Closing the window on fuzzy dark matter with the 21cm signal

Jordan Flitter$^1$, $^*$ and Ely D. Kovetz$^1$

$^1$Physics Department, Ben-Gurion University of the Negev, Beer-Sheva 84105, Israel

Fuzzy dark matter (FDM) is a well motivated candidate for dark matter (DM) as its tiny mass and large de-Broglie wavelength suppress small-scale matter fluctuations, thereby solving some of the small-scale discrepancies in ΛCDM. Although it has been ruled out as the single component of DM by several observables, there is still a region in the FDM parameter space (the “FDM window”), $10^{-25}$ eV $\lesssim m_{\text{FDM}} \lesssim 10^{-23}$ eV where FDM is allowed to comprise a large portion of the total DM. In this work, for the first time, we study the signature of FDM (comprised of ultra-light axions) in fractions less than unity on the 21cm signal and its detectability by 21cm interferometers such as HERA, taking into account the degeneracy with both astrophysical and cosmological parameters, using a new pipeline that combines modified versions of the CAMB and 21cmFAST codes. Our forecasts imply that HERA in its design performance will be sensitive to FDM fractions as small as 1% in the FDM window, and improve over existing bounds for other masses by up to an order of magnitude.

I. INTRODUCTION

One of the most studied models of DM is ultra-light axions [1–29], also known in the literature as fuzzy dark matter (FDM) in the mass range $10^{-27}$ eV $\lesssim m_{\text{FDM}} \lesssim 10^{-20}$ eV. FDM became an intriguing candidate for DM as it was shown to ameliorate several problems in cosmology [30], such as the core-cusp problem, the missing satellites problem and the too-big-to-fail problem$^1$, if the FDM component comprises a meaningful fraction of the total DM. Recently, Ref. [32] proposed that $\mathcal{O} (10\%)$ of DM in the form of FDM with particle mass in the window $m_{\text{FDM}} \approx 10^{-25}$ eV could explain the tension between inferences of $H_0$, the current expansion rate of the Universe, which are based on the time-delay in lensed quasar measurements, and those based on CMB observations. Moreover, a fraction $\sim 10\%$ of FDM was suggested to explain the suppressed amplitude of the matter power spectrum at late times (a.k.a. the $\sigma_8/S_8$ tension) [33–35].

The key physical property of FDM that impacts the aforementioned observables is that its tiny mass corresponds to an astronomically-large de-Broglie wavelength of $\mathcal{O} (1 \text{kpc})$. As a result, quantum pressure is exerted on the DM fluid which suppresses small scale fluctuations [8, 36]. The smaller the FDM mass, the less power to be found on small scales.

The small-scale signature of FDM has been well studied in the literature. Refs. [7, 34] obtained constraints on the FDM fraction from CMB and large scale structure (LSS) measurements. They concluded that if FDM exists in the mass range $10^{-32}$ eV $\lesssim m_{\text{FDM}} \lesssim 10^{-26}$ eV it can only comprise a few percent of the total DM in the Universe. For higher values of $m_{\text{FDM}}$, the bound becomes weaker because the FDM power suppression becomes less efficient, while for smaller values of $m_{\text{FDM}}$ the FDM behaves as dark energy (DE) and is strongly degenerate with $\Omega_\Lambda$. Another constraint on FDM was obtained from Lyα-forest data, indicating that DM cannot be fully described by FDM with mass of $10^{-21}$ eV $\lesssim m_{\text{FDM}} \lesssim 2 \times 10^{-20}$ eV [37–39], while FDM with mass of $10^{-22}$ eV $\lesssim m_{\text{FDM}} \lesssim 10^{-21}$ eV must not comprise more than $\mathcal{O} (10\%)$ of the total DM [40]. Furthermore, the reionization history of our Universe, inferred from the UV-luminosity function and optical depth to reionization, excludes DM models where the FDM fraction is 50% or higher for $m_{\text{FDM}}$ down to $10^{-23}$ eV [41]. Finally, data from the Dark Energy Survey year 1 (DES-Y1) [42] was used to search for shear-correlation suppression caused by FDM, ruling out the existence of FDM in the mass range $10^{-25}$ eV $\lesssim m_{\text{FDM}} \lesssim 10^{-23}$ eV, if DM is entirely made by FDM [43]. However, current constraints suggest that it is possible for FDM to exist in large portions in the region $10^{-25}$ eV $\lesssim m_{\text{FDM}} \lesssim 10^{-23}$ eV (referred to below as the FDM window), as can be seen in Fig. 1.

