November 23, 2020

Abstract

Worst-case complexity guarantees for nonconvex optimization algorithms have been a topic of growing interest. Multiple frameworks that achieve the best known complexity bounds among a broad class of first- and second-order strategies have been proposed. These methods have often been designed primarily with complexity guarantees in mind and, as a result, represent a departure from the algorithms that have proved to be the most effective in practice. In this paper, we consider trust-region Newton methods, one of the most popular classes of algorithms for solving nonconvex optimization problems. By introducing slight modifications to the original scheme, we obtain two methods—one based on exact subproblem solves and one exploiting inexact subproblem solves as in the popular “trust-region Newton-Conjugate-Gradient” (trust-region Newton-CG) method—with iteration and operation complexity bounds that match the best known bounds for the aforementioned class of first- and second-order methods. The resulting trust-region Newton-CG method also retains the attractive practical behavior of classical trust-region Newton-CG, which we demonstrate with numerical comparisons on a standard benchmark test set.

Key words. smooth nonconvex optimization, trust-region methods, Newton’s method, conjugate gradient method, Lanczos method, worst-case complexity, negative curvature

1 Introduction

Consider the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} f(x),$$

where $f : \mathbb{R}^n \to \mathbb{R}$ is twice Lipschitz continuously differentiable and possibly nonconvex. We propose and analyze the complexity of two trust-region algorithms for solving problem (1). Our main interest is in an algorithm that, for each subproblem, uses the conjugate gradient (CG) method to minimize an exact second-order Taylor series approximation of $f$ subject to a trust-region constraint, as in so-called trust-region methods.
Newton-CG methods. Our complexity analysis for both methods is based on approximate satisfaction of second-order necessary conditions for stationarity, that is,

$$\nabla f(x) = 0 \text{ and } \nabla^2 f(x) \text{ positive semidefinite.}$$

(2)

Specifically, given a pair of (small) real positive tolerances ($\epsilon_g, \epsilon_H$), our algorithms terminate when they find a point $x^\epsilon$ such that

$$\|\nabla f(x^\epsilon)\| \leq \epsilon_g \text{ and } \lambda_{\min}(\nabla^2 f(x^\epsilon)) \geq -\epsilon_H,$$

(3)

where $\lambda_{\min}(\cdot)$ denotes the minimum eigenvalue of its symmetric matrix argument. Such a point is said to be $(\epsilon_g, \epsilon_H)$-stationary. By contrast, any point satisfying the approximate first-order condition $\|\nabla f(x)\| \leq \epsilon_g$ is called an $\epsilon_g$-stationary point.

Recent interest in complexity bounds for nonconvex optimization stems in part from applications in machine learning, where for certain interesting classes of problems all local minima are global minima. We have a particular interest in trust-region Newton-CG algorithms since they have proved to be extremely effective in practice for a wide range of large-scale applications. We show in this paper that by making fairly minor modifications to such an algorithm, we can equip it with strong theoretical complexity properties without significantly degrading important performance measures such as the number of iterations, function evaluations, and gradient evaluations required until an $(\epsilon_g, \epsilon_H)$-stationary point is reached. This is in contrast to other recently proposed schemes that achieve good complexity properties, but have not demonstrated such good performance in practice against a state-of-the-art trust-region Newton-CG algorithm; see, e.g., [1, 6].

We prove results concerning both iteration complexity and operation complexity. The former refers to a bound on the number of “outer” iterations required to identify a point that satisfies (3). For the latter, we identify a unit operation and find a bound on the number of such operations required to find a point satisfying (3). As in earlier works on Newton-CG methods [30, 29], the unit operation is either a gradient evaluation or a Hessian-vector multiplication. In both types of complexity—iteration and operation—we focus on the dependence of bounds on the tolerances $\epsilon_g$ and $\epsilon_H$.

Our chief contribution is to show that a trust-region Newton-CG method can be modified to have state-of-the-art operation complexity properties for locating an $(\epsilon_g, \epsilon_H^{1/2})$-stationary point, matching recent results for modified line search Newton methods, cubic regularization methods, and other approaches based on applying accelerated gradient to nonconvex functions (see Section 1.3). The setting $\epsilon_H = \epsilon_g^{1/2}$ is known to yield the lowest operation complexity bounds for several classes of second-order algorithms.

1.1 Outline

We specify assumptions and notation used throughout the paper in Section 1.2, and discuss relevant literature briefly in Section 1.3. Section 2 describes a trust-region Newton method in which we assume that the subproblem is solved exactly at each iteration, and in which the minimum eigenvalue of the Hessian is calculated as necessary to verify the conditions (3). We prove the iteration complexity of this method, setting the stage for our investigation of a method using inexact subproblem solves. In Section 3, we describe an inexact implementation of the solution of the trust-region subproblem by a conjugate gradient method, and find bounds on the number of matrix-vector multiplications required for this method. We also discuss the use of iterative methods to obtain approximations to the minimum eigenvalue of the Hessian. Section 4 describes a trust-region Newton-CG method that incorporates the inexact solvers of Section 3, and analyzes its iteration and operation complexity properties. We describe implementation challenges in Section 5, then detail our computational experiments in Section 6. Finally, we make some concluding observations in Section 7.

1.2 Assumptions and notation

We write $\mathbb{R}$ for the set of real numbers (that is, scalars), $\mathbb{R}^n$ for the set of $n$-dimensional real vectors, $\mathbb{R}^{m \times n}$ for the set of $m$-by-$n$-dimensional real matrices, $\mathbb{S}^n \subset \mathbb{R}^{n \times n}$ for the set of $n$-by-$n$-dimensional real symmetric
matrices, and \( \mathbb{N} \) for the set of nonnegative integers. For \( v \in \mathbb{R}^n \), we use \( \|v\| \) to denote the \( \ell_2 \)-norm of \( v \). Given scalars \((a, b) \in \mathbb{R} \times \mathbb{R} \), we write \( a \perp b \) to mean \( ab = 0 \).

In reference to problem (1), we use \( g := \nabla f : \mathbb{R}^n \to \mathbb{R} \) and \( H := \nabla^2 f : \mathbb{R}^n \to \mathbb{S}^n \) to denote the gradient and Hessian functions of \( f \), respectively. For each iteration \( k \in \mathbb{N} = \{0, 1, 2, \ldots\} \) of an algorithm for solving (1), we let \( x_k \) denote the \( k \)th solution estimate (that is, iterate) computed. For brevity, we append \( k \in \mathbb{N} \) as a subscript to a function to denote its value at the \( k \)th iterate, e.g., \( f_k := f(x_k), g_k := g(x_k), \) and \( H_k := H(x_k) \). The subscript \( j \in \mathbb{N} \) is similarly used for the iterates of the subroutines used for computing search directions for an algorithm for solving (1). Given \( H_k \in \mathbb{S}^n \), we let \( \lambda_k := \lambda_{\min}(H_k) \) denote the minimum eigenvalue of \( H_k \) with respect to \( \mathbb{R} \).

Given functions \( \phi : \mathbb{R} \to \mathbb{R} \) and \( \varphi : \mathbb{R} \to [0, \infty) \), we write \( \phi(\cdot) = \mathcal{O}(\varphi(\cdot)) \) to indicate that \( |\phi(\cdot)| \leq C \varphi(\cdot) \) for some \( C \in (0, \infty) \). Similarly, we write \( \phi(\cdot) = \tilde{\mathcal{O}}(\varphi(\cdot)) \) to indicate that \( |\phi(\cdot)| \leq C \varphi(\cdot) \log^c(\cdot) \) for some \( C \in (0, \infty) \) and \( c \in (0, \infty) \). In this manner, one finds that \( \mathcal{O}(\varphi(\cdot) \log^c(\cdot)) = \tilde{\mathcal{O}}(\varphi(\cdot)) \) for any \( c \in (0, \infty) \).

The following assumption on the objective function in (1) is made throughout.

**Assumption 1.** The objective function value sequence \( \{f_k\} \) is bounded below by \( f_{\text{low}} \in \mathbb{R} \). The sequence of line segments \( \{[x_k, x_k + s_k]\} \) lies in an open set over which \( f \) is twice continuously differentiable and the gradient and Hessian functions are Lipschitz continuous with constants \( L_g \in (0, \infty) \) and \( L_H \in (0, \infty) \), respectively.

The following bounds are implied by Assumption 1 (see e.g., [26]):

\[
\begin{align*}
  f(x_k + s_k) - f_k - g_k^T s_k - \frac{1}{2} s_k^T H_k s_k & \leq \frac{L_H}{6} \|s_k\|^3 & \text{for all } k \in \mathbb{N}, \\
  \|g(x_k + s_k) - g_k - H_k s_k\| & \leq \frac{L_H}{2} \|s_k\| & \text{for all } k \in \mathbb{N}, \\
  \text{and } \|H_k\| & \leq L_g & \text{for all } k \in \mathbb{N}.
\end{align*}
\]

### 1.3 Literature review

Complexity results for smooth nonconvex optimization algorithms abound in recent literature. We discuss these briefly and give some pointers below, with a focus on methods with best known complexity.

Cubic regularization [27, Theorem 1] has iteration complexity \( \mathcal{O}(\epsilon_g^{-3/2}) \) to find an \( (\epsilon_g, \epsilon_g^{1/2}) \)-stationary point; see also [7, 9]. Algorithms that find such a point with operation complexity \( \tilde{\mathcal{O}}(\epsilon_g^{-7/4}) \), with high probability, were proposed in [1, 6]. (The “high probability” is due to the use of randomized iterative methods for calculating a minimum eigenvalue and/or solving a linear system.) A method that deterministically finds an \( \epsilon_g \)-stationary point in \( \tilde{\mathcal{O}}(\epsilon_g^{-7/4}) \) gradient evaluations was described in [5].

Line search methods that make use of Newton-like steps, the conjugate gradient method for inexactly solving linear systems, and randomized Lanczos for calculating negative curvature directions are described in [30, 29]. These methods also have operation complexity \( \tilde{\mathcal{O}}(\epsilon_g^{-7/4}) \) to find a \( (\epsilon_g, \epsilon_g^{1/2}) \)-stationary point, with high probability. The method in [29] finds an \( \epsilon_g \)-stationary point deterministically in \( \tilde{\mathcal{O}}(\epsilon_g^{-7/4}) \) operations, showing that the conjugate gradient method on nonconvex quadratics shares properties with accelerated gradient on nonconvex problems as described in [5].

**Trust-region methods** An early result of [19] shows that standard trust-region methods require \( \mathcal{O}(\epsilon_g^{-2}) \) iterations to find an \( \epsilon_g \)-stationary point; this complexity was shown to be sharp in [8]. A trust-region Newton method with iteration complexity of \( \mathcal{O}(\max\{\epsilon_g^{-3/2}, \epsilon_H^{-3}\}) \) for finding an \( (\epsilon_g, \epsilon_H) \)-stationary point is described in [11]. This complexity matches that of cubic regularization methods [27, 7, 9].

Another method that uses trust regions in conjunction with a cubic model to find an \( (\epsilon_g, \epsilon_H) \)-stationary point with guaranteed complexity appears in [23]. This is not a trust-region method in the conventional sense because it fixes the trust-region radius at a constant value. Other methods that combine trust-region and cubic-regularization techniques in search of good complexity bounds are described in [12, 14, 15, 2, 3].
Solving the trust-region subproblem

Efficient solution of the trust-region subproblem is a core aspect of both the theory and practice of trust-region methods. In the context of this paper, such results are vital in turning an iteration complexity bound into an operation complexity bound. The fact that the trust-region subproblem (with a potentially nonconvex objective) can be solved efficiently remains surprising to many. This is especially true since it has some complicating features, particularly the “hard case” in which, in iteration \( k \in \mathbb{N} \), the gradient \( g_k \) is orthogonal to the eigenspace of the Hessian \( H_k \) corresponding to its minimum eigenvalue.

