Phylogenetic evidence for independent origins of GDF1 and GDF3 genes in anurans and mammals

Juan C. Opazo & Kattina Zavala

Growth differentiation factors 1 (GDF1) and 3 (GDF3) are members of the transforming growth factor superfamily (TGF-β) that is involved in fundamental early-developmental processes that are conserved across vertebrates. The evolutionary history of these genes is still under debate due to ambiguous definitions of homologous relationships among vertebrates. Thus, the goal of this study was to unravel the evolution of the GDF1 and GDF3 genes of vertebrates, emphasizing the understanding of homologous relationships and their evolutionary origin. Our results revealed that the GDF1 and GDF3 genes found in anurans and mammals are the products of independent duplication events of an ancestral gene in the ancestor of each of these lineages. The main implication of this result is that the GDF1 and GDF3 genes of anurans and mammals are not 1:1 orthologs. In other words, genes that participate in fundamental processes during early development have been reinvented two independent times during the evolutionary history of tetrapods.
frog (Xenopus tropicalis), opening new avenues to define homologous relationships and the origin of genes that accomplish fundamental roles during early development in vertebrates.

With emphasis on understanding homologous relationships and their evolutionary origin, the goal of this study was to unravel the evolution of the GDF1 and GDF3 genes of vertebrates. Our phylogenetic analyses revealed that the GDF1 and GDF3 genes of anurans and mammals are the products of independent duplication events of an ancestral gene in the ancestor of each of these groups. We also found the signature of two chromosomal translocations, the first occurred in the ancestor of tetrapods whereas the second was found in the ancestor of mammals. Thus, our results support the hypothesis that in anurans and mammals, descendent copies of the same ancestral gene (GDF1/3) have independently subfunctionalized to perform key developmental functions in vertebrates.
Results and Discussion
Phylogenetic analyses suggest an independent origin of the GDF1 and GDF3 genes in mammals and anurans. From an evolutionary perspective, the definition of homologous relationships among GDF1 and GDF3 genes is still a matter of debate. The resolution of this homology is important as these genes are involved in fundamental developmental processes which are conserved all across vertebrates. Thus, if extant species inherited these genes from the vertebrate ancestor, the developmental processes in which GDF1 and GDF3 are involved have a single evolutionary origin and are comparable among species.

Based on evolutionary analyses and the developmental processes in which GDF1 has been shown to participate, it has been suggested that GDF1 in mammals, birds, and amphibians are 1:1 orthologs. Given that it has not been possible to identify copies of the GDF3 gene in amphibians and birds, it has been proposed that this gene is an evolutionary innovation of mammals, and the single gene copy found in amphibians and birds is co-ortholog to the mammalian duplicates. However, a second copy of a GDF gene has been annotated in the genome of the western clawed frog (Xenopus tropicalis). This newly described gene is located at the 3’ side of the GDF1 gene and indicates that amphibians, like mammals, also have a repertoire of two GDF genes (GDF1 (Vg1) and GDF3 (derrière)). This finding opens new ways to define homologous relationships and the origin of genes involved in the early development of all vertebrates.

Our maximum likelihood and Bayesian reconstructions strongly suggest that the GDF1 and GDF3 genes of anurans and mammals originated independently in each of these lineages (Fig. 1). In the case of anurans, our phylogenetic tree suggests that the duplication event occurred after the divergence between caudata and anura but before the radiation of anurans. In mammals, the origin of the duplicated genes would have occurred after the divergence between mammals and sauropsids but before mammalian radiation. In agreement with the literature, we found only one gene in sauropsids (e.g. birds, turtles, lizards and allies), suggesting that they retained the ancestral condition of a single gene copy as found caudata, coelacanths, bony fish, chondrichthyes and cyclostomes (Fig. 1). Dot-plot comparisons in representative species of all main groups of sauropsids provided further support for the presence of a single gene copy in sauropsids as no traces of an extra GDF gene were present in the syntenic region of representative species of the group (Fig. 2). However, we cannot rule out an alternative scenario of duplication and subsequent gene loss in the ancestor of sauropsids. Thus, our evolutionary analyses suggest that the GDF1 and GDF3 genes present in anurans and mammals diversified independently in the ancestor of each of these lineages. In other words, genes that participate in fundamental processes during early development have been reinvented two independent times during the evolutionary history of tetrapods. As a consequence of the independent origin of these genes in anurans and mammals, they are not 1:1 orthologs.

