Abstract

We review the physics potential of top mass measurements and the GigaZ/MegaW options of the International Linear Collider (ILC) for probing New Physics models and especially the Minimal Supersymmetric Standard Model (MSSM). We demonstrate that the anticipated experimental accuracies at the ILC for the top-quark mass, $m_t$, the W boson mass, $M_W$, and the effective leptonic weak mixing angle, $\sin^2 \theta_{\text{eff}}$, will provide a high sensitivity to quantum effects of New Physics. In particular, a new and more precise measurement of $\sin^2 \theta_{\text{eff}}$, for which the experimental central value is currently obtained from an average where the most precise single measurements differ by more than three standard deviations, could lead to a situation where both the Standard Model and the MSSM in its most general form are ruled out. Alternatively, the precision measurements may resolve virtual effects of SUSY particles even in scenarios where the SUSY particles are so heavy that they escape direct detection at the LHC and the first phase of the ILC.
We review the physics potential of top mass measurements and the GigaZ/MegaW options of the International Linear Collider (ILC) for probing New Physics models and especially the Minimal Supersymmetric Standard Model (MSSM). We demonstrate that the anticipated experimental accuracies at the ILC for the top-quark mass, $m_t$, the $W$ boson mass, $M_W$, and the effective leptonic weak mixing angle, $\sin^2 \theta_{\text{eff}}$, will provide a high sensitivity to quantum effects of New Physics. In particular, a new and more precise measurement of $\sin^2 \theta_{\text{eff}}$, for which the experimental central value is currently obtained from an average where the most precise single measurements differ by more than three standard deviations, could lead to a situation where both the Standard Model and the MSSM in its most general form are ruled out. Alternatively, the precision measurements may resolve virtual effects of SUSY particles even in scenarios where the SUSY particles are so heavy that they escape direct detection at the LHC and the first phase of the ILC.

1 Introduction

Electroweak precision observables (EWPO) are a very powerful tool for testing the Standard Model (SM) and extensions of it. A particularly attractive extension is the Minimal Supersymmetric Standard Model (MSSM), see Ref. [1] for a review of electroweak precision physics in the MSSM. In this context the $Z$-pole observables and $W$ boson physics play an important role. The most sensitive observables are the effective leptonic weak mixing angle, $\sin^2 \theta_{\text{eff}}$, and the $W$ boson mass, $M_W$. Performing fits in constrained supersymmetric (SUSY) models a certain preference for not too heavy SUSY particles has been found [2–5], see Ref. [6] for other approaches; a detailed list of references can be found in Ref. [4]. The prospective improvements in the experimental accuracies, in particular at the ILC with GigaZ option (high luminosity running at the $Z$ pole) and the MegaW option (high luminosity running at the $WW$ threshold), will provide a high sensitivity to deviations both from the SM and the MSSM. In Tab. [1] we summarize the current experimental results [7–9] together with the anticipated improvements at the LHC and the ILC with GigaZ option, see Refs. [1, 10–12] for details.

The mass of the top quark, $m_t$, is a fundamental parameter of the electroweak theory. It is by far the heaviest of all quark masses and it is also larger than the masses of all other known fundamental particles. It is evident that a comprehensive program of high-precision measurements at the top threshold will have to be a key element in the physics program of a future Linear Collider. The top quark is deeply connected to many other issues of high-energy physics:

- The top quark could play a special role in/for electroweak symmetry breaking.
- The experimental uncertainty of $m_t$ induces the largest parametric uncertainty in the prediction for electroweak precision observables [13] and can thus obscure new physics effects.