Approaches for solving trust-region subproblems based on matrix factorizations are described in [24]; see also [28, Chapter 4]. For large-scale problems, iterative techniques based on the conjugate gradient (CG) algorithm [31, 32] and the Lanczos method [16, 25] have been described in the literature. Convergence rates for the method of [16] are presented in [34], though results are weaker in the hard case.

Global convergence rates in terms of the objective function values for the trust-region subproblem are a recent focus; see for example [20], wherein the authors use an SDP relaxation, and [33], wherein the authors apply an accelerated gradient method to a convex reformulation of the trust-region subproblem (which requires an estimate of the minimum eigenvalue of the Hessian). Both solve the trust-region subproblem to within \( \epsilon \) of the optimal subproblem objective value in \( \tilde{O} (\epsilon^{-1/2}) \) time.

A recent method based on Krylov subspaces is presented in [4]. This method circumvents the hard case by its use of randomization. Subsequent work in [18] derives a convergence rate for the norm of the residual vectors in the Krylov-subspace approach.

The hard case does not present a serious challenge to the main algorithm that we propose (Algorithm 4). When it occurs, either the conjugate gradient procedure (Algorithm 2) returns an acceptable trial step, or else the minimum-eigenvalue procedure (Algorithm 3) will be invoked to find a negative curvature step.

2 An exact trust-region Newton method

In this section, we propose a trust-region Newton method that uses, during each iteration, the exact solution of a (regularized) trust-region subproblem. The algorithm is described in Section 2.1 and its complexity guarantees are analyzed in Section 2.2. Our analysis of this method sets the stage for our subsequent method that uses inexact subproblem solutions.

2.1 The algorithm

Our trust-region Newton method with exact subproblem solves, which is inspired in part by the line search method proposed in [30], is written as Algorithm 1. Unlike a traditional trust-region method, the second-order stationarity tolerance \( \epsilon_H \in (0, \infty) \) is used to quantify a regularization of the quadratic model \( m_k : \mathbb{R}^n \rightarrow \mathbb{R} \) of \( f \) at \( x_k \) used in the subproblem, which is given by

\[
m_k(x) := f_k + g_k^T(x - x_k) + \frac{1}{2}(x - x_k)^T H_k(x - x_k);
\]

see (6). Our choice of regularization makes for a relatively straightforward complexity analysis because it causes the resulting trial step \( s_k \) to satisfy certain desirable objective function decrease properties. Of course, a possible downside is that the practical behavior of the method may be affected by the choice of the stationarity tolerance \( \epsilon_H \), which is not the case for a traditional trust-region framework. In any case, the remainder of Algorithm 1 is identical to a traditional trust-region Newton method.

Before presenting our analysis of Algorithm 1, we remark that the sequence \( \{\lambda_k\} \) of minimum eigenvalues of the Hessians \( \{H_k\} \) does not influence the iterate sequence \( \{x_k\} \). The only use of these values is in the termination test in line 6 to determine when an \((\epsilon_g, \epsilon_H)\)-stationary point has been found.
Algorithm 1 Trust-Region Newton Method (exact version)

Require: Tolerances $\epsilon_g \in (0, \infty)$ and $\epsilon_H \in (0, \infty)$; trust-region adjustment parameters $\gamma_1 \in (0, 1)$, $\gamma_2 \in [1, \infty)$, and $\psi \in (1/\gamma_2, 1]$; initial iterate $x_0 \in \mathbb{R}^n$; initial trust-region radius $\delta_0 \in (0, \infty)$; maximum trust-region radius $\delta_{\text{max}} \in [\delta_0, \infty)$; and step acceptance parameter $\eta \in (0, 1)$.

1: for $k = 0, 1, 2, \ldots$ do
2: Evaluate $g_k$ and $H_k$.
3: Initialize $\lambda_k \leftarrow \infty$.
4: if $\|g_k\| \leq \epsilon_g$ then
5: Compute $\lambda_k \leftarrow \lambda_{\text{min}}(H_k)$.
6: if $\lambda_k \geq -\epsilon_H$ then
7: return $x_k$ as an $(\epsilon_g, \epsilon_H)$-stationary point for problem (1).
8: end if
9: end if
10: Compute a trial step $s_k$ as a solution to the regularized trust-region subproblem
\[
\min_{s \in \mathbb{R}^n} m_k(x_k + s) + \frac{1}{2} \epsilon_H \|s\|^2 \quad \text{s.t.} \quad \|s\| \leq \delta_k. \tag{6}
\]
11: Compute the ratio of actual-to-predicted reduction in $f$, defined as
\[
\rho_k \leftarrow \frac{f_k - f(x_k + s_k)}{m_k(x_k) - m_k(x_k + s_k)}. \tag{7}
\]
12: if $\rho_k \geq \eta$ then
13: Set $x_{k+1} \leftarrow x_k + s_k$.
14: if $\|s_k\| \geq \psi \delta_k$ then
15: Set $\delta_{k+1} \leftarrow \min\{\gamma_2 \delta_k, \delta_{\text{max}}\}$.
16: else
17: Set $\delta_{k+1} \leftarrow \delta_k$.
18: end if
19: else
20: Set $x_{k+1} \leftarrow x_k$ and $\delta_{k+1} \leftarrow \gamma_1 \|s_k\|$.
21: end if
22: end for

2.2 Iteration complexity

We show that Algorithm 1 reaches an $(\epsilon_g, \epsilon_H)$-stationary point in a number of iterations that is bounded by a function of $\epsilon_g$ and $\epsilon_H$. To this end, let us define the set of iteration numbers
\[ K := \{k \in \mathbb{N} : \text{iteration } k \text{ is completed without algorithm termination}\} \]
along with the subsets
\[ I := \{k \in K : \|s_k\| < \delta_k\} \quad \text{and} \quad B := \{k \in K : \|s_k\| = \delta_k\} \]
and
\[ S := \{k \in K : \rho_k \geq \eta\} \quad \text{and} \quad U := \{k \in K : \rho_k < \eta\}. \]
The pairs $(I, B)$ and $(S, U)$ are each partitions of $K$. The iterations with $k \in I$ are those with $s_k$ in the interior of the trust region, and those with $k \in B$ are those with $s_k$ on the boundary of the trust region. The iterations with $k \in S$ are called the successful iterations and those with $k \in U$ are called the unsuccessful
iterations. Due to the termination conditions in line 6, it follows for Algorithm 1 that
\[ \mathcal{K} = \{ k \in \mathbb{N} : \text{iteration } k \text{ is reached and either } \| g_k \| > \epsilon_g \text{ or } \lambda_k < -\epsilon_H \}. \] (8)
It follows that, for a run of Algorithm 1, the cardinalities of all of the index sets \( \mathcal{K}, \mathcal{I}, \mathcal{B}, \mathcal{S}, \) and \( \mathcal{U} \) are functions of the tolerance parameters \( \epsilon_g \) and \( \epsilon_H \).

Since \( s_k \) is computed as the global solution of the trust-region subproblem (6), it is well known [24, 28] that there exists a scalar Lagrange multiplier \( \mu_k \) such that
\[
\begin{align*}
&g_k + (H_k + \epsilon_H I + \mu_k I)s_k = 0, \quad \text{(9a)} \\
&H_k + \epsilon_H I + \mu_k I \succeq 0, \quad \text{(9b)} \\
&0 \leq \mu_k \perp (\delta_k - \| s_k \|) \geq 0. \quad \text{(9c)}
\end{align*}
\]

Our first result is a lower bound on the model reduction achieved by a trial step.

**Lemma 1.** For all \( k \in \mathcal{K} \), the model reduction satisfies
\[
m_k(x_k) - m_k(x_k + s_k) \geq \frac{1}{2} \epsilon_H \| s_k \|^2. \tag{10}\]

**Proof.** The definition of \( m_k \) in (5) and the optimality conditions in (9) give
\[
m_k(x_k) - m_k(x_k + s_k) = -g_k^T s_k - \frac{1}{2} s_k^T H_k s_k
\]
\[
= s_k^T (H_k + \epsilon_H I + \mu_k I)s_k - \frac{1}{2} s_k^T H_k s_k
\]
\[
= \frac{1}{2} s_k^T (H_k + \epsilon_H I + \mu_k I)s_k + \frac{1}{2} \epsilon_H \| s_k \|^2 + \frac{1}{2} \mu_k \| s_k \|^2
\]
\[
\geq \frac{1}{2} \epsilon_H \| s_k \|^2,
\]
as desired. \( \Box \)

Next, we show that all sufficiently small trial steps lead to successful iterations.

**Lemma 2.** For all \( k \in \mathcal{K} \), if \( k \in \mathcal{U} \), then \( \delta_k > 3(1-\eta)\epsilon_H/L_H \). Hence, by the trust-region radius update procedure, it follows that
\[
\delta_k \geq \delta_{\min} := \min \left\{ \delta_0, \left( \frac{3\gamma_1(1-\eta)}{L_H} \right) \epsilon_H \right\} \in (0, \infty) \quad \text{for all } k \in \mathcal{K}.
\]

**Proof.** We begin by proving the first statement of the lemma. To that end, suppose that \( k \in \mathcal{U} \) (meaning that \( \rho_k < \eta \)), which from the definition of \( \rho_k \) means that
\[
\eta (m_k(x_k + s_k) - m_k(x_k)) \leq f(x_k + s_k) - f_k.
\]
(11)

Combining (11) with (4a), (6), Lemma 1, and (5) leads to
\[
\begin{align*}
\eta (m_k(x_k + s_k) - m_k(x_k)) &< g_k^T s_k + \frac{1}{2} s_k^T H_k s_k + \frac{L_H \epsilon_H}{6} \| s_k \|^3 \\
&\Rightarrow (\eta - 1)(m_k(x_k + s_k) - m_k(x_k)) < \frac{L_H \epsilon_H}{6} \| s_k \|^3 \\
&\Rightarrow \frac{1-\eta}{2} \epsilon_H \| s_k \|^2 < \frac{L_H \epsilon_H}{6} \| s_k \|^3 \\
&\Rightarrow \frac{3(1-\eta)}{L_H} \epsilon_H < \| s_k \|.
\end{align*}
\]
We have shown that \( k \in \mathcal{U} \) implies \( \delta_k \geq \| s_k \| > 3(1-\eta)\epsilon_H/L_H \), as desired. Using a contraposition argument, we also have that \( \| s_k \| \leq 3(1-\eta)\epsilon_H/L_H \) implies \( k \in \mathcal{S} \). Combining this with the trust-region radius update procedure and accounting for the initial radius \( \delta_0 \) completes the proof. \( \Box \)

We now establish that each successful step guarantees that a certain amount of decrease in the objective function value is achieved.