In this work we explore in detail the signature of FDM on the 21cm signal. Previous works [50–53] have demonstrated the delaying effect of FDM on the 21cm signal due to impeding structure formation, but have all assumed an FDM fraction of unity, an assumption that is relaxed in this work. Unlike Refs. [36, 52], which evolved the FDM evolution equations in the fluid approximation starting from matter-radiation equality (MRE) or even at recombination, we start evolving the FDM field equation before MRE to yield consistent initial conditions for the 21cm signal simulation. We apply our analysis to the Hydrogen Epoch of Reionization Array (HERA) [54] and Ely D. Kovetz

$^1$ See Ref. [51] and references therein for a review of these problems.
signal and the underlying physics of FDM. In Section III we describe how we simulate the 21cm signal in an FDM universe, and show the impact of different FDM parameters on the 21cm signal as well as their degeneracies. We discuss our forecasts in Section IV and conclude in Section V.

II. FORMALISM

The origin of the 21cm signal is the 21cm-wavelength photon that is emitted whenever a hydrogen atom undergoes the hyperfine transition from the triplet state (where the spins of the electron and proton are aligned) to the singlet state (where the spins are anti-aligned) [56–58]. Between recombination and reionization, the Universe was permeated with neutral hydrogen atoms that could get excited to the triplet state through absorption of CMB photons, collisions between the gas particles, and Lyα pumping (Wouthuysen-Field effect [59, 60]) as a result of the radiation from the first generations of stars.

The cosmological 21cm signal is manifested as a brightness temperature,

\[ T_{21} = T_s - T_{\text{rad}} \left( \frac{1}{1+z} \right) \left( 1 - e^{-\tau_{21}} \right), \]  

where \( T_{\text{rad}} \) is usually assumed to be the CMB temperature, \( T_{\text{CMB}} \propto (1+z) \), and \( \tau_{21} \) is the 21cm optical depth. The quantity \( T_s \) is known as the spin temperature, and is defined by the ratio between the number densities of hydrogen atoms in the triplet and singlet states, \( n_1/n_0 = 3 \exp \left( -\frac{h\nu_{21}}{k_B T_s} \right) \), where \( h \) and \( k_B \) are the Planck and Boltzmann constants, and \( \nu_{21} \approx 1420 \text{ MHz} \) is the frequency of the 21cm photon. In thermal equilibrium, the spin temperature is given by [53]

\[ T_s^{-1} = \frac{x_{\text{rad}} T_{\text{rad}}^{-1} + x_c T_c^{-1} + x_{\alpha} T_{\alpha}^{-1}}{x_{\text{rad}} + x_c + x_{\alpha}}, \]  

where \( T_k \) is the gas kinetic temperature, \( T_c \approx T_k \) is the effective color temperature of the Lyα photons, and \( x_{\text{rad}}, x_c \) and \( x_{\alpha} \) are the radiation, collision, and Lyα coupling coefficients, respectively.

Because \( x_{\alpha} \) is proportional to the Lyα flux \( J_\alpha \) [61], and \( J_\alpha \) is in turn proportional to the integrated value of the star formation rate (SFR), the onset of cosmic dawn can be identified as the moment when \( x_{\alpha} \) is dominant. At that time, the spin temperature closely follows \( T_k \), and because the gas cools adiabatically, i.e. faster than the CMB, we expect to see an absorption signal in the brightness temperature. For \( \Lambda \text{CDM} \), the location of the minimum of \( T_{21} \) strongly depends on the assumed astrophysical model, but is expected to be found at \( 10 \lesssim z \lesssim 20 \).

However, the minimum of the global 21cm signal can shift towards smaller redshifts if the Universe contains
large portions of FDM. The FDM particle is the excited state of the scalar field $\phi$ which obeys the Klein-Gordon equation, $(\Box - m_{\text{FDM}}^2) \phi = 0$ \cite{7, 8, 26, 30, 36}. Initially, the field slowly rolls down its potential when $m_{\text{FDM}} \ll H$ and behaves as DE with equation of state $w = -1$, where $H$ is the Hubble parameter. However, as $m_{\text{FDM}} \sim 3H$, the field begins to oscillate and its energy density dilutes as for matter, $\rho_{\text{FDM}} \propto a^{-3}$, where $a$ is the scale factor of the Universe \cite{7, 8}. If the mass of the field is $m_{\text{FDM}} \gtrsim 10^{-28} \text{eV}$ (which we assume throughout this work), the oscillation phase of the field starts well before MRE, and the field can be characterized as matter throughout its evolution. In that case, the impact of the FDM field on the Boltzmann equation for the dark matter fluid comes in the form of new terms that are proportional to $c_{s,a}^2$, where $c_{s,a}$ is the FDM (or axion) sound speed, and is given by\(^2\) \cite{7}

$$c_{s,a}^2 = \frac{k^2/(4m_{\text{FDM}}^2 a^2)}{1 + k^2/(4m_{\text{FDM}}^2 a^2)}.$$  

