cell membrane, often causing the cell to rupture\textsuperscript{27}. Other studies have suggested that the parasite exits the host cell by disrupting the cytoskeleton in a manner similar to *Plasmodium*, resulting in cell lysis\textsuperscript{28}. In the previous report by Agordzo *et al.*, (2019), results obtained for seropositive and seronegative

individuals were generally similar. This is not different from the present study where the haematological data had been expanded and comparisons made between similar groups. These observations agree with other findings where haematological parameters sometimes remain stable even in times of infection. With the exception of pregnant women, we found significant differences in the mean corpuscular volumes of *T. gondii* seropositive and seronegative males and females. The mean corpuscular volumes increased significantly in seropositive individuals for both males and females as compared to the seronegative groups. Furthermore, the mean corpuscular volume was reported to have reduced significantly in seropositive pregnant women in Libya which is not the case in our study. We observed an increase in the MCV of seropositive males and females whereas an increase in their counts were observed for pregnant women. The lymphocyte levels in seropositive males reduced significantly as opposed to the seronegative groups. In the case of the pregnant women, the lymphocyte count increased significantly in the seropositive group and this conforms with the findings of Hassen et al., even though they did not report a significant observation. Per the experimental observations of Biswas et al., depletion of neutrophils results in a reduction in the IFN-γ production which resulted in an increase parasite burden in the central nervous system. While the exact molecular processes driving these differences are still unclear, there is increasing evidence that latent toxoplasmosis may cause chronic low-grade inflammation, which may, in turn, lead to anaemia.

**Conclusion**

The seroprevalence of *T. gondii* infection was high among our study population, including among pregnant participants.
In addition, cat ownership, contact with cat litter and age were identified as major risk factors for infection. Furthermore, additional research is needed to fully clarify the links between latent toxoplasmosis and anaemia. In conclusion, we recommend that testing for infection by the parasite be included in routine screening of pregnant women seeking antenatal care and further studies should investigate the impact of infection on blood parameters of humans.

The manuscript titled “Seroprevalence, risk factors and impact of Toxoplasma gondii infection on haematological parameters in the Ashanti region of Ghana: a cross sectional study” by Agordzo et al., presented evidence on the current serological prevalence of T. gondii and association with selected haematological parameters.

Though the seroprevalence of T. gondii has been widely published in different risk groups in Ghana, this research adds to the body of existing literature and knowledge and presents evidence on the possible association between T. gondii infections and haematological parameters. Additionally, this research provides additional evidence on possible regional variations in seroprevalence in Ghana, as most of the existing research has been conducted on the coastal regions of the country. Different geographical regions may possibly present additional evidence of variations in infections and associated risk patterns of T. gondii.

Comments:
1. In providing the data for the seroprevalence for the study in Table 1, the authors provided the general seroprevalence from the study. However, considering that the data was obtained from different populations i.e. Pregnant women, infants, critically ill persons and general hospital attendees, it will be more informative to show which of these groups showed higher prevalence in IgG only, IgM only and both IgG and IgM. Such details would provide details as to which groups are most susceptible to T. gondii infections.

2. In Table 2, do the authors group seropositive individuals together in the different geographical settings. However, a breakdown on the type of seropositivity i.e. IgG only, IgM only and both IgG and IgM may be more beneficial to the readers for a critical understanding as to which geographical setting is recording more acute cases and which is showing more in exposure to T. gondii

3. In Table 3, the authors provide details of seropositivity in pregnant women. In total, 110 pregnant women comprising of 37 in first trimester, 41 in second trimester and 32 in third trimester are presented. Although this information may have a degree of importance, the gestation period alone is scanty to make any meaningful deductions. It will be more beneficial if the authors can add the
gravidity and parity status of the pregnant women to show whether they have had previous live births or abortions. This additional information coupled with the specific seropositivity i.e. IgG only, IgM only and both IgG and IgM will provide information to discuss the significance of past or acute infections have on seropositivity.