**Lemma 3.** The following hold for all successful iterations:
(i) If \( k \in \mathcal{B} \cap \mathcal{S} \), then

\[
    f_k - f_{k+1} \geq \frac{n}{2} \epsilon_H \delta_k^2.
\]

(ii) If \( k \in \mathcal{I} \cap \mathcal{S} \), then

\[
    f_k - f_{k+1} \geq \frac{n}{2(1+2L_H)} \min \left\{ \|g_{k+1}\|^2 \epsilon_H^{-1}, \epsilon_H^3 \right\}.
\]

Proof. Part (i) follows from Lemma 1 and the definition of \( \mathcal{B} \), which implies that

\[
    f_k - f_{k+1} \geq \eta (m_k(x_k) - m_k(x_k + s_k)) \geq \frac{n}{2} \epsilon_H \|s_k\|^2 = \frac{n}{2} \epsilon_H \delta_k^2.
\]

For part (ii), from \( k \in \mathcal{I} \) we know that \( \|s_k\| < \delta_k \). This fact along with (9c) and (9a) imply that \( \mu_k = 0 \) and \( g_k + (H_k + \epsilon_H I)s_k = 0 \). Now, with (4b), we have

\[
    \|g_{k+1}\| = \|g_{k+1} - g_k - (H_k + \epsilon_H I)s_k\|
    \leq \|g_{k+1} - g_k - H_k s_k\| + \epsilon_H \|s_k\| \leq \frac{L_H}{\epsilon_H} \|s_k\|^2 + \epsilon_H \|s_k\|,
\]

which after rearrangement yields

\[
    \frac{L_H}{\epsilon_H} \|s_k\|^2 + \epsilon_H \|s_k\| - \|g_{k+1}\| \geq 0.
\]

Treating the left-hand side as a quadratic scalar function of \( \|s_k\| \) implies that

\[
    \|s_k\|^2 \geq \frac{-\epsilon_H + \sqrt{\epsilon_H^2 + 2L_H \|g_{k+1}\|}}{L_H} = \frac{-1 + \sqrt{1+2L_H \|g_{k+1}\|}}{L_H} \epsilon_H.
\]

To put this lower bound into a slightly more useful form, we use [30, Lemma 17 in Appendix A], which states that for scalars \( (a, b, t) \in (0, \infty) \times (0, \infty) \times [0, \infty) \), we have

\[
    -a + \sqrt{a^2 + bt} \geq (-a + \sqrt{a^2 + b}) \min \{t, 1\}. \tag{12}
\]

By setting \( a = 1, b = 2L_H \), and \( t = \|g_{k+1}\| \epsilon_H^{-2} \), we obtain

\[
    \|s_k\|^2 \geq \left( \frac{-1 + \sqrt{1+2L_H \|g_{k+1}\|}}{L_H} \right) \min \{\|g_{k+1}\| \epsilon_H^{-2}, 1\} \epsilon_H = \left( \frac{2L_H}{L_H + 1 + \sqrt{1+2L_H \|g_{k+1}\|}} \right) \min \{\|g_{k+1}\| \epsilon_H^{-1}, \epsilon_H \}
    \geq \left( \frac{1}{\sqrt{1+2L_H}} \right) \min \{\|g_{k+1}\| \epsilon_H^{-1}, \epsilon_H \}.
\]

Using this inequality in conjunction with \( k \in \mathcal{S} \) and Lemma 1 proves that

\[
    f_k - f(x_k + s_k) \geq \eta (m_k(x_k) - m_k(x_k + s_k)) \geq \frac{n}{2} \epsilon_H \|s_k\|^2 \geq \frac{n}{2(1+2L_H)} \min \{\|g_{k+1}\|^2 \epsilon_H^{-1}, \epsilon_H^3\},
\]

which completes the proof for part (ii). \( \square \)

We now bound the number of successful iterations before termination.

Lemma 4. The number of successful iterations performed by Algorithm 1 before an \((\epsilon_g, \epsilon_H)\)-stationary point is reached satisfies

\[
    |S| \leq \left[ \mathcal{C}_S \max \{ \epsilon_H^{-1}, \epsilon_g^2 \epsilon_H, \epsilon_H^3 \} \right] + 1, \tag{13}
\]

where

\[
    \mathcal{C}_S := \frac{4(f_0 - f_{\text{low}})}{n} \max \left\{ \frac{1}{\delta^2}, \frac{L_H^2}{\delta(1-\delta)^2}, 1 + 2L_H \right\}. \tag{14}
\]
Proof. The successful iterations may be written as $S = S_L \cup S_{GG} \cup S_{GL}$, where
\[
S_L := \{ k \in S : \|g_k\| \leq \epsilon_g \},
\]
\[
S_{GG} := \{ k \in S : \|g_k\| > \epsilon_g \text{ and } \|g_{k+1}\| > \epsilon_g \},
\]
and $S_{GL} := \{ k \in S : \|g_k\| > \epsilon_g \text{ and } \|g_{k+1}\| \leq \epsilon_g \}$.

We first bound $|S_L \cup S_{GG}|$, for which we will make use of the constant
\[
c := \frac{\eta}{2} \min \left\{ \epsilon_0^2, \frac{\gamma_1(1-\eta)^2}{L_H}, \frac{1}{1+2L_H} \right\}. \tag{15}
\]
For $k \in S_L$, the fact that the algorithm has not yet terminated implies (see (8)) that $\lambda_k < -\epsilon_H$. By (9), it follows that $\mu_k > 0$ and $\|s_k\| = \delta_k$, and thus $k \in B$. Thus, for $k \in S_L \cap B$, Lemma 3(i), Lemma 2, and (15) imply that
\[
f_k - f_{k+1} \geq \frac{\eta}{2} \epsilon_H \delta_k^3 \geq \frac{\eta}{2} \min \left\{ \epsilon_0^2 \epsilon_H, \frac{\gamma_1^2(1-\eta)^2}{L_H} \epsilon_H^3 \right\} \geq c \min \{ \epsilon_H, \epsilon_H^3 \}. \tag{16}
\]
Now consider $k \in S_{GG}$. Since in this case either of the cases in Lemma 3 may apply, one can only conclude that, for each $k \in S_{GG}$, the following bound holds:
\[
f_k - f_{k+1} \geq \frac{\eta}{2} \min \left\{ \epsilon_0^2 \epsilon_H, \left(\frac{\|g_{k+1}\|^2}{1+2L_H}\right) \epsilon_H^{-1}, \left(\frac{1}{1+2L_H}\right) \epsilon_H^3 \right\}.
\]
Combining this with the definition of $S_{GG}$, the lower bound on $\delta_k$ in Lemma 2, and the definition of $c$ in (15), it follows that
\[
f_k - f_{k+1} \geq c \min \{ \epsilon_H, \epsilon_0^2, \epsilon_H, \epsilon_H^3 \}. \tag{17}
\]
To bound $|S_L \cup S_{GG}|$, we sum the objective function decreases obtained over all such iterations, which with Assumption 1 and the monotonicity of $\{f_k\}$ gives
\[
f_0 - f_{low} \geq \sum_{k \in K} (f_k - f_{k+1}) \geq \sum_{k \in S_L} (f_k - f_{k+1}) + \sum_{k \in S_{GG}} (f_k - f_{k+1}).
\]
Combining this inequality with (16) and (17) shows that
\[
f_0 - f_{low} \geq \sum_{k \in S_L} c \min \{ \epsilon_H, \epsilon_H^3 \} + \sum_{k \in S_{GG}} c \min \{ \epsilon_H, \epsilon_0^2, \epsilon_H^{-1}, \epsilon_H^3 \}
\]
\[
\geq c (|S_L| + |S_{GG}|) \min \{ \epsilon_H, \epsilon_0^2, \epsilon_H^{-1}, \epsilon_H^3 \},
\]
from which it follows that
\[
|S_L| + |S_{GG}| \leq \left( \frac{f_0 - f_{low}}{c} \right) \max \{ \epsilon_H^{-1}, \epsilon_0^2 \epsilon_H, \epsilon_H^3 \}. \tag{18}
\]
Next, let us consider the set $S_{GL}$. Since $k \in S_{GL}$ means $\|g_{k+1}\| \leq \epsilon_g$, the index corresponding to the next successful iteration (if one exists) must be an element of the index set $S_L$. This implies that $|S_{GL}| \leq |S_L| + 1$, where the 1 accounts for the possibility that the last successful iteration (prior to termination) has an index in $S_{GL}$. Combining this bound with (18) yields
\[
|S| = |S_L| + |S_{GG}| + |S_{GL}| \leq \frac{2(f_0 - f_{low})}{c} \max \{ \epsilon_H^{-1}, \epsilon_0^2 \epsilon_H, \epsilon_H^3 \} + 1,
\]
which completes the proof when we substitute for $c$ from (15). $\square$

We now bound the number of unsuccessful iterations.

Lemma 5. The number of unsuccessful iterations that occur before an $(\epsilon_g, \epsilon_H)$-stationary point is reached is either zero or else satisfies
\[
|\mathcal{U}| \leq \left\lfloor 1 + \log_{\gamma_1} \left( \frac{3(1-\eta)}{L_H s_{max}} \right) + \log_{\gamma_1} (\epsilon_H) \right\rfloor |S|. \tag{19}
\]
Proof. If the number of successful iterations is zero, then the initial point must be \((\epsilon_g, \epsilon_H)\)-stationary and there are no unsuccessful iterations. Hence, let us proceed under the assumption that \(|S| \geq 1\). Let us denote the successful iteration indices as \(\{k_1, \ldots, k_{|S|}\} := S\). If the number of unsuccessful iterations is zero, then there is nothing left to prove, so we may proceed under the assumption that there is at least one unsuccessful iteration. Thus, we may consider arbitrary \(i \in \{1, \ldots, |S| - 1\}\) such that \(k_{i+1} - k_i - 1 \geq 1\), that is, there is at least one unsuccessful iteration between iterations \(k_i\) and \(k_{i+1}\). We seek a bound on \(k_{i+1} - k_i - 1\). From the update formulas for the trust-region radius, one finds for all unsuccessful iteration indices \(l \in \{k_i + 1, \ldots, k_{i+1} - 1\}\) that \(\delta_l = \gamma_1\|s_{l-1}\| \leq \gamma_1\delta_l-1\), so

\[
\delta_l \leq \min\{\gamma_2\delta_{k_i}, \delta_{\max}\}\gamma_1^{l-k_i-1} \leq \delta_{\max}\gamma_1^{l-k_i-1}. \tag{20}
\]

Moreover, for any unsuccessful iteration index \(l \in \{k_i + 1, \ldots, k_{i+1} - 1\}\) we have from Lemma 2 that \(\delta_l > 3(1-\eta)\epsilon_H/L_H\). Thus, for such \(l\), (20) implies that

\[
\frac{3(1-\eta)}{L_H}\epsilon_H < \delta_{\max}\gamma_1^{l-k_i-1} \implies l - k_i - 1 \leq \log_{\gamma_1} \left(\frac{3(1-\eta)\epsilon_H}{L_H\delta_{\max}}\right).
\]

Consequently, using the specific choice \(l = k_{i+1} - 1\), one finds that

\[
k_{i+1} - k_i - 1 \leq 1 + \log_{\gamma_1} \left(\frac{3(1-\eta)}{L_H\delta_{\max}}\right) + \log_{\gamma_1} (\epsilon_H),
\]

and because the left-hand side is an integer, we have

\[
k_{i+1} - k_i - 1 \leq \left[1 + \log_{\gamma_1} \left(\frac{3(1-\eta)}{L_H\delta_{\max}}\right) + \log_{\gamma_1} (\epsilon_H)\right]. \tag{21}
\]

Since \(i\) was chosen arbitrarily such that \(k_{i+1} - k_i - 1 \geq 1\), the right-hand side in (21) is at least 1 if there are any unsuccessful iterations between iteration \(k_1\) and \(k_{|S|}\).