Thus, while for large scales ($k \ll 2m_{\text{FDM}} a$) the evolution of the matter-density fluctuations remains the same as in ΛCDM, small-scale fluctuations ($k \gg 2m_{\text{FDM}} a$) in an FDM universe are washed out. Ref. \cite{30} found that the scale at which the matter power spectrum drops by a factor of 2 is $k_{1/2} \approx 4.5 (m_{\text{FDM}}/10^{-22} \text{eV})^{1/3} \text{Mpc}^{-1}$, so smaller $m_{\text{FDM}}$ implies less power, and therefore structure formation is impeded along with the SFR, consequently leading to a shift of the minimum of the 21cm signal towards smaller redshifts. This behavior was demonstrated in Refs. \cite{50–53} where FDM was assumed to comprise the entirety of DM in the Universe. Yet, if FDM makes up only a small fraction of the total DM, its signature in the 21 cm cosmic dawn signal might be completely lost.

### III. SIMULATION

We simulate the effect of the FDM mass, $m_{\text{FDM}}$, and fraction, $f_{\text{FDM}} = \Omega_{\text{FDM}}/\Omega_{\text{DM}}$, on the matter transfer function with AxionCAMB\(^3\) \cite{7}, a modified version of CAMB \cite{62} which takes into account the impact of the FDM on the Boltzmann equations even before MRE. We then study the 21 cm signal in an FDM universe by feeding the matter transfer function obtained with AxionCAMB into 21cmFast\(^4\) version 3.1.3 \cite{63}. In this version, the Lyman-Werner (LW) feedback \cite{64, 65} as well as the relative velocity between baryons and DM ($v_{cb}$) \cite{66, 67} are taken into account in each voxel. As these effects suppress structure formation on small scales, they delay cosmic dawn, much like FDM. In addition, version 3.1.3 of 21cmFast separates the pop-II and pop-III stars into atomic and molecular cooling galaxies (MCGs), respectively. We have also modified 21cmFast and incorporated the Ly$\alpha$ heating mechanism \cite{53, 68, 69}.

Our fiducial values for the cosmological parameters were taken from Planck 2018 \cite{70} while the fiducial values for the astrophysical parameters were taken from Table 1 (EOS2021) of Ref. \cite{63}, except we set $L_X^{(II)} = L_X^{(III)} = 39$ to compensate for the extra heating caused by Ly$\alpha$ heating (see description of the free parameters in our analysis below Eq. 6). In our simulations, we use a box size of 200 Mpc and resolution of 1/3 Mpc. This is a fairly small box, but its high resolution allowed us to better probe the fluctuations on small scales, which are the ones most affected by FDM. Nevertheless, we have confirmed that our results are insensitive to the simulation box size.

#### A. The 21 cm global signal

We demonstrate in Fig. 2 (top panel) how the 21 cm global signal is affected by FDM with varying $m_{\text{FDM}}$ and $f_{\text{FDM}} = 3\%$, 10\%. As expected, the absorption signal shifts to smaller redshifts as we decrease the FDM particle mass. Evidently, the delaying effect of FDM is more pronounced as its fraction is greater, but the dependence of the brightness temperature on $f_{\text{FDM}}$ only becomes evident at small $m_{\text{FDM}}$. Naturally, the information encoded in the power spectrum dwarfs that in the global signal and allows to break degeneracies with competing effects \cite{53}.

#### B. The 21 cm power spectrum

Our goal is to examine what is the lowest $f_{\text{FDM}}$ that 21 cm interferometers such as HERA will be able to probe. In order to answer that question, we use the powerbox\(^5\) module \cite{71} to compute the 21 cm power spectrum from the lightcone box produced by 21cmFast,

$$\Delta_{21}^2(k,z) = \frac{k^3P_{21}(k,z)}{2\pi^2},$$  

where $P_{21}(k,z) = \langle \tilde{T}_{21}(\hat{k},z)\tilde{T}_{21}^*(\hat{k},z)\rangle$, and $\tilde{T}_{21}(\hat{k},z)$ is the Fourier transform of $T_{21}(\vec{x},z) - \langle T_{21}(\vec{x},z) \rangle$.