LCWS/ILC 2010
Table 1: Summary of the electroweak precision observables, including the top-quark mass, their current experimental central values and experimental errors, $\sigma \equiv \sigma^{\text{today}}$ [7–9]. Also shown are the anticipated experimental accuracies at the LHC, $\sigma^{\text{LHC}}$, and the ILC (including the GigaZ/MegaW options), $\sigma^{\text{ILC}}$. Each number represents the combined results of all detectors and channels at a given collider, taking into account correlated systematic uncertainties, see Refs. [1, 10–12] for details.

| observable | central exp. value | $\sigma \equiv \sigma^{\text{today}}$ | $\sigma^{\text{LHC}}$ | $\sigma^{\text{ILC}}$ |
|------------|--------------------|-------------------------------------|----------------------|----------------------|
| $M_W$ [GeV] | 80.399             | 0.023                               | 0.015                | 0.007                |
| $\sin^2 \theta_{\text{eff}}$ | 0.23153           | 0.00016                             | 0.00020–0.00014      | 0.000013             |
| $m_t$ [GeV] | 173.3              | 1.1                                 | 1.0                  | 0.1                  |

The current world average for the top-quark mass from the measurement at the Tevatron is $m_t = 173.3 \pm 1.1$ GeV [10]. The prospective accuracy at the LHC is $\delta m_t^{\text{exp}} = 1$ GeV [17], while at the ILC a very precise determination of $m_t$ with an accuracy of $\delta m_t^{\text{exp}} \lesssim 100$ MeV will be possible [18,19]. This error contains both the experimental error of the mass parameter extracted from the $t\bar{t}$ threshold measurements at the ILC and the envisaged theoretical uncertainty from its transition into a suitable short-distance mass (like the $\overline{\text{MS}}$ mass).

2 Top quark mass measurement at the ILC and its implications

In the following we show for some examples that in many physics applications the experimental error on $m_t$ achievable at the LHC would be the limiting factor, demonstrating the need for the ILC precision. More examples can be found in Ref. [13].
2.1 The top quark mass and electroweak precision observables

In order to confront the predictions of supersymmetry (SUSY) with the electroweak precision data and to derive constraints on the supersymmetric parameters, it is desirable to achieve the same level of accuracy for the SUSY predictions as for the SM. In Refs. [20, 21] an evaluation of $M_W$ and the $Z$-pole observables in the MSSM has been presented. It includes the full one-loop result (for the first time with the full complex phase dependence), all available MSSM two-loop corrections (entering via the $\rho$ parameter [22–24]), as well as the full SM results, see Refs. [20, 21] for details. The Higgs-boson sector has been implemented including higher-order corrections (as evaluated with FeynHiggs [25–28]).

In addition to the experimental uncertainties, summarized in Tab. 1, there are two sources of theoretical uncertainties: those from unknown higher-order corrections (“intrinsic” theoretical uncertainties), and those from experimental errors of the input parameters (“parametric” theoretical uncertainties). The current and estimated future intrinsic uncertainties within the SM are [10,29]

$$\Delta M_{W,\text{intr},\text{today}},\text{SM} \approx 4 \text{ MeV}, \quad \Delta \sin^2 \theta_{\text{eff},\text{intr},\text{today}},\text{SM} \approx 5 \times 10^{-5},$$

$$\Delta M_{W,\text{intr},\text{future}},\text{SM} \approx 2 \text{ MeV}, \quad \Delta \sin^2 \theta_{\text{eff},\text{intr},\text{future}},\text{SM} \approx 2 \times 10^{-5},$$

while in the MSSM the current intrinsic uncertainties are estimated to [1,23,24]

$$\Delta M_{W,\text{intr},\text{today,MSSM}} \approx (5 - 9) \text{ MeV}, \quad \Delta \sin^2 \theta_{\text{eff},\text{intr},\text{today,MSSM}} \approx (5 - 7) \times 10^{-5},$$

depending on the supersymmetric (SUSY) mass scale. In the future one expects that they can be brought down to the level of the SM, see Eq. (2).