Consider now the first successful iteration \(k_1\). We seek a bound on the number of unsuccessful iterations prior to iteration \(k_1\). If there are no such unsuccessful iterations, then there is nothing left to prove; hence, we may assume \(k_1 \geq 1\). We have that \(\delta_{k_1} \leq \gamma_1^{k_1}\delta_0 \leq \gamma_1^{k_1}\delta_{\max}\), and thus from Lemma 2 it follows that

\[
\min \left\{\delta_0, \frac{3\gamma_1(1-\eta)}{L_H}\epsilon_H\right\} \leq \delta_{k_1} \leq \gamma_1^{k_1}\delta_0 \leq \gamma_1^{k_1}\delta_{\max}.
\]

From the first two of these inequalities and the facts that \(\gamma_1 \in (0, 1)\) and \(k_1 \geq 1\), the “min” on the left-hand side is not achieved by \(\delta_0\), so we have

\[
\frac{3\gamma_1(1-\eta)}{L_H}\epsilon_H \leq \gamma_1^{k_1}\delta_{\max},
\]

which, when we take into account that \(k_1\) is an integer, leads to

\[
k_1 \leq \left[1 + \log_{\gamma_1} \left(\frac{3(1-\eta)}{L_H\delta_{\max}}\right) + \log_{\gamma_1} (\epsilon_H)\right]. \tag{22}
\]

Under our assumption that \(k_1 \geq 1\), the right-hand side of (22) is at least 1.

Since the iteration immediately prior to termination is \(k_{|S|}\) (except in the trivial case in which termination occurs at the initial point), we have

\[
|U| = k_1 + \sum_{i=1}^{|S|-1} (k_{i+1} - k_i - 1). \tag{23}
\]

If \(U \neq \emptyset\), we have that \(k_1 \geq 1\) and/or at least one of the terms in the summation is at least 1. We can in this case bound every term on the right-hand side of (23) by the right-hand sides of (21) and (22) to deduce the result. \(\square\)

The main result for iteration complexity of Algorithm 1 may now be proved.
Theorem 1. Under Assumption 1, the number of successful iterations (and objective gradient and Hessian evaluations) performed by Algorithm 1 before an \((\epsilon_g, \epsilon_H)\)-stationary point is obtained satisfies
\[ |S| = O \left( \max\{\epsilon_H^{-3}, \epsilon_H^{-1}, \epsilon_g^{-2}\} \right) \tag{24} \]
and the total number of iterations (and objective function evaluations) performed before such a point is obtained satisfies
\[ |K| = O \left( \log_1/\gamma_1 \left( \epsilon_H^{-1} \right) \max\{\epsilon_H^{-3}, \epsilon_H^{-1}, \epsilon_g^{-2}\} \right). \tag{25} \]

Proof. Formula (24) follows from Lemma 4. Formula (25) follows from Lemma 4, Lemma 5, and the fact that \(\log_1/\gamma_1 \left( \epsilon_H^{-1} \right) = \log_1/\gamma_1 \left( \epsilon_H^{-1} \right)\).

If one chooses \(\epsilon_H = \epsilon_g^{1/2}\) in (24) and (25) as well as any positive scalar \(\bar{\epsilon}_g \in \mathbb{R}\), then Theorem 1 implies that, for all \(\epsilon_g \in (0, \bar{\epsilon}_g]\), one has
\[ |S| = O \left( \epsilon_g^{-3/2} \right) \quad \text{and} \quad |K| = O \left( \epsilon_g^{-3/2} \log_1/\gamma_1 \left( \epsilon_g^{-1/2} \right) \right) = \tilde{O} \left( \epsilon_g^{-3/2} \right) \]
for the numbers of successful and total iterations, respectively. These correspond to the results obtained for the line search method in \([30, \text{Theorem 5, Theorem 6}]\).

3 Iterative methods for solving the subproblems inexactly

This section describes the algorithms needed to develop an inexact trust-region Newton method, which will be presented and analyzed in Section 4. A truncated CG method for computing directions of descent is discussed in Section 3.1 and an iterative algorithm for computing directions of negative curvature is described in Section 3.2.

3.1 A truncated CG method

We propose Algorithm 2 as an appropriate iterative method for approximately solving the trust-region subproblem
\[ \min_{s \in \mathbb{R}^n} \ g^T s + \frac{1}{2} s^T (H + 2\epsilon I) s \quad \text{s.t.} \quad \|s\| \leq \delta, \tag{26} \]
where \(g \in \mathbb{R}^n\) is assumed to be a non-zero vector, \(H \in \mathbb{S}^n\) is possibly indefinite, \(\epsilon \in (0, \infty)\) plays the role of a regularization parameter, and \(\delta \in (0, \infty)\). Algorithm 2 is based on the CG method and builds on the Steihaug-Toint approach \([31, 32]\). (The factor of 2 in the regularization term in (26) is intentional. For consistency in the termination condition, the inexact trust-region Newton method in Section 4 employs a larger regularization term than the exact method analyzed in Section 2.)

For the most part, Algorithm 2 is identical to traditional truncated CG. For example, termination occurs in line 18 when the next CG iterate \(y_{j+1}\) would lie outside the trust region, and we return \(s\) as the largest feasible step on the line segment connecting \(y_j\) to \(y_{j+1}\). In this situation, we also set \textbf{outCG} \leftarrow \text{BND-NORM} to indicate that \(s\) lies on the boundary of the trust-region constraint.

However, there are three key differences between Algorithm 2 and truncated CG. First, the residual termination criterion in line 21 enforces the condition
\[ \|(H + 2\epsilon I) s + g\| \leq \tilde{\xi} \min\{\|g\|, \epsilon\|s\|\}, \tag{27} \]
which is stronger than the condition traditionally used in truncated CG (which typically has \(\frac{1}{2}\|g\|\) for the right-hand side) and incorporates a criterion typical of Newton-type methods with optimal complexity \([10, 30]\) (which use \(\epsilon\|s\|\) for the right-hand side). If this criterion is satisfied, then we return the current CG iterate as the step (that is, we set \(s \leftarrow y_{j+1}\)) and indicate that \(s\) lies in the interior of the trust region and satisfies the residual condition (27) by setting \textbf{outCG} \leftarrow \text{INT-RES}. 
Lemma 6. Suppose $\epsilon I \prec H + 2\epsilon I \preceq (M + 2\epsilon)I$ for $M \in \|H\|, \infty$ and define
\[
\kappa(M, \epsilon) := (M + 2\epsilon)/\epsilon \quad \text{and} \quad J(M, \epsilon, \zeta) := \frac{1}{2} \sqrt{\kappa(M, \epsilon)} \ln \left(4\kappa(M, \epsilon)^{3/2}/\zeta\right),
\] (28)
where $\zeta \in (0, 1)$ is input to Algorithm 2. If lines 3–7 were simply to set $k_{\text{max}} \leftarrow \infty$, then Algorithm 2 would terminate at either line 18 or line 22 after a number of iterations (equivalently, matrix-vector products) equal to at most
\[
\min \{n, J(M, \epsilon, \zeta)\} = \min \left\{n, \tilde{O}(\epsilon^{-1/2}) \right\}.
\] (29)

Proof. Since $H + 2\epsilon I \succ \epsilon I$ by assumption, a direction of curvature less than $\epsilon$ for $H + 2\epsilon I$ does not exist, meaning that termination in line 12 cannot occur. It follows from the fact that $\epsilon I \prec H + 2\epsilon I \preceq (M + 2\epsilon)I$ and [30, proof of Lemma 11] that CG would reach an iterate satisfying (27)—so that termination in line 22 would occur—in at most the number of iterations given by (29). Of course, if termination occurs earlier in line 18, the bound (29) still holds. \(\Box\)

When employing the trust-region method of Section 4 for minimizing $f$, Algorithm 2 is invoked without knowing whether or not $H + 2\epsilon I \succ \epsilon I$. Nevertheless, Lemma 6 allows us to make the following crucial observation.

Lemma 7. If the iteration limit in Algorithm 2 is exceeded (that is, termination occurs at line 28), then $H \not\succ -\epsilon I$.

Proof. If $k_{\text{max}}$ is set to $n$ in line 4 or line 6, then it would follow from standard CG theory that Algorithm 2 cannot reach line 28, because either $r_{j+1} = 0$ for some $j < n$ (thus termination would have occurred at line 21) or else one of the other termination conditions would have been activated before this point. Hence, $k_{\text{max}}$ must have been set in line 4 to some value less than $n$. In this case, it follows from Lemma 6, the choice of $M$, and the choice of $k_{\text{max}}$ in line 4 that $H + 2\epsilon I \not\succ \epsilon I$. \(\Box\)

When Algorithm 2 returns because the inequality in Line 10 holds, it is possible that the objective function in (26) evaluated at the returned vector $s$ is larger than its value at $s = 0$, a situation that is typically not possible when CG is used as a subproblem solver in trust-region methods. This is because, although the inequality in Line 10 implies that $p_j$ is a direction of negative curvature for $H$, $p_j$ is not necessarily a direction of negative curvature for the matrix $H + 2\epsilon I$ that defines the quadratic model in (26). Since, in this case, $s$ is obtained by moving to the boundary of the trust-region along the direction $p_j$ (similar to the behavior of Steihaug’s CG method in [31], and needed for our complexity result), we require the following result, which establishes that any step computed by Algorithm 2 possesses a decrease property with respect to the non-regularized version of the quadratic model.

Lemma 8. The step $s$ returned by Algorithm 2 satisfies
\[
g^T s + \frac{1}{2} s^T H s \leq -\frac{1}{2} \epsilon \|s\|^2.
\]
Algorithm 2: Truncated CG Method for the Trust-Region Subproblem

1: **Input:** Nonzero $g \in \mathbb{R}^n$; $H \in \mathbb{S}^n$; regularization parameter $\epsilon \in (0, \infty)$; trust-region radius $\delta \in (0, \infty)$; accuracy parameter $\zeta \in (0, 1)$; flag $\text{capCG} \in \{\text{TRUE, FALSE}\}$; and (if $\text{capCG} = \text{TRUE}$) upper bound $M \in \|H\|_{\infty}$.
2: **Output:** trial step $s$ and flag $\text{outCG}$ indicating termination type.