In the bottom of Fig. 2 we show $\Delta_{21}^2(z)$ for $k = 0.2 \text{Mpc}^{-1}$. As a zero order approximation, we see from Eq. (4) that $\Delta_{21}^2(z) \propto (T_{21}(z))^2$. In other words, we expect the 21 cm power spectrum to follow the global signal. This feature is evident in Fig. 2, and in particular we can see that the power spectrum is also delayed by FDM. However, there are some exceptions — for example, the amplitude of the global signal for $m_{\text{FDM}} = 10^{-22} \text{eV}$ is greater than the amplitude for $m_{\text{FDM}} = 10^{-24} \text{eV}$, but

\(^2\) In natural units where $c = \hbar = 1$.

\(^4\) \url{github.com/21cmfast/21cmFAST}

\(^5\) \url{github.com/steven-murray/powerbox}
FIG. 2. Top panel: the 21cm global signal for several FDM masses. Solid (dashed) curves correspond to fractions $f_{\text{FDM}} = 10\%$ ($3\%$). Bottom panel: the 21cm power spectrum at $k = 0.2\text{Mpc}^{-1}$. The error bars correspond to the noise of full HERA, calculated with 21cmSense for moderate foregrounds scenario (see Section III C), while the shaded region corresponds to redshifts where the noise surpasses the signal, $\delta \Delta_{21}^2 > \Delta_{21}^2$. For this foregrounds scenario, HERA can detect the signal with a finite uncertainty (i.e. beyond the horizon wedge) at scales between $0.1 \lesssim k \lesssim 0.6\text{Mpc}^{-1}$, where the noise mildly increases as $k$ increases.

the power spectrum of the former reaches to smaller values compared to the latter. Moreover, on large scales $\Delta_{21}^2 (z)$ exhibits additional features [53]. Regardless, to understand our forecasts the approximation $\Delta_{21}^2 (z) \propto (T_{21} (z))^2$ is still useful.

C. Degeneracies

To calculate the uncertainty in the measurement of $\Delta_{21}^2 (k, z)$ (which we denote by $\delta \Delta_{21}^2 (k, z)$), we use 21cmSense$^6$ [72, 73] and simulate HERA at its design performance (full HERA). We use the built-in configuration of a hexagonal array with 11 antennae at its base (311 antennae overall), each of which has a diameter of 14 m, and we assume a receiver temperature of $T_{\text{rec}} = 100\text{K}$. The frequency range for HERA is taken to be $50 - 225\text{MHz}$ and we divide the corresponding redshift range into 15 bins. We assume that HERA operates six hours per night for three years with bandwidth 8 MHz, and we assume the sky temperature obeys $T_{\text{sky}} (\nu) = 60\text{K} (\nu/300\text{MHz})^{-2.55}$. We also assume in our analysis the moderate (pessimistic) foregrounds scenario in which the wedge is assumed to extend to $\Delta k = 0.1\text{hMpc}^{-1}$ beyond the horizon wedge limit, and all baselines are added coherently (incoherently).

We perform a Fisher analysis and calculate the Fisher matrix according to [74–77]

$$F_{\alpha,\beta} = \sum_{k,z} \frac{\partial \Delta_{21}^2 (k, z)}{\partial \alpha} \frac{\partial \Delta_{21}^2 (k, z)}{\partial \beta} \frac{1}{[\delta \Delta_{21}^2 (k, z)]^2},$$

where $\alpha$ and $\beta$ represent the varied parameters of the model. In our analysis, they are

$$(\alpha, \beta) \in \{h, \Omega_m, \Omega_b, A_s, \log_{10} m_{\text{FDM}}, \log_{10} f_{\text{FDM}}, \log_{10} L_X^{(\text{II})}, \log_{10} f_s^{(\text{II})}, \log_{10} f_{\text{esc}}^{(\text{II})}, A_{\text{LW}}, A_{\text{cb}} \},$$