In the literature there are other cases of groups of genes that perform similar biological functions in a diversity of species but that have originated via lineage independent duplication events. Among these, the independent
origin of the β-globin gene cluster in all main groups of tetrapods (e.g. therian mammals, monotremes, birds, crocodiles, turtles, squamates, amphibians) represents a well-documented phenomenon. This case is of particular interest as the two β-globin subunits that come from a gene family that has been reinvented several times during the evolutionary history of tetrapods are assembled in a tetramer with two α-globin subunits that belong to a group of genes that possess a single origin. Besides this example, the independent origin of gene families makes the task of comparison difficult, as the repertoire of genes linked to physiological processes in different lineages do not have the same evolutionary origin. Additionally, the fact that the evolutionary process can give rise to similar phenotypes following different mutational pathways makes the problem of comparing even more difficult. This is particularly important when extrapolating the results of physiological studies performed in model species to other organisms.

Two translocation events during the evolutionary history of the GDF1 and GDF3 genes of tetrapods. Based on the location of the GDF1 and GDF3 genes in the different chromosomes and the conservation pattern of flanking genes, we propose that during the evolutionary history of tetrapods, these genes underwent two chromosomal translocation events (Fig. 3). According to our analyses the genomic region that harbors the single gene copy of chondrichthyes, bony fish, and coelacanths is conserved, yet this region in these groups differs from the regions in which GDF1 and GDF3 are located in tetrapods. Overall this suggests that the first translocation event occurred in the ancestor of tetrapods (Fig. 3). Interestingly, the genomic region where the single gene copy is located in non-tetrapod vertebrates, which is defined by the presence of upstream (BMP2, HA01, TMX4 and PLCB1) and downstream genes (FERMT1, LRRN4, CRLS1), is conserved in tetrapods. Given this, it is possible to identify the chromosomal location where the gene was located in the tetrapod ancestor before the first translocation event (Fig. 3). On the other hand, the fact that the mammalian GDF1 and GDF3 genes are located in different chromosomes suggests that the second translocation event occurred in the ancestor of the group (Fig. 3). In humans, the GDF1 gene is located on chromosome 19 while GDF3 is located on chromosome 12. In opossum (Didelphis virginiana) the GDF1 and GDF3 genes are located on chromosomes 3 and 8, respectively.

Evolution of GDF1 and GDF3 genes in vertebrates. In this study we present compelling evidence suggesting that genes involved in fundamental roles during early development in anurans and mammals are the product of independent duplications events. As such, these results indicate that the GDF1 and GDF3 genes of anurans and mammals are not 1:1 orthologs.

**Figure 3.** Structure of the chromosomal region containing the GDF1 and GDF3 genes of vertebrates. Asterisks denote that the orientation of the genomic piece is from 3' to 5', gray lines represent intervening genes that do not contribute to conserved synteny.
Thus, according to our results the last common ancestor of vertebrates had a repertoire of one gene (GDF1/3), and this condition is maintained in actual species of cylostomes, chondrichthyes, bony fish, coelacanths, caudata and sauropsids. In the ancestor of tetrapods, the single gene copy was translocated to a different chromosomal location. After that, in the anuran ancestor, the single gene copy underwent a duplication event giving rise to the anuran GDF1 (Vg1) and GDF3 (derrière) genes. In the ancestor of mammals, the single gene copy also underwent a duplication event, giving rise to the mammalian GDF1 and GDF3 genes. After the duplication, but before the radiation of the group, a second translocation event occurred in the ancestor of the group. Thus, all mammals inherited a repertoire of two genes (GDF1 and GDF3) that were located on two chromosomes.

Concluding remarks. This study provides a comprehensive evolutionary analysis of the GDF1 and GDF3 genes in representative species of all main groups of vertebrates. The main focus of this study was to unravel the duplicative history of the GDF1 and GDF3 genes and to understand homologous relationships among vertebrates. Understanding homology in this case is particularly important as these genes perform fundamental roles during early development that are conserved across vertebrates. Our results revealed that the GDF1 and GDF3 genes present in anurans and mammals are the product of independent duplication events in the ancestor of each of these groups. Subsequently, the GDF1 and GDF3 genes of anurans and mammals are not 1:1 orthologs. Our results also show that all other vertebrate groups - i.e non-tetrapods, caudata and sauropsids – maintained the ancestral condition of a single gene copy (GDF1/3).