3: if $\text{capCG} = \text{TRUE}$ then
4:  Set $k_{\max} \leftarrow \min\left\{ n, \frac{1}{2} \sqrt{n} \ln \left( 4 \kappa^3 / \zeta \right) \right\}$ where $\kappa \leftarrow (M + 2\epsilon) / 2$.
5: else
6:  Set $k_{\max} \leftarrow n$.
7: end if
8: Set $y_0 \leftarrow 0$, $r_0 \leftarrow g$, $p_0 \leftarrow -g$, and $j \leftarrow 0$.
9: while $j < k_{\max}$ do
10:  if $p_j^T (H + 2\epsilon I)p_j \leq \epsilon \|p_j\|^2$ then
11:     Compute $\sigma \geq 0$ such that $\|y_j + \sigma p_j\| = \delta$.
12:     return $s \leftarrow y_j + \sigma p_j$ and $\text{outCG} \leftarrow \text{BND-NEG}$.
13: end if
14:  Set $\alpha_j \leftarrow \|r_j\|^2 / (p_j^T (H + 2\epsilon I)p_j)$.
15:  Set $y_{j+1} \leftarrow y_j + \alpha_j p_j$.
16:  if $\|y_{j+1}\| \geq \delta$ then
17:     Compute $\sigma \geq 0$ such that $\|y_j + \sigma p_j\| = \delta$.
18:     return $s \leftarrow y_{j+1}$ and $\text{outCG} \leftarrow \text{BND-NORM}$.
19: end if
20:  Set $r_{j+1} \leftarrow r_j + \alpha_j (H + 2\epsilon I)p_j$.
21:  if $\|r_{j+1}\| \leq \frac{1}{2} \min \{ \|g\|, \|y_{j+1}\| \}$ then
22:     return $s \leftarrow y_{j+1}$ and $\text{outCG} \leftarrow \text{INT-RES}$.
23: end if
24:  Set $\beta_{j+1} \leftarrow (r_{j+1}^T r_{j+1}) / (r_j^T r_j)$.
25:  Set $p_{j+1} \leftarrow -r_{j+1} + \beta_{j+1} p_j$.
26:  Set $j \leftarrow j + 1$.
27: end while
28: return $s \leftarrow y_{k_{\max}}$ and $\text{outCG} \leftarrow \text{INT-MAX}$.

**Proof.** Basic CG theory ensures that for any $j$ up to termination, the sequence $\{g^T y_j + \frac{1}{2} y_j^T (H + 2\epsilon I) y_j\}$ is monotonically decreasing. Since $y_0 = 0$, we thus have

$$g^T y_i + \frac{1}{2} y_i^T (H + 2\epsilon I) y_i \leq 0 \text{ for all } i \in \{0, 1, \ldots, j\}. \quad (30)$$

Suppose $\text{outCG} \in \{\text{BND-NORM, INT-RES, INT-MAX}\}$. From (30) and the fact (by [31, Theorem 2.1]) that $g^T s + \frac{1}{2} s^T (H + 2\epsilon I) s \leq g^T y_j + \frac{1}{2} y_j^T (H + 2\epsilon I) y_j$ when $\text{outCG} \leftarrow \text{BND-NORM}$, we have

$$g^T s + \frac{1}{2} s^T (H + 2\epsilon I) s \leq 0 \iff g^T s + \frac{1}{2} s^T H s \leq -\epsilon \|s\|^2,$$

which implies the desired result.

Second, suppose that $\text{outCG} \leftarrow \text{BND-NEG}$, meaning that Algorithm 2 terminates because iteration $j$ yields $p_j^T (H + 2\epsilon I)p_j \leq \epsilon \|p_j\|^2$. If $j = 0$, then the fact that $p_0 = -g$ allows us to conclude that $s = \delta (p_0 / \|p_0\|) = -\delta (g / \|g\|)$, $\|s\| = \delta$, and

$$\frac{1}{2} s^T (H + 2\epsilon I) s = \frac{1}{2} \delta^2 (p_0^T (H + 2\epsilon I)p_0) / \|p_0\|^2 \leq \frac{1}{2} \epsilon \delta^2 = \frac{1}{2} \epsilon \|s\|^2,$$

from which it follows that

$$g^T s + \frac{1}{2} s^T H s = -\delta \|g\| + \frac{1}{2} s^T (H + 2\epsilon I) s - \epsilon \|s\|^2 \leq -\frac{1}{2} \epsilon \|s\|^2,$$
as desired. On the other hand, if \( j \geq 1 \), then the fact that \( \text{outCG} \leftarrow \text{bnd-neg} \) means that \( s \leftarrow y_j + \sigma p_j \) with \( \sigma \geq 0 \) such that \( \|s\| = \delta \). The CG process yields:

\[
y_i = \sum_{\ell=0}^{i-1} \alpha_{i\ell} p_\ell \in \text{span} \{p_0, \ldots, p_{i-1}\} \quad \text{for all} \quad i \in \{1, 2, \ldots, j\},
\]

\[
p_i^T (H + 2\epsilon I)p_\ell = 0 \quad \text{for all} \quad \{i, \ell\} \subseteq \{0, 1, \ldots, j\} \text{ with } i \neq \ell,
\]

\[
r_i^T p_j = -\|r_j\|^2 \quad \text{for all} \quad i \in \{0, 1, \ldots, j\},
\]

and \( y_i^T p_i \geq 0 \) for all \( i \in \{0, 1, \ldots, j\} \).

(Referring to Algorithm 2, the property (31a) follows from Line 15; (31b) is the well known conjugacy property; and (31c) is obtained by successively substituting for \( p_j, p_{j-1}, \ldots, p_{j+1} \) from Line 25, using the property that \( r_i^T r_j = 0 \) for \( i \neq j \), and using the definition of \( \beta_j \) from Line 24. For (31d), see [31, eq. (2.13)].) Together, (31) and \( s = y_j + \sigma p_j \) imply

\[
g^T p_j = r_0^T p_j = -\|r_j\|^2 \leq 0
\]

\[
s^T (H + 2\epsilon I)s = y_j^T (H + 2\epsilon I)y_j + \sigma^2 p_j^T (H + 2\epsilon I)p_j
\]

and \( \|s\|^2 = \|y_j\|^2 + 2\sigma y_j^T p_j + \sigma^2 \|p_j\|^2 \geq \sigma^2 \|p_j\|^2 \).

Combining (30), (32), \( \sigma \geq 0 \), and \( p_j^T (H + 2\epsilon I)p_j \leq \epsilon \|p_j\|^2 \) shows that

\[
g^T s + \frac{1}{2} s^T H s = g^T s + \frac{1}{2} s^T (H + 2\epsilon I)s - \epsilon \|s\|^2
\]

\[
= g^T y_j + \frac{1}{2} y_j^T (H + 2\epsilon I)y_j + \sigma g^T p_j + \frac{1}{2} \sigma^2 p_j^T (H + 2\epsilon I)p_j - \epsilon \|s\|^2
\]

\[
\leq \frac{1}{2} \sigma^2 p_j^T (H + 2\epsilon I)p_j - \epsilon \|s\|^2 \leq \frac{1}{2} \sigma^2 \|p_j\|^2 - \epsilon \|s\|^2 \leq -\frac{1}{2} \epsilon \|s\|^2,
\]

which completes the proof. \( \square \)

Lemma 8 shows that if \( \epsilon = \epsilon_H \), then the bound on the model decrease obtained by the truncated CG step \( s \) is the same as the bound guaranteed by the global solution computed for Algorithm 1 (see Lemma 1). However, we note that this decrease is obtained by using a larger regularization term.

### 3.2 A minimum eigenvalue oracle

The truncated CG algorithm presented in Section 3.1 is only one of the tools we need for our proposed inexact trust-region Newton method. Two complicating cases require an additional tool.

The first case is when \( \text{outCG} = \text{int-max} \) is returned by Algorithm 2. In this case, it must hold that the maximum allowed number of iterations satisfies \( k_{\text{max}} < n \) and, as a consequence of Lemma 7, that \( H \neq -\epsilon I \). Thus, there exists a direction of sufficient negative curvature for \( H \), and we need a means of computing one. The second case is when Algorithm 2 terminates with \( \text{outCG} = \text{int-res} \). In this case, we only know that the curvature is not sufficiently negative along the directions computed by the algorithm. However, it may still be true that \( H \neq -\epsilon I \).

These two cases motivate the need for a minimum eigenvalue oracle that estimates the minimum eigenvalue of \( H \), or else returns an indication that (with some desired probability) no sufficiently negative eigenvalue exists. The oracle that we employ is given by Algorithm 3.

### 4 An inexact trust-region Newton method

In this section, we propose a trust-region Newton method that may use, during each iteration, an inexact solution to the trust-region subproblem computed using the iterative procedures described in Section 3. The proposed algorithm is described in Section 4.1 and a second-order complexity analysis is presented in Section 4.2.
Algorithm 3 Minimum Eigenvalue Oracle (MEO)

**Input:** $g \in \mathbb{R}^n$; $H \in \mathcal{S}^n$; regularization parameter $\epsilon \in (0, \infty)$; trust-region radius $\delta \in (0, \infty)$; failure probability tolerance $\xi \in (0, 1)$; and $M \in [\|H\|, \infty)$.

**Output:** Either (i) a vector $s = \pm \delta v$ satisfying
\[
ge^T s \leq 0, \quad s^T H s \leq -\frac{1}{2} \epsilon \|s\|^2, \quad \text{and} \quad \|s\| = \delta,
\] (33)

where $v$ has been computed to satisfy $\|v\| = 1$ and $v^T H v \leq -\epsilon/2$, or (ii) an indication that $H \succeq -\epsilon I$ holds. The probability that the indication in case (ii) is made yet $H \prec -\epsilon I$ is at most $\xi$. (The bound $M$ may be needed for algorithm termination; see Assumption 2 on page 14.)

4.1 The algorithm

Algorithm 4 can be viewed as an inexact version of Algorithm 1. We aim at remaining close to the traditional Newton-CG approaches in [31, 32] by having Algorithm 4 compute, when appropriate, a truncated CG step in line 4. Once such a step is computed (or set to zero since the current iterate is first-order stationary), Algorithm 4 deviates from traditional Newton-CG in the “else” branch (line 10), which accounts for the two situations described in Section 3.2, where an additional check for a negative curvature direction is needed. (There is one minor difference: when $\text{outCG} = \text{INT-RES}$, the MEO need be called only when $\|g_k\| \leq \epsilon_g$.)

4.2 Complexity

As in [29], we make the following assumption on the MEO in order to obtain complexity results for Algorithm 4.

**Assumption 2.** When Algorithm 3 is called by Algorithm 4, the number of Hessian-vector products required is no more than
\[
N_{\text{meo}} = N_{\text{meo}}(\epsilon_H) := \min\left\{ n, \left[ \frac{C_{\text{meo}} \epsilon_H^{-1/2}}{2} \right] \right\}
\] (34)

where the quantity $C_{\text{meo}}$ depends at most logarithmically on $\xi$.

The following instances of Algorithm 3 satisfy Assumption 2.

- The Lanczos algorithm applied to $H$ starting with a random vector uniformly distributed on the unit sphere. For any $\xi \in (0, 1)$, this satisfies the conditions in Assumption 2 with $C_{\text{meo}} = \ln(2.75n/\xi^2)\sqrt{M}/2$; see [29, Lemma 2].

- The conjugate gradient algorithm applied to $(H + \frac{\epsilon_H}{2} I) s = b$, where $b$ is a random vector uniformly distributed on the unit sphere. For any $\xi \in (0, 1)$, this offers Assumption 2 with the same value of $C_{\text{meo}}$ as in the Lanczos-based approach; see [29, Theorem 1].

Since for each instance the conditions of Assumption 2 hold with $C_{\text{meo}}$ equal to the given value, it follows that throughout a run of Algorithm 4, the conditions hold with $C_{\text{meo}} = \ln(2.75n/\xi^2)\sqrt{T_g}/2$. Algorithm 3 could also be implemented by means of an exact (minimum) eigenvalue calculation of the Hessian. In that case, up to $n$ Hessian-vector products may be required to evaluate the full Hessian.