The parametric errors of $M_W$ and $\sin^2 \theta_{\text{eff}}$ induced by the top quark mass, the uncertainty of $\Delta \alpha_{\text{had}}$ (we assume a future determination of $\delta (\Delta \alpha_{\text{had}}) = 5 \times 10^{-5}$ [30]) and the experimental uncertainty of the $Z$ boson mass, $\delta M_Z = 2.1$ MeV, are collected in Tab. 2

| $\delta m_t = 1 \text{ GeV}$ | $\delta m_t = 0.1 \text{ GeV}$ | $\delta (\Delta \alpha_{\text{had}})$ | $\delta M_Z$ |
|---------------------------|---------------------------|---------------------------|---------------------------|
| $\delta \sin^2 \theta_{\text{eff}} [10^{-5}]$ | 3 | 0.3 | 1.8 | 1.4 |
| $\Delta M_W [\text{MeV}]$ | 6 | 1 | 1 | 2.5 |

Table 2: Parametric errors on the prediction of $M_W$ and $\sin^2 \theta_{\text{eff}}$.

In order to keep the theoretical uncertainty induced by $m_t$ at a level comparable to or smaller than the other parametric and intrinsic uncertainties, $\delta m_t$ has to be of $O(0.1 \text{ GeV})$ in the case of $M_W$, and about 0.5 GeV in the case of $\sin^2 \theta_{\text{eff}}$. If the experimental error of $m_t$ remains substantially larger, it would constitute the limiting factor of the theoretical uncertainty. Using the EWPO to distinguish different models from each other or to determine indirectly the unknown model parameters, the ILC precision on $m_t$ is crucial, in particular in view of the precision measurement of $\sin^2 \theta_{\text{eff}}$ at GigaZ [13].

2.2 Top quark mass measurement and Higgs physics

Because of its large mass, the top quark is expected to have a large Yukawa coupling to Higgs bosons, being proportional to $m_t$. In each model where the Higgs boson mass is not

LCWS/ILC 2010
a free parameter but predicted in terms of the the other model parameters (as e.g. in the MSSM), the diagram in Fig. 1 contributes to the Higgs mass. This diagram gives rise to a leading $m_t$ contribution of the form

$$\Delta m_h^2 \sim G_F N_C C m_t^4,$$  

(4)

where $G_F$ is the Fermi constant, $N_C$ is the color factor, and the coefficient $C$ depends on the specific model. Thus the experimental error of $m_t$ necessarily leads to a parametric error in the Higgs boson mass evaluation.

![Figure 1: Loop contribution of the top quark to the Higgs boson mass.](image)

Taking the MSSM as a specific example (including also the scalar top contributions and the appropriate renormalization) $N_C C$ is given for the light $\mathcal{CP}$-even Higgs boson mass in leading logarithmic approximation by

$$N_C C = \frac{3}{\sqrt{2} \pi^2 \sin^2 \beta} \log \left( \frac{m_{\tilde{t}_1} m_{\tilde{t}_2}}{m_t^2} \right).$$  

(5)

Here $m_{\tilde{t}_1,2}$ denote the two masses of the scalar tops. The optimistic LHC precision of $\delta m_t = 1$ GeV leads to an uncertainty of $\sim 2.5\%$ in the prediction of $m_h$, while the ILC will yield a precision of $\sim 0.2\%$. These uncertainties have to be compared with the anticipated precision of the future Higgs boson mass measurements. With a precision of $\delta m_h^{\exp,LHC} \approx 0.2$ GeV [31, 32] the relative precision is at the level of $\sim 0.2\%$. It is apparent that only the ILC precision of $m_t$ will yield a parametric error small enough to allow a precise comparison of the Higgs boson mass prediction and its experimental value.

Another issue that has to be kept in mind here (in SUSY as in any other model predicting $m_h$) is the intrinsic theoretical uncertainty due to missing higher-order corrections. Within the MSSM currently this uncertainty is estimated to $\delta m_h^{\text{intr.,today}} \approx 3$ GeV [1, 27]. This uncertainty could go down by $\sim 1$ GeV once the recent three-loop corrections obtained in Ref. [33] will be included. In the future one can hope for an improvement down to $\lesssim 0.5$ GeV or better [1, 34], i.e. with sufficient effort on higher-order corrections it should be possible to reduce the intrinsic theoretical uncertainty to the level of $\delta m_h^{\exp,LHC}$.