where $h$ is Hubble’s constant, $\Omega_m$ ($\Omega_b$) is the matter (baryons) density parameter, $A_s$ is the primordial curvature fluctuation amplitude, $L_X^{(\text{II})}$ is the X-ray luminosity of pop-II stars (normalized by the SFR, in units of erg s$^{-1}$ M$^{-1}$ yr$^{-1}$), $f_s^{(\text{II})}$ is the pop-II star formation efficiency, $f_{\text{esc}}^{(\text{II})}$ is the fraction of photons that were produced by pop-II stars and managed to escape the host galaxy and ionize the inter-galactic medium, and $A_{\text{LW}}$ ($A_{\text{cb}}$) is the amplitude of the LW feedback ($v_{\text{cb}}$) on the minimum MCG mass that can still host stars$^7$. We note that $m_{\text{FDM}}$ in Eq. (6) is given in units of eV. Plus, we note that whenever an astrophysical pop-II parameter is varied in our analysis, the corresponding pop-III parameter is varied as well.

The sensitivity of HERA to FDM depends on the degeneracies between the FDM parameters and other cosmological/astrophysical parameters that shape the 21cm signal. Once we have the Fisher matrix at our disposal, we can study these degeneracies, as we do in Fig. 3

---

$^6$ github.com/steven-murray/21cmSense

$^7$ See more details on the exact definitions of the astrophysical parameters of Eq. (6) in Ref. [63].
FIG. 3. Degeneracies of the FDM parameters, for $f_{\text{FDM}} = 1\%$. The ellipses correspond to 1-$\sigma$ and 2-$\sigma$ confidence levels. Here, we take no priors and marginalize over the rest of the parameters in Eq. (6).

(to clearly see the degeneracies, we do not impose any priors at this stage). We can clearly see how the degeneracies change as $m_{\text{FDM}}$ is varied. At large masses ($m_{\text{FDM}} \gtrsim 10^{-22}$ eV) $m_{\text{FDM}}$ and $f_{\text{FDM}}$ are positively correlated, while at small masses ($m_{\text{FDM}} \lesssim 10^{-27}$ eV) they exhibit negative correlation. This feature is due to the unique properties of the FDM at the extreme sides of the mass spectrum. At the large mass regime, smaller $m_{\text{FDM}}$ tends to delay cosmic dawn. On the other end, if $m_{\text{FDM}} \lesssim 10^{-27}$ eV, the field $\phi$ is on the verge of being DE-like [7] and contributes to the DE energy budget, so reducing $m_{\text{FDM}}$ while lowering the value of $\Omega_\Lambda$ to maintain the flatness of the Universe) yields greater power at all scales, shifting cosmic dawn to earlier redshifts. However, in both $m_{\text{FDM}}$ regimes, smaller $f_{\text{FDM}}$ impacts the cosmic dawn in the same manner, by shifting it to higher redshifts. Another strong degeneracy between $A_s$ and $f_{\text{FDM}}$ can be seen in the small $m_{\text{FDM}}$ regime, where increasing $f_{\text{FDM}}$ is equivalent to reducing $A_s$. Although $A_{\text{LW}}$ and $A_{\text{vcb}}$ impose a delaying effect on the 21cm signal [53, 78], similarly to FDM, we find that their degeneracy with the FDM parameters is not significant.

IV. FORECASTS

In order to derive the sensitivity of HERA to FDM, we now add priors on the cosmological parameters from Planck 2018 [70], take the inverse matrix, and find the 1-$\sigma$ uncertainty of $f_{\text{FDM}}$, $\sigma(f_{\text{FDM}})$, by marginalizing over the rest of the parameters of Eq. (6). For each $m_{\text{FDM}}$ we simulate, we repeat the above process for several values of $f_{\text{FDM}}$, and solve for $f_{\text{FDM}} = 2\sigma(f_{\text{FDM}})$ to find the 2-$\sigma$ forecasts. We show our results in Fig. 1 with respect to the moderate foreground scenario (solid curve).