In the following analysis, we use similar notation as in Section 2, although the analysis here is notably different due to the randomness of the MEO. For consistency, we use the same definitions of the index sets $\mathcal{K}, \mathcal{I}, \mathcal{B}, \mathcal{S}$, and $\mathcal{U}$ that appear in the beginning of Section 2.2; in particular, we define $\mathcal{K}$ as the index set of iterations completed prior to termination. However, note that for Algorithm 4 these sets are random variables, in the sense that for the same objective function and algorithm inputs, they may have different realizations due to the randomness in Algorithm 3. Thus, when we refer, for example, to $k \in \mathcal{K}$, we are referring to $k \in \mathcal{K}$ for a given realization of a run of Algorithm 4. We also prove bounds on quantities that are shown to hold for all realizations of a run of the algorithm (for a given objective function and algorithm
Algorithm 4 Trust-Region Newton-CG Method (inexact version)

Require: Tolerances $\epsilon_g \in (0, \infty)$ and $\epsilon_H \in (0, \infty)$; trust-region adjustment parameters $\gamma_1 \in (0, 1)$, $\gamma_2 \in [1, \infty)$, and $\psi \in (1/\gamma_2, 1]$; initial iterate $x_0 \in \mathbb{R}^n$; initial trust-region radius $\delta_0 \in (0, \infty)$; maximum trust-region radius $\delta_{\text{max}} \in [\delta_0, \infty)$; step acceptance parameter $\eta \in (0, 1)$; truncated CG accuracy parameter $\zeta \in (0, 1)$; MEO failure probability tolerance $\xi \in (0, 1)$; flag $\text{capCG} \in \{\text{TRUE}, \text{FALSE}\}$; and upper bound $M \in [L_g, \infty)$.

1: for $k = 0, 1, 2, \ldots$ do
2: Evaluate $g_k$ and $H_k$.
3: if $g_k \neq 0$ then
4: Call Algorithm 2 with input $g = g_k$, $H = H_k$, $\epsilon = \epsilon_H$, $\delta = \delta_k$, $\zeta$, $\text{capCG}$, and (if $\text{capCG} = \text{TRUE}$) $M$ to compute $s_k^{\text{CG}}$ and output flag $\text{outCG}$.
5: else
6: Set $s_k^{\text{CG}} \leftarrow 0$ and $\text{outCG} \leftarrow \text{INT-RES}$.
7: end if
8: if $\text{outCG} \in \{\text{BND-NEG}, \text{BND-NORM}\}$ or ($\|g_k\| > \epsilon_g$ and $\text{outCG} = \text{INT-RES}$) then
9: Set $s_k \leftarrow s_k^{\text{CG}}$.
10: else (that is, $\text{outCG} = \text{INT-MAX}$ or ($\|g_k\| \leq \epsilon_g$ and $\text{outCG} = \text{INT-RES}$))
11: Call Algorithm 3 with inputs $g = g_k$, $H = H_k$, $\epsilon = \epsilon_H$, $\delta = \delta_k$, $\xi$, and $M$, obtaining either $s_k$ satisfying (33) or an indication that $H_k \geq -\epsilon_H I$.
12: if Algorithm 3 predicts that $H_k \geq -\epsilon_H I$ then
13: return $x_k$.
14: end if
15: end if
16: Compute the ratio of actual to predicted decrease in $f$ defined as
   $\rho_k \leftarrow \frac{f(x_k) - f(x_k + s_k)}{m_k(x_k) - m_k(x_k + s_k)}$.
17: if $\rho_k \geq \eta$ then
18: Set $x_{k+1} \leftarrow x_k + s_k$.
19: if $\|s_k\| \geq \psi \delta_k$ then
20: Set $\delta_{k+1} \leftarrow \min\{\gamma_2 \delta_k, \delta_{\text{max}}\}$.
21: else
22: Set $\delta_{k+1} \leftarrow \delta_k$.
23: end if
24: else
25: Set $x_{k+1} \leftarrow x_k$ and $\delta_{k+1} \leftarrow \gamma_1 \|s_k\|$.
26: end if
27: end for

Our first result provides a lower bound on the reduction in the quadratic model of the objective function achieved by each trial step.

Lemma 9. Consider any realization of a run of Algorithm 4. For all $k \in \mathcal{K}$,

$$m_k(x_k) - m_k(x_k + s_k) \geq \frac{1}{4} \epsilon_H \|s_k\|^2.$$

Proof. If $s_k = s_k^{\text{CG}}$, where $s_k^{\text{CG}}$ is computed from Algorithm 2, then, it follows by Lemma 8 that the desired bound holds. Now suppose that $s_k$ is computed from Algorithm 3 in line 11. Since $k \in \mathcal{K}$, Algorithm 4 inputs). To emphasize that these bounds hold for all realizations, their constants are written with a bar over the letter in the definition.
Reasoning as in the proof of Lemma 3, with realization of a run.

Lemma 10. Consider any realization of a run of Algorithm 4. For all \( k \in K \), if \( k \in \mathcal{U} \), then \( \delta_k > 3(1 - \eta)\epsilon_H / (2L_H) \). Hence, by the trust-region radius update procedure, it follows that for any realization of a run of Algorithm 4 that

\[
\delta_k \geq \delta_{\min} := \min \left\{ \delta_0, \left( \frac{3\gamma_1(1 - \eta)}{2L_H} \right) \epsilon_H \right\} \in (0, \infty) \quad \text{for all } k \in K.
\]

Proof. For any realization of a run of the algorithm, we can follow the proof of Lemma 2, using Lemma 9 in lieu of Lemma 1. Hence, the lower bound in (35) holds, where \( \delta_{\min} \) is independent of any particular realization of a run.

Lemma 11. Consider any realization of a run of Algorithm 4. The following hold for all successful iterations:

(i) If \( k \in B \cap S \), then

\[
f_k - f_{k+1} \geq \frac{7}{4} \epsilon_H \delta_k^2.
\]

(ii) If \( k \in I \cap S \), then \( \|g_k\| > \epsilon_g \), \( \text{outCG} = \text{INT-RES} \), and

\[
f_k - f_{k+1} \geq \frac{7}{4} \epsilon_H \min \left\{ \|g_{k+1}\| \epsilon_H^{-1}, \epsilon_H^3 \right\}.
\]

Proof. For part (i), we combine \( k \in B \cap S \) with Lemma 9 to obtain, as desired,

\[
f_k - f_{k+1} \geq \eta (m_k(x_k) - m_k(x_k + s_k)) \geq \frac{7}{4} \epsilon_H \|s_k\|^2 = \frac{7}{4} \epsilon_H \delta_k^2.
\]

Now consider part (ii). Note that since \( k \in I \), \( s_k \) cannot have been computed from a call to Algorithm 3 in line 11, since such steps always have \( \|s_k\| = \delta_k \). Thus, \( s_k = s_k^{\text{CG}} \). Moreover, from line 8 and the fact that \( k \in I \), we have that \( \|g_k\| > \epsilon_g \) and \( \text{outCG} = \text{INT-RES} \), as desired. In turn, the fact that \( \text{outCG} = \text{INT-RES} \) implies that (27) holds with \( H = H_k \), \( g = g_k \), \( s = s_k \), and \( \epsilon = \epsilon_H \) so that

\[
r_k := (H_k + 2\epsilon_H)s_k + g_k \quad \text{has} \quad \|r_k\| \leq \frac{5}{2} \epsilon_H \|s_k\|.
\]

Combining this bound with (4b) and \( \zeta \in (0, 1) \), we have

\[
\|g_{k+1}\| = \|g_{k+1} - g_k - (H_k + 2\epsilon_H)s_k + r_k\|
\leq \|(g_{k+1} - g_k) - H_k s_k\| + 2\epsilon_H \|s_k\| + \|r_k\|
\leq \frac{L_H}{2} \|s_k\|^2 + \left( \frac{5+\zeta}{2} \right) \epsilon_H \|s_k\| \leq \frac{L_H}{2} \|s_k\|^2 + \frac{5}{2} \epsilon_H \|s_k\|,
\]

which can be rearranged to yield

\[
\frac{L_H}{2} \|s_k\|^2 + \frac{5}{2} \epsilon_H \|s_k\| - \|g_{k+1}\| \geq 0.
\]

Reasoning as in the proof of Lemma 3, with \( \frac{5}{2} \epsilon_H \) replacing \( \epsilon_H \), we obtain

\[
\|s_k\| \geq \frac{-5}{2} \epsilon_H + \sqrt{\frac{5}{2}^2 \epsilon_H^2 + 2L_H \|g_{k+1}\|} = \left( -5 + \sqrt{25 + 8L_H \|g_{k+1}\|} \right) \epsilon_H.
\]

\[16\]
By setting \((a, b, t) = (5, 8L_H, \|g_{k+1}\|_H^2)\) in the inequality (12), we have
\[
\|s_k\| \geq \left(\frac{-5+\sqrt{25+8L_H}}{2L_H}\right) \min\left\{\|g_{k+1}\|_H^2, 1\right\} \epsilon_H
\]
\[
= \left(\frac{8L_H}{5+\sqrt{25+8L_H}}\right) \min\left\{\|g_{k+1}\|_H^2, \epsilon_H\right\}
\]
\[
= \left(\frac{4}{\sqrt{25+8L_H}}\right) \min\left\{\|g_{k+1}\|_H^2, \epsilon_H\right\}
\]
which may be combined with (37), we have for \(k \in I \cap S\) and Lemma 9 to obtain
\[
f_k - f_{k+1} \geq \eta(m_k(x_k) - m_k(x_{k+1})) \geq \frac{1}{4} \eta \epsilon_H \|s_k\| \geq \frac{\eta}{4(\gamma + 2L_H)} \min\left\{\|g_{k+1}\|_H^2, \epsilon_H^3\right\},
\]
which completes the proof. □

The next result is analogous to Lemma 4 and takes randomness in the MEO into account.

**Lemma 12.** For any realization of a run of Algorithm 4, the number of successful iterations performed before termination occurs satisfies
\[
|S| \leq \tilde{K}_S(\epsilon_g, \epsilon_H) := \left[\tilde{C}_S \max\{\epsilon_H^{-1}, \epsilon_g^{-2} \epsilon_H, \epsilon_H^{-3}\}\right] + 1,
\]
where
\[
\tilde{C}_S := \frac{8(\tilde{f}_0 - \tilde{f}_{\text{low}})}{\eta} \max\left\{\frac{1}{\tilde{g}^2}, \frac{4L_H}{\rho \gamma (1-\eta)^2}, 7 + 2L_H\right\}.
\]

**Proof.** For a given realization of a run of the algorithm, we can follow the reasoning of the proof for Lemma 4. In what follows, \(\mathcal{S}_L, \mathcal{S}_{GG}, \text{ and } \mathcal{S}_{GL}\) are defined as in the proof of Lemma 4. (As is the case for \(\mathcal{K}\), we note that these index sets are now realizations of random index sets.)