Confronting the theoretical prediction of $m_h$ with a precise measurement of the Higgs boson mass constitutes a very sensitive test of the MSSM (or any other model that predicts $m_h$), which allows one to obtain constraints on the model parameters. However, the sensitivity of the $m_h$ measurement cannot directly be translated into a prospective indirect determination of a single model parameter. In a realistic situation the anticipated experimental errors of all relevant SUSY parameters have to be taken into account. For examples including these parametric errors see Refs. [13, 35].

---

1We are not aware of any such estimate in other New Physics models.
3 \( M_W \) and \( \sin^2 \theta_{\text{eff}} \) in a global MSSM scan

The effective weak mixing angle is determined from various asymmetries and other EWPO as shown in Fig. 2 [36]. The world average for the effective weak mixing angle is

\[
\delta \sin^2 \theta_{\text{eff}}^{\text{exp}} = 0.23153 \pm 0.00016 ,
\]

with a \( \chi^2 / \text{d.o.f} \) of 11.8/5, corresponding to a probability of 3.7% [7, 36]. The large \( \chi^2 \) is driven by the two single most precise measurements, \( A_{\text{FB}}^{b} \) by SLD and \( A_{\text{FB}}^{b} \) by LEP, corresponding to

\[
\begin{align*}
A_{\text{FB}}^{b}(\text{SLD}) : \sin^2 \theta_{\text{eff}}^{\text{exp}, \text{SLD}} &= 0.23098 \pm 0.00026 , \\
A_{\text{FB}}^{b}(\text{LEP}) : \sin^2 \theta_{\text{eff}}^{\text{exp}, \text{LEP}} &= 0.23221 \pm 0.00029 ,
\end{align*}
\]

The earlier (latter) one prefers a value of \( M_{H^{\text{SM}}} \sim 32(437) \text{ GeV} [37] \). The two measurements differ by more than 3 \( \sigma \). The averaged value of \( \sin^2 \theta_{\text{eff}} \), as shown in Fig. 2, prefers \( M_{H^{\text{SM}}} \sim 110 \text{ GeV} [37] \).

![Figure 2: Individual measurements and world-average of \( \sin^2 \theta_{\text{eff}} \). The experimental results are compared with the prediction within the SM as a function of \( M_{H^{\text{SM}}} \) for \( m_{t} = 170.9 \pm 1.8 \text{ GeV} \) and \( \Delta \alpha^{\text{had}}_{\text{pole}} = 0.02758 \pm 0.00035 \) [36].](image)

We now analyse the sensitivity of \( M_W \) and \( \sin^2 \theta_{\text{eff}} \) to higher-order effects in the MSSM by scanning over a broad range of the SUSY parameter space. The following SUSY parameters
are varied independently of each other in a random parameter scan within the given range:

- sleptons: \( M_{\tilde{e}, \tilde{\nu}} = 100 \ldots 2000 \text{ GeV} \),
- light squarks: \( M_{\tilde{u}, \tilde{d}, \tilde{\nu}} = 100 \ldots 2000 \text{ GeV} \),
- \( \tilde{t}/\tilde{b} \) doublet: \( M_{\tilde{t}, \tilde{b}} = 100 \ldots 2000 \text{ GeV} \), \( A_{\tau, t, b} = -2000 \ldots 2000 \text{ GeV} \),
- gauginos: \( M_{1, 2} = 100 \ldots 2000 \text{ GeV} \), \( m_{\tilde{g}} = 195 \ldots 1500 \text{ GeV} \), \( \mu = -2000 \ldots 2000 \text{ GeV} \),
- Higgs: \( M_A = 90 \ldots 1000 \text{ GeV} \), \( \tan \beta = 1.1 \ldots 60 \). (9)

Here \( M_{\tilde{e}, \tilde{\nu}} \) are the diagonal soft SUSY-breaking parameters in the sfermion sector, \( A_f \) denote the trilinear couplings, \( M_{1, 2} \) are the soft SUSY-breaking parameters in the chargino and neutralino sectors, \( m_{\tilde{g}} \) is the gluino mass, \( \mu \) the Higgs mixing parameter, \( M_A \) the CP-odd Higgs boson mass, and \( \tan \beta \) is the ratio of the two vacuum expectation values. Only the constraints on the MSSM parameter space from the LEP Higgs searches \([38, 39]\) and the lower bounds on the SUSY particle masses from direct searches as given in Ref. \([40]\) were taken into account. Apart from these constraints no other restrictions on the MSSM parameter space were made.