From an evolutionary perspective the independent duplication events that occurred in the ancestors of mammals and anurans could have resulted in the division of labor, with some degree of redundancy of the function performed by the ancestral gene. In support of this idea, it has been shown that the GDF1 and GDF3 genes of mammals have partially redundant functions during development where GDF1 can to some degree compensate for the lack of GDF3. Additionally, it has also been shown that double knockout animals (GDF1−/− and GDF3−/−) present more severe phenotypes than those of either single knockout (GDF1−/− or GDF3−/−)30. Detailed comparisons of the developmental roles of the GDF1 and GDF3 genes between mammals and anurans will shed light regarding the reinvention of genes that possess fundamental roles during early development. On the other hand, comparing mammals and anurans with sauropsids will provide useful information regarding the evolutionary fate of duplicated genes. Finally, it would be interesting to study the evolutionary history of genes in the context of speciation events and translocation events.
that cooperate with GDF1 and GDF3 during early development (e.g. nodal)\textsuperscript{16,33,45} in order to understand the evolutionary nature of the entire developmental network.

Material and Methods

DNA sequences and phylogenetic analyses. We annotated GDF1 and GDF3 genes in representative species of chordates. Our study included representative species from mammals, birds, reptiles, amphibians, coelacanths, holostean fish, teleost fish, cartilaginous fish, cyclostomes, urochordates and cephalochordates (Supplementary dataset 1). We identified genomic pieces containing GDF 1 and GDF3 genes in the Ensembl database using BLASTN with default settings or NCBI database (refseq_genomes, hgts, and wgs) using tblastn (Altschul et al., 1990) with default settings. Conserved synteny was also used as a criterion to define the genomic region containing GDF1 and GDF3 genes. Once identified, genomic pieces were extracted including the 5′ and 3′ flanking genes. After extraction, we curated the existing annotation by comparing known exon sequences to genomic pieces using the program Blast2seq with default parameters (Tatusova and Madden 1999). Putatively functional genes were characterized by an open intact reading frame with the canonical exon/intron structure typical of vertebrate GDF1 and GDF3 genes. Sequences derived from shorter records based on genomic DNA or cDNA were also included in order to attain a broad and balanced taxonomic coverage. Amino acid sequences were aligned using the L-INS-i strategy from MAFFT v.7\textsuperscript{46} (Supplementary Dataset 2). Phylogenetic relationships were estimated using maximum likelihood and Bayesian approaches. We used the proposed model tool from IQ-Tree\textsuperscript{47} to select the best-fitting model (JT + F + R5). Maximum likelihood analysis was also performed in IQ-Tree\textsuperscript{47} to obtain the best tree. Node support was assessed with 1000 bootstrap pseudoreplicates using the ultra-fast routine (Supplementary dataset 3). Bayesian searches were conducted in MrBayes v.3.1.2\textsuperscript{48}. Two independent runs of six simultaneous chains for 10 × 10\textsuperscript{6} generations were set, and every 2,500 generations were sampled using default priors. The run was considered to have reached convergence once the likelihood scores formed an asymptote and the average standard deviation of the split frequencies remained < 0.01. We discarded all trees that were sampled before convergence, and we evaluated support for the nodes and parameter estimates from a majority rule consensus of the last 2,000 trees (Supplementary dataset 4). Sea squirt (Ciona intestinalis) and Florida lancelet (Branchiostoma floridae) BMP2 sequences were used as outgroups.

Assessment of conserved synteny. We examined genes found up- and downstream of GDF1 and GDF3 in species representative of vertebrates. Synteny assessment were conducted for human (Homo sapiens), chicken (Gallus gallus), western-clawed frog (Xenopus tropicalis), axolotl (Ambystoma mexicanum), coelacanth (Lamprimia chalumnae), spotted gar (Lepisosteus oculatus), elephant shark (Callorhinchus milii) and sea lamprey (Petromyzon marinus). Initial ortholog predictions were derived from the EnsemblCompara database\textsuperscript{49} and were visualized using the program Gnomics v91.01\textsuperscript{50}. In other cases, the genome data viewer platform from the National Center for Biotechnology information was used.