Consider first \(k \in \mathcal{S}_L\), and let us define the constant
\[
c_1 := \frac{\eta}{4} \min\left\{\frac{\gamma^2 (1-\eta)^2}{4L_H^2}, \frac{\gamma^2 (1-\eta)^2}{4L_H^2}, \frac{1}{\gamma + 2L_H}\right\}.
\]

We can use Lemma 11 to conclude that \(k \in \mathcal{K} \cap \mathcal{B}\), so that \(\|s_k\| = \delta_k\). By combining Lemma 11(i), Lemma 10, and (39), we have for \(k \in \mathcal{S}_L\) that
\[
f_k - f_{k+1} \geq \frac{\gamma}{4} \epsilon_H \delta_k^2 \geq \frac{\gamma}{4} \min\left\{\frac{\epsilon_H^2}{\delta_k^2}, \frac{\gamma^2 (1-\eta)^2}{4L_H^2} \epsilon_H^3\right\} \geq c_1 \min\left\{\epsilon_H, \epsilon_H^3\right\}.
\]

For \(k \in \mathcal{S}_{GG}\), we have from Lemma 11 (either (i) or (ii)) and Lemma 10 that
\[
f_k - f_{k+1} \geq \frac{\gamma}{4} \min\left\{\frac{\epsilon_H^2}{\delta_k^2}, \frac{\gamma^2 (1-\eta)^2}{4L_H^2} \epsilon_H^3, \frac{\epsilon_H^{-1}}{1 + 2L_H} \epsilon_H^{-1}, \frac{\epsilon_H^3}{\gamma + 2L_H} \epsilon_H^3\right\}
\]
\[
\geq c_1 \min\left\{\epsilon_H, \epsilon_H^3\right\}.
\]

By following the reasoning that led to (18), we obtain from (40) and (41) that
\[
|\mathcal{S}_L| + |\mathcal{S}_{GG}| \leq \left(\frac{\tilde{f}_0 - \tilde{f}_{\text{low}}}{c_1}\right) \max\{\epsilon_H^{-1}, \epsilon_g^{-2} \epsilon_H, \epsilon_H^{-3}\}.
\]

As in the proof of Lemma 4, we have that \(|\mathcal{S}_{GL}| \leq |\mathcal{S}_L| + 1\), so that
\[
|S| = |\mathcal{S}_L| + |\mathcal{S}_{GG}| + |\mathcal{S}_{GL}| \leq 2\left(\frac{\tilde{f}_0 - \tilde{f}_{\text{low}}}{c_1}\right) \max\{\epsilon_H^{-1}, \epsilon_g^{-2} \epsilon_H, \epsilon_H^{-3}\} + 1.
\]

The desired bound follows by substituting the definition (39) into this bound. To complete the proof, we note that the right-hand side of (37) is identical for any realization of the algorithm run with the same inputs. □

We now provide a bound on the maximum number of unsuccessful iterations.
Lemma 13. For any realization of a run of Algorithm 4, the number of unsuccessful iterations performed before termination occurs is either zero or else satisfies

$$|U| \leq 1 + \log_{\gamma_1} \left( \frac{3(1-\eta)}{2LHg_{\text{max}}} \right) + \log_{\gamma_1} (\epsilon_H) \left( |S| + 1 \right). \quad (42)$$

Proof. For a given realization of a run of the algorithm, the bound follows from the argument in the proof of Lemma 5 with two changes. First, Lemma 10 is used in place of Lemma 2. Second, we do not know that the iteration immediately prior to termination must be a successful iteration for Algorithm 4, as was the case for Algorithm 1. However, using the argument in the proof of Lemma 5 along with Lemma 10 shows that if a sequence of consecutive unsuccessful iterations is taken after the final successful iteration, there can be no more than

$$1 + \log_{\gamma_1} \left( \frac{3(1-\eta)}{2LHg_{\text{max}}} \right) + \log_{\gamma_1} (\epsilon_H)$$

such iterations in this sequence, since otherwise an additional successful iteration would be performed. Taking this fact into account leads to the extra 1 on the right-hand side of (42) as compared to (19). \qed

We assume in our remaining complexity results that the following common-sense rule is used in the implementation of Algorithm 4.

Implementation Strategy 4.1. For any realization of a run of Algorithm 4, suppose $k \in K$ is an index of an iteration such that (i) Algorithm 3 is called in line 11 and returns a negative curvature direction $s_k$ for $H_k$ and (ii) the step $s_k$ is subsequently rejected (that is, $k \in U$). Then, the negative curvature direction (call it $v = v_k$) used to compute $s_k$ is stored and used until the next successful iteration. Until then, every call to Algorithm 3 is replaced by an access to $v_k$, scaled appropriately to compute $s_k$ with norm $\delta_k$.

This strategy implies that Algorithm 4 cannot terminate following a sequence of unsuccessful iterations if any one of them yields a direction of sufficiently negative curvature. In practice, this means that Algorithm 4 calls Algorithm 3 at most once between successful iterations. In the next iteration complexity result, this assumption is used to obtain the probabilistic result for returning an ($\epsilon_g, \epsilon_H$)-stationarity point.

Theorem 2. Under Assumption 1, for any realization of a run, the number of successful iterations (and objective gradient evaluations) performed by Algorithm 4 before termination occurs satisfies (with $K_S(\epsilon_g, \epsilon_H)$ defined in (37))

$$|S| \leq K_S(\epsilon_g, \epsilon_H) = \mathcal{O} \left( \max\{\epsilon_H^{-3}, \epsilon_H^{-1}, \epsilon_g^{-2}\epsilon_H\} \right) \quad (43)$$

and the total number of iterations (and objective function evaluations) performed before termination occurs satisfies

$$|K| \leq \left[ 1 + \log_{\gamma_1} \left( \frac{3(1-\eta)}{2LHg_{\text{max}}} \right) + \log_{\gamma_1} (\epsilon_H) \right] \left( K_S(\epsilon_g, \epsilon_H) + 1 \right) \quad (44)$$

If $\text{capCG} = \text{false}$, then $\|g_k\| \leq \epsilon_g$ holds at termination. In any case, given Implementation Strategy 4.1, the vector $x_k$ returned by Algorithm 4 is an ($\epsilon_g, \epsilon_H$)-stationary point with probability at least $(1 - \xi)^{K_S(\epsilon_g, \epsilon_H)}$.

Proof. The results in (43) and (44) follow from Lemma 12 and Lemma 13. If $\text{capCG} = \text{false}$, then the flag output by Algorithm 2 has $\text{outCG} \neq \text{INT-MAX}$. Combining this fact with line 8 of Algorithm 4 allows us to conclude that $\|g_k\| \leq \epsilon_g$ when termination occurs in this case.

Suppose that Implementation Strategy 4.1 is used. Then, the vector $x_k$ returned by Algorithm 4 is not an ($\epsilon_g, \epsilon_H$)-stationary point only if the MEO (Algorithm 3) makes an inaccurate indication of near-positive-definiteness, which, each time it is called, can occur with probability at most $\xi$. Our goal now is to prove that the vector $x_k$ returned by Algorithm 4 is an ($\epsilon_g, \epsilon_H$)-stationary point with probability at least $(1 - \xi)^{K_S(\epsilon_g, \epsilon_H)}$. To that end, for all $k \in \mathbb{N}$, let $P_k$ be the probability that the algorithm reaches iteration $k$ and $x_k$ is not ($\epsilon_g, \epsilon_H$)-stationary. Similarly, for all $k \in \mathbb{N}$, let $P_k$ be the probability that the algorithm reaches iteration $k$ and $x_k$ is not ($\epsilon_g, \epsilon_H$)-stationary, yet the algorithm terminates in iteration $k$ due to an
inaccurate indication from the MEO. It follows from the aforementioned property of the MEO in this setting that $P_k \leq \xi \hat{P}_k$ for all $k \in \mathbb{N}$. Thus, since it is trivially true that

$$\hat{P}_k + \sum_{i=0}^{k-1} P_i \leq 1 \quad \text{for all } k \in \mathbb{N},$$

it follows that

$$P_k \leq \xi \hat{P}_k \leq \xi \left(1 - \sum_{i=0}^{k-1} P_i\right) \quad \text{for all } k \in \mathbb{N}. \quad (45)$$

We now define $M_k$ to be the number of calls to the MEO that have occurred up to and including iteration $k$, for any $k \in \mathbb{N}$. Let us now prove by induction that $\sum_{i=0}^{k} P_i \leq 1 - (1 - \xi)^{M_k}$ for all $k \in \mathbb{N}$. For $k = 0$, the claim holds trivially both when $M_0 = 0$ (in which case $P_0 = 0$) and when $M_0 = 1$ (in which case $P_0 \leq \xi$). Now suppose that the claim is true for some $k \in \mathbb{N}$; we aim to prove that it remains true for $k + 1$. If the algorithm reaches iteration $k + 1$ in which $x_{k+1}$ is not $\epsilon$-stationary and the MEO is not called in iteration $k + 1$, then $M_{k+1} = M_k$ and $P_{k+1} = 0$, so by the induction hypothesis it follows that

$$\sum_{i=0}^{k+1} P_i = \sum_{i=0}^{k} P_i \leq 1 - (1 - \xi)^{M_k} = 1 - (1 - \xi)^{M_{k+1}},$$

as desired. On the other hand, if the algorithm reaches iteration $k + 1$, the iterate $x_{k+1}$ is not $(\epsilon_g, \epsilon_H)$-stationary, and the MEO is called in iteration $k + 1$, then $M_{k+1} = M_k + 1$ and along with (45) and the induction hypothesis it follows that

$$\sum_{i=0}^{k+1} P_i = \sum_{i=0}^{k} P_i + P_{k+1} \leq \sum_{i=0}^{k} P_i + \xi \left(1 - \sum_{i=0}^{k} P_i\right) = \xi (1 - \xi) \sum_{i=0}^{k} P_i \leq \xi (1 - \xi) \sum_{i=0}^{k} P_i = 1 - (1 - \xi)^{M_{k+1}} = 1 - (1 - \xi)^{M_{k+1}},$$

as desired, again. Since $|S|$ is an upper bound on the number of successful steps, which in turn bounds the number of calls to MEO when Implementation Strategy 4.1 is used, we have $M_k \leq |S| \leq \bar{K}_g(\epsilon_g, \epsilon_H)$ for all $k$. We conclude that the probability that the algorithm terminates incorrectly due to an incorrect indication from MEO on any iteration is bounded above by $1 - (1 - \xi)^{\bar{K}_g(\epsilon_g, \epsilon_H)}$. Consequently, the probability that the algorithm outputs an $(\epsilon_g, \epsilon_H)$-stationary point is at least $(1 - \xi)^{\bar{K}_g(\epsilon_g, \epsilon_H)}$, as claimed. \qed

Finally, we state a complexity result for the number of Hessian-vector products. For simplicity, we focus on the case of a small tolerance $\epsilon_g$.

**Theorem 3.** Let Assumption 1 and Assumption 2 hold, and suppose that Implementation Strategy 4.1 is used. Suppose that $\epsilon_H = \epsilon_g^{1/2}$ with $\epsilon_g \in (0, 1)$. Then, for any realization of a run of Algorithm 4, the total number of Hessian-vector products performed satisfies:

(i) If $\text{capCG} = \text{FALSE}$, then the number of Hessian-vector products is bounded by

$$n|K| + N_{\text{meo}}(\epsilon_H)|\bar{K}_g(\epsilon_g, \epsilon_H)| = n\tilde{O}(\epsilon_g^{-3/2}).$$

(ii) If $\text{capCG} = \text{TRUE}$, then the number of Hessian-vector products is bounded by

$$\min\{n, J(L_g, \epsilon_H, \zeta)|K| + N_{\text{meo}}(\epsilon_H)|\bar{K}_g(\epsilon_g, \epsilon_H)| = \min\{n, \epsilon_g^{-1/4}\}\tilde{O}(\epsilon_g^{-3/2}).$$
Proof. First, suppose $\text{capCG} = \text{false}$. Then, for any $k \in \mathcal{K}$ in any realization of a run of the algorithm, the maximum number of Hessian-vector products computed by the truncated CG algorithm is $n$. In addition, over any realization of a run, the maximum number of Hessian-vector products computed by the MEO is $N_{\text{meo}}(\epsilon_g)$ (see (34)) each of the (at most) $|K_g(\epsilon_g, \epsilon_H)|$ times it is called. Since the number of Hessian-vector products performed by Algorithm 4 is the sum of these two, we have proved the left-hand side of part (i).