In Fig. 3, we compare the SM and the MSSM predictions for \( M_W \) and \( \sin^2 \theta_{\text{eff}} \) as obtained from the scatter data. The predictions within the two models give rise to two bands in the \( M_W-\sin^2 \theta_{\text{eff}} \) plane with only a relatively small overlap region (indicated by a dark-shaded (blue) area). The allowed parameter region in the SM (the medium-shaded (red) and dark-shaded (blue) bands) arises from varying the mass of the SM Higgs boson, from \( M_{H_{\text{SM}}} = 114 \text{ GeV} \), the LEP exclusion bound \([39]\) (lower edge of the dark-shaded (blue) area), and from varying \( m_t \) in the range of \( m_t = 165 \ldots 175 \text{ GeV} \). The light shaded (green) and the dark-shaded (blue) areas indicate allowed regions for the unconstrained MSSM. The decoupling limit with SUSY masses of \( \mathcal{O}(2 \text{ TeV}) \) yields the upper edge of the dark-shaded (blue) area. Thus, the overlap region between the predictions of the two models corresponds to the case where all superpartners are heavy, i.e., the decoupling region of the MSSM.

The experimental results for \( M_W \) and \( \sin^2 \theta_{\text{eff}} \) are indicated in the plot. The center ellipse corresponds to the current world average given in Eq. (6). Also shown are the error ellipses corresponding to the two individual main measurements of \( \sin^2 \theta_{\text{eff}} \) as given in Eqs. (7), (8). The anticipated improvement with the GigaZ/MegaW options, indicated as small ellipse, is shown around the current experimental central data. One can see that the current averaged value is compatible with the SM (favoring a light Higgs boson and a heavier top quark) and with the MSSM. The value of \( \sin^2 \theta_{\text{eff}} \) obtained from \( A_{\text{FB}}^{\text{SLD}} \) clearly favors the MSSM over the SM. On the other hand, the value of \( \sin^2 \theta_{\text{eff}} \) obtained from \( A_{\text{FB}}^{\text{LEP}} \) together with the \( M_W \) data from LEP and the Tevatron would correspond to an experimentally preferred region that deviates from the predictions of both models. Thus, the unclear experimental situation regarding the two single most precise measurements entering the combined value for \( \sin^2 \theta_{\text{eff}} \) has a significant impact on the constraints that can be obtained from this precision observable on possible New Physics scenarios. Measurements at a new \( e^+e^-Z \) factory, which could be realized in particular with the GigaZ option of the ILC, would be needed to resolve this issue. As indicated by the solid light shaded (red)
Figure 3: MSSM parameter scan for $M_W$ and $\sin^2 \theta_{\text{eff}}$ over the ranges given in Eq. (9) with $m_t = 165 \ldots 175$ GeV. Today’s 68% C.L. ellipses (from $A_{FB}^{\text{LEP}}$, $A_{LR}^{\text{SLD}}$ and the world average) are shown as well as the anticipated GigaZ/MegaW precisions, drawn around today’s central value.

The anticipated GigaZ/MegaW precision of the combined $M_W - \sin^2 \theta_{\text{eff}}$ measurement could put severe constraints on each of the models and resolve the discrepancy between the $A_{FB}^{\text{LEP}}$ and $A_{LR}^{\text{SLD}}$ measurements. If the central value of an improved measurement with higher precision should turn out to be close to the central value favored by the current measurement of $A_{FB}^{\text{LEP}}$, this would mean that the electroweak precision observables $M_W$ and $\sin^2 \theta_{\text{eff}}$ could rule out both the SM and the most general version of the MSSM.