As expected, for large $m_{\text{FDM}}$ the sensitivity of HERA monotonically increases as the mass of the FDM decreases. This is because small $m_{\text{FDM}}$ implies greater suppression in the matter power spectrum, which causes additional delay in the global signal as we demonstrated in Fig. 2. Since the observable, $\Delta^2_{21}$, is roughly proportional to the square of the global signal, the 21cm power spectrum exhibits the same delaying feature. The suppression/delaying effect of FDM becomes more pronounced as its mass further decreases, rendering it more detectable. Moreover, as the 21cm signal gets pushed to smaller redshifts (by decreasing $m_{\text{FDM}}$ accordingly), the sensitivity of HERA improves. For $m_{\text{FDM}} = 10^{-24}$ eV, HERA is still sensitive to FDM with a fraction of $f_{\text{FDM}} \sim O(1\%)$. For such a small fraction, even when $m_{\text{FDM}}$ keeps decreasing, the impact of the FDM on the 21cm signal saturates, which is the reason for the plateau in Fig. 1. At $m_{\text{FDM}} \lesssim 10^{-27}$ eV, as was discussed earlier, this is the regime where the field $\phi$ is DE-like and an upward trend in our forecasts can be seen. In this regime, for a given fraction, as $m_{\text{FDM}}$ decreases the field $\phi$ behaves more similarly to DE, and thus for a given set of cosmological parameters the matter power spectrum approaches the $\Lambda$CDM prediction, making FDM (or more precisely at this regime, the axions) less detectable.

V. CONCLUSIONS

In this work we have simulated the 21cm signal in universes where FDM comprises only a fraction of the total DM. Motivated by the large delaying effect that FDM imposes on the 21cm signal, even at small fractions, we simulated the sensitivity of HERA to FDM. Our results
indicate that HERA can yield constraints on FDM which are nearly twice tighter than current CMB +LSS bounds (for $m_{\text{FDM}} \lesssim 10^{-26}$ eV) and are competitive with CMB-S4 forecasts [49], and constraints that are stronger by an order of magnitude than current Ly-forest bounds (for $m_{\text{FDM}} \gtrsim 10^{-23}$ eV). In the poorly constrained \textit{FDM window}, $10^{-25}$ eV $\lesssim m_{\text{FDM}} \lesssim 10^{-24}$ eV, we forecast that HERA will be sensitive to $f_{\text{FDM}} \gtrsim \mathcal{O}(1\%)$. We note that our forecasts are robust to changes in the fiducial values of the astrophysical parameters\(^8\), or considering a pessimistic foreground scenario.

With these results, we could not resist the temptation of deriving the potential constraining power of HERA in its early stage (\textit{early HERA}). Following Ref. [79], we modelled early HERA as a hexagon core with seven antennae at its base (127 antennae overall) and assumed a total operation time of one year. We also limited the frequency range to 100–200MHz and used only four redshift bins, centered at $z = 7.5, 8.3, 9.3, 10.1$. All the other specifications remain the same. With these settings, we recalculated the forecasts and plotted them as a dashed curve in Fig. 1. The constraining power of early HERA is degraded by an order of magnitude compared to the constraining power of full HERA, but the results are still impressive nonetheless. Provided there are no significant systematics [80–83], we find that early HERA is able to detect FDM in a wide range of masses, including the \textit{FDM window}, if $f_{\text{FDM}} \gtrsim \mathcal{O}(1\%)$.

In our analysis, we have adopted the phenomenological astrophysical model of Refs. [63, 84]. According to this model, the star formation efficiencies are redshift independent and assumed to be a power-law in halo mass. This is the standard model of 21cmFast version 3.1.3, although photo-heating and reionization feedbacks at $z \lesssim 7$ seem to lower both the amplitude of the star formation efficiency and the power-law index at small halos [85, 86], thus rendering the SFR to have more complicated time dependence than implemented in 21cmFast. We leave the study of advanced time dependent star formation efficiency models (along with studying degeneracies of the FDM parameters with additional astrophysical parameters) for future work.

Our main conclusion is that in the near future HERA could discover evidence for FDM in the form of ultralight axions with unrivaled sensitivity in the \textit{FDM window}. This demonstrates the crucial role that 21cm interferometers will have in unveiling the fundamental properties of some (if not all) the dark matter in our Universe.

\section*{Acknowledgments}

We thank Debanjan Sarkar for reviewing our implementation of the Ly\(\alpha\) heating in 21cmFast version 3.1.3. We would like to thank David Marsh, Selim Hotinli and Edoardo Vitagliano for useful discussions. We would like also to thank the anonymous referees for their comments that helped to improve the quality of the paper. JF is supported by the Zin fellowship awarded by the BGU Kreitmann School. \footnote{We have recalculated the forecasts for a fiducial case where $L_X^{(11)}$ and $I_\nu^{(31)}$ are stronger by an order of magnitude. For $\Lambda$CDM, this leads to an absorption signal at $z \approx 17$ and a later emission feature which is absent in Fig. 2. For the masses we have tested, the deviation in the forecasts was no more than a few percent.}