4. In Table 5, the authors provide data on the haematological parameters analyzed and the seropositivity of the participants. Although this seems to be the crux and novelty of the paper, the manner the data has been presented provides the reader with less clarity. Because the participants were drawn from different population groups, it will be more prudent to provide a breakdown of the haematological data in sub-populations. This is so because the haematological parameters of pregnant women will be significantly different from children and also different from general hospital attendees. Thus, whiles providing a composite data is good, it does little to clearly draw out the differences between the various study groups. Additionally, I will suggest that the seropositivity data is clearly distinguished between IgG only, IgM only and both IgG and IgM. This provides greater clarity and brings out the different nuances in the data set.

5. The authors provide no data on the risk factors in this manuscript although it is an integral part in their title. I suggest they add the data or modify their title to reflect the data that is presented.

Minor Comments:
1. In paragraph 4, of sub-title “Seroprevalence of T. gondii” the authors state discuss results pertaining to risk factors and incorrectly attribute it to Table 3.

2. On the haematological data discussion, the authors should discuss the differences in mean corpuscular volumes. I am highly convinced that the differences observed could be due to large percentage of the participants being pregnant women.

3. A major limitation to this study is the use of a qualitative commercial kit for determining seropositivity. An additional method such as an avidity ELISA or molecular identification of specific genes of T. gondii such as the Dense granules (GRA) or surface antigens (SAG) may have provided more information whether the infections were latent or acute. I suggest the authors add the limitations of this study into their conclusions.

Is the work clearly and accurately presented and does it cite the current literature?
Yes

Is the study design appropriate and is the work technically sound?
Yes

Are sufficient details of methods and analysis provided to allow replication by others?
Yes

If applicable, is the statistical analysis and its interpretation appropriate?
Yes

Are all the source data underlying the results available to ensure full reproducibility?
Yes

Are the conclusions drawn adequately supported by the results?
Partly
**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** Molecular Parasitology and Microbial genetics

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

I studied the manuscript with interest. The manuscript studied the prevalence and related risk factors of infection with *T. gondii* in Ghana. There are some issues that need to be addressed as below.

1. There is extensive research on the seroprevalence of toxoplasmosis, and most of the risk factors and epidemiological aspects of the infection are relatively known. The findings of the manuscript are not so novel, mostly known; however it has regional importance in the studied area of Ghana.

2. The method for determining anti-*Toxoplasma* IgG and IgM is not quantitative, and I do not suggest rapid tests for research. If the author may have used ELISA, ECLA or CLA, data may have been more accurate and they may analyze the quantitative concentration of antibodies among risk factors.

3. For studying the hematological parameters, authors should be aware of the fact that the study population must be similar in seropositive and seronegative individuals. In women, anemia is prevalent and the authors could not compare the parameters between men and women; they may analyze it separately among both sexes. Pregnancy and nutritional status during pregnancy (food, vitamin and iron supplements) are other issues affecting blood parameters, that are not addressed, which can bias the results.

4. The authors could discuss other risk factors reported in the literature, such as having contact with soil and food habits such as eating raw vegetables, etc.

5. Why are different mean corpuscular volumes among seronegative and seropositive cases? The authors should discuss this issue and I think it may reflect the fact that the majority of the studied group were female and pregnant.

6. The language is relatively good; however, few misspellings and punctuation-errors need to be corrected.
Is the work clearly and accurately presented and does it cite the current literature?
Partly

Is the study design appropriate and is the work technically sound?
Partly

Are sufficient details of methods and analysis provided to allow replication by others?
Yes

If applicable, is the statistical analysis and its interpretation appropriate?
Yes

Are all the source data underlying the results available to ensure full reproducibility?
Yes

Are the conclusions drawn adequately supported by the results?
Yes

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** Molecular and serological epidemiology of parasitic diseases (e.g., toxoplasmosis, cryptosporidiosis and hydatid disease)

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.