For the estimate $n \tilde{O}(\epsilon_g^{-3/2})$, we use $\epsilon_H = \epsilon_g^{1/2}$, the bound on $\mathcal{K}$ from Theorem 2, the estimate of $N_{\text{meo}}$ from Assumption 2, and the fact that $\max\{\epsilon_H^{-3/2}, \epsilon_g^{-1/2}\} = \max\{\epsilon_g^{-3/2}, \epsilon_g^{-3/2}\} = \epsilon_g^{-3/2}$ when $\epsilon_g \in (0, 1)$.

For part (ii), we use the same estimates as well as the estimate of $J(L_g, \epsilon_H, \zeta)$ from Lemma 6 and (4c), noting that both $|\mathcal{K}|$ and $K_g(\epsilon_g, \epsilon_H)$ are $\tilde{O}(\epsilon_g^{-3/2})$ while $J(L_g, \epsilon_H, \zeta)$ and $N_{\text{meo}}$ are both $\min\{n, \tilde{O}(\epsilon_g^{-1/4})\}$.

Note that for $n \gg \epsilon_g^{-1/4}$, the bound in part (ii) of this theorem is $\tilde{O}(\epsilon_g^{-7/4})$, which is a familiar quantity in the literature on the operation complexity required to find an $(\epsilon_g, \epsilon_g^{1/2})$-stationary point [1, 6, 30].

Theorem 3 illustrates the benefits of using a capped truncated CG routine in terms of attaining good computational complexity guarantees. As a final remark, we expect the “cap” of Algorithm 2 to be triggered only in rare cases, due to the conservative nature of the CG convergence bounds that gave rise to this cap.

5 Practical considerations

Having presented an analysis of the theoretical complexity of our inexact trust-region Newton-CG approach, we consider several practical issues that arise in developing a computational implementation of this method.

The randomness inherent in Algorithm 3 is central to the complexity analysis of Algorithm 4 that was presented in Section 4. Since the randomness carries with it a small probability of failure of Algorithm 3, two unsavory situations can occur that lead to “failure modes” for Algorithm 4. First, suppose that Algorithm 3 is called in line 11 because $\|q_k\| \leq \epsilon_g$ and $\text{outCG} = \text{lng}$. In this case, if $\text{capCG} = \text{true}$ and Algorithm 3 predicts that $\lambda_{\min}(H_k) \geq -\epsilon_H$, then with probability up to $\xi$ this indication is incorrect and a direction of sufficiently negative curvature actually exists but was not found. Second, suppose that Algorithm 3 is called because $\text{outCG} = \text{lng}$. Here, it is again possible with probability up to $\xi$ that the indication $\lambda_{\min}(H_k) > -\epsilon_H$ will be made, even though we know from Lemma 7 that $\lambda_{\min}(H_k) \leq -\epsilon_H$. This second case can occur even when $\|q_k\| > \epsilon_g$, meaning that termination can occur at a point that is not even $\epsilon_g$-stationary. Note, however, that in a given iteration the probability of these two situations is bounded by $\xi$, which appears only logarithmically in the constant $C_{\text{meo}}$ of Assumption 2, and thus can be chosen to be extremely small. We can avoid this second case by replacing Algorithm 2 with the alternative truncated CG method of [29, Algorithm 1], which computes and returns a negative curvature direction whenever it detects that one exists. This “implicitly capped” method is more complicated to describe than the “explicitly capped” version of CG that we consider here, so in this paper we opted for simplicity of description at the expense of a (small) probability of failure in the subsequent call to Algorithm 3.

Our experiments with the inexact algorithms reported in Section 6 use the randomized Lanczos procedure of [21, 22]. In practice, Algorithm 3 is rarely invoked by Algorithm 4—in the vast majority of test problems, it is invoked only once on the last iteration of Algorithm 4 as a final check that the Hessian is approximately positive semidefinite. Rather than explicitly capping the number of iterations to the value described in Assumption 2 and the comments that follow it, we use an adaptive criterion to decide when a close approximation to the minimum eigenvalue has been detected. Specifically, we stop at iteration $t$ if $\lambda_{t-1} - \lambda_t \leq 10^{-5}$, where $t = \min\{t, n, 10\}$ and $\lambda_t$ is the estimate of the minimum eigenvalue at the $t$th iteration of randomized Lanczos. It makes sense to use such a tight tolerance, since Algorithm 3 is rarely invoked by Algorithm 4, so that the cost of doing a careful check for approximate semidefiniteness is worthwhile.

In our implementations of the Truncated CG procedure (Algorithm 2), we use the quantity $\hat{n} := \min\{n + 2, 1, 2n\}$ in place of $n$, in determining the maximum number of iterations $k_{\max}$. This relaxation can be beneficial in practice since loss of conjugacy due to numerical rounding can result in a zero residual not being attained by CG after $n$ steps. Typically, a small number of additional iterations beyond $n$ suffices to obtain a more accurate solution. Another key parameter in this algorithm, the value $\zeta$ used as a convergence
threshold for the residual, is set to .25 in our tests. (We discuss the settings of the parameters in Algorithm 4 in the next section.)

6 Computational experiments

We implemented several variants of trust-region Newton methods in Matlab, as follows.

- **TR-Newton.** An implementation of Algorithm 1 with the trust-region subproblem solved using a Moré-Sorensen approach [24].

- **TR-Newton (no reg.).** The same as TR-Newton, except that the regularization term involving $\epsilon_H$ is omitted from the subproblem objective (6). This variant demonstrates the effect of this regularization term on the practical performance of TR-Newton.

- **TR-Newton-CG-explicit.** An implementation of Algorithm 4 with an explicit cap on the number of CG iterations (that is, $\text{capCG} = \text{true}$).

- **TR-Newton-CG-explicit (no reg.).** The same as TR-Newton-CG-explicit, except that the regularization term involving $\epsilon_H$ is omitted from the subproblem objective, again to illustrate the impact of this regularization.

- **TR-Newton-CG.** An implementation of Algorithm 4 without an explicit cap (that is, $\text{capCG} = \text{false}$).

- **TR-Newton-CG (no reg.).** The same as TR-Newton-CG, except that the regularization term involving $\epsilon_H$ is omitted from the subproblem objective. This method is the most similar to traditional trust-region Newton-CG with Steihaug-Toint stopping rules for the CG routine. The only differences with the latter approach is that, for consistency with the other methods, we use the stopping test on line 21 of Algorithm 2, and still use the MEO (Algorithm 3) to ensure convergence to an $(\epsilon_g, \epsilon_H)$-stationary point (with high probability).

- **TRACE.** The trust-region algorithm with guaranteed optimal complexity proposed and analyzed in [11].

For the six instances of our algorithms, we used a regularization of $2\epsilon_H$ while computing the Newton-type step. We set $\gamma_1 = \gamma_2^{-1} = 0.5$, $\psi = 0.75$, $\eta = 0.1$, $\zeta = 0.25$, $\delta_{\text{max}} = 10^{20}$ and $\delta_0 = 10$.

Our experiments show that the empirical performance of these methods is similar in terms of the number of iterations, function evaluations, and gradient evaluations required to locate an $(\epsilon_g, \epsilon_H)$-stationary point. In particular, the performance of the Newton-CG variants in terms of iterations, function and gradient evaluations is almost unaffected by the presence of a cap. A second observation is that the regularization term in the trust-region subproblem objective in Algorithm 4, which is required to ensure optimal iteration and operation complexity properties for this method, has a noticeable effect on practical performance, mostly in terms of Hessian-vector products. We discuss this effect further below.

We tested the algorithms using problems from the CUTEst test collection [17]. Many problems in this benchmark come with different size options. If the default size (according to the sizes that come with the distribution, downloaded July 1, 2020) was in the range [100,1000], then we used the default size. Otherwise, we choose the size closest to the range [100,1000] from the default value. This resulted in a test set of 233 problems. In order to focus on the results of experiments for the larger problems in the set, the following discussion and presentation of results considers only the problems with $n \geq 100$; this is a test set of 109 problems.

Figure 1 shows performance profiles for various metrics [13]. The horizontal axis is capped at $\tau = 10$ in order to distinguish the performance of the methods more clearly. We considered two termination tolerances. In the first set of experiments, corresponding to the left column of plots in Figure 1, termination was declared when the algorithm encountered a $(10^{-5}, 10^{-5/2})$-stationary point. In the second set of experiments (the right column of plots in Figure 1) we terminate at $(10^{-5}, 10^{-5})$-stationary points. In both sets of runs, we
imposed an iteration limit of $10^4$. For the trust-region Newton-CG methods, we also imposed an overall Hessian-vector product limit of $10^4n$. A run was declared to be unsuccessful if this limit is reached without a stationary point of the specified precision being found. Although not evident from the performance profiles due to the cap on $\tau$, all algorithms solved at least 101 test problems out of 109 for both stationarity tolerances, a reliability of about 93%.

Figure 1 shows the performance of all algorithms to be similar in terms of required iterations and gradient evaluations. We do however see significant differences in the number of Hessian-vector products required for the four TR-Newton-CG methods. The variants with no regularization term in the subproblems outperform the others in this respect; recall that these variants do not possess optimal complexity guarantees. The practical significance of this difference in performance depends on the cost of computing a gradient relative to the cost of a Hessian-vector product. If gradient evaluations are significantly more expensive, our results suggest no substantial difference in computation time between the four Newton-CG methods. On the other hand, if Hessian-vector products are expensive relative to gradients, there may be a significant increase in run time as a result of including the regularization term. We remark that the vast majority of the Hessian-vector products in the Newton-CG variants were computed in Algorithm 2: on all problems but three, Algorithm 3 was only called at the last iteration to assess termination.

7 Conclusion

We have established that, with a few critical modifications, the popular trust-region Newton-CG method can be equipped with second-order complexity guarantees that match the best known bounds for second-order methods for solving smooth nonconvex optimization problems. We derived iteration complexity results for both exact and inexact variants of the approach, and for the inexact variant we leveraged iterative linear algebra techniques to obtain strong operation complexity guarantees (in terms of gradient computations and Hessian-vector products) that again match the best known methods in the literature. Finally, we showed that the practical effects of including these modifications can be relatively minor.

Our results could be modified to obtain alternative complexity results for approximate $\epsilon_g$-stationary points. For instance, we could modify Algorithm 2 by monitoring the decrease rate of the residual norm in a way that the number of CG iterations is subject to an implicit cap [29], in place of the explicit cap used here (when $\text{capCG} = \text{true}$). With appropriate modifications in Algorithm 4, and under the assumptions of Theorem 3, one could establish a deterministic operation complexity bound of $\tilde{O}(\epsilon_g^{-7/4})$ for reaching an $\epsilon_g$-stationary point. However, the resulting method is significantly more delicate to implement, and must be paired with Algorithm 3 to be endowed with a second-order complexity analysis.

Acknowledgments

We thank Yue Xie for providing most of the proof of Theorem 2. We are grateful to the editor and two anonymous referees, whose comments led to significant improvements to the paper.