4 Scenario where no SUSY particles are observed at the LHC

It is interesting to investigate whether the high accuracy achievable at the GigaZ option of the ILC would provide sensitivity to indirect effects of SUSY particles even in a scenario where the (strongly interacting) superpartners are so heavy that they escape detection at the LHC.

We consider in this context a scenario with very heavy squarks and a very heavy gluino.
Figure 4: Theoretical prediction for $\sin^2 \theta_{\text{eff}}$ in the SM and the MSSM (including prospective parametric theoretical uncertainties) compared to the experimental precision at the ILC with GigaZ option. An SPS1a’ inspired scenario is used, where the squark and gluino mass parameters are fixed to 6 times their SPS 1a’ values. The other mass parameters are varied with a common scalefactor.

It is based on the values of the SPS 1a’ benchmark scenario [41], but the squark and gluino mass parameters are fixed to 6 times their SPS 1a’ values. The other masses are scaled with a common scale factor except $M_A$ which we keep fixed at its SPS 1a’ value. In this scenario the strongly interacting particles are too heavy to be detected at the LHC, while, depending on the scale-factor, some color-neutral particles may be in the ILC reach. In Fig. 4 we show the prediction for $\sin^2 \theta_{\text{eff}}$ in this SPS 1a’ inspired scenario as a function of the lighter chargino mass, $m_{\tilde{\chi}^\pm_1}$. The prediction includes the parametric uncertainty, $\sigma_{\text{para-ILC}}$, induced by the ILC measurement of $m_t$, $\delta m_t = 100$ MeV [19], and the numerically more relevant prospective future uncertainty on $\Delta \alpha_{\text{had}}^{(5)}$, $\delta(\Delta \alpha_{\text{had}}^{(5)}) = 5 \times 10^{-5}$ [30]. The MSSM prediction for $\sin^2 \theta_{\text{eff}}$ is compared with the experimental resolution with GigaZ precision, $\sigma_{\text{ILC}} = 0.000013$, using for simplicity the current experimental central value. The SM prediction (with $M_{H_{\text{SM}}} = M_{h_{\text{MSSM}}}$) is also shown, applying again the parametric uncertainty $\sigma_{\text{para-ILC}}$.

Despite the fact that no colored SUSY particles would be observed at the LHC in this scenario, the ILC with its high-precision measurement of $\sin^2 \theta_{\text{eff}}$ in the GigaZ mode could resolve indirect effects of SUSY up to $m_{\tilde{\chi}^\pm} \lesssim 500$ GeV. This means that the high-precision measurements at the ILC with GigaZ option could be sensitive to indirect effects of SUSY even in a scenario where SUSY particles have neither been directly detected at the LHC nor the first phase of the ILC with a centre of mass energy of up to 500 GeV.

LCWS/ILC 2010
5 Conclusions

EWPO provide a very powerful test of the SM and the MSSM. We have reviewed results for $M_W$ and $\sin^2 \theta_{\text{eff}}$. The sensitivity to higher-order effects will drastically improve with the ILC precision (including the GigaZ/MegaW options) on the EWPO and $m_t$. This has been illustrated in three examples. A precise $m_t$ determination is crucial.

A general scan over the MSSM parameter space for $\sin^2 \theta_{\text{eff}}$ and $m_t$ currently does not prefer the SM or the MSSM over the other. However, the anticipated GigaZ precision indicates the high potential for a significant improvement of the sensitivity of the electroweak precision tests. In a second example we have assumed a scenario with very heavy SUSY particles, outside the reach of the LHC and the first stage of the ILC with $\sqrt{s} = 500$ GeV. It has been shown that even in such a scenario the GigaZ precision on $\sin^2 \theta_{\text{eff}}$ may resolve virtual effects of SUSY particles, providing a possible hint to the existence of new physics.
