Compress the curve: a cross-sectional study of variations in COVID-19 infections across California nursing homes

Ram Gopal 1, Xu Han 2, Niam Yaraghi 3,4

ABSTRACT

Objective Nursing homes’ residents and staff constitute the largest proportion of the fatalities associated with COVID-19 epidemic. Although there is a significant variation in COVID-19 outbreaks among the US nursing homes, we still do not know why such outbreaks are larger and more likely in some nursing homes than others. This research aims to understand why some nursing homes are more susceptible to larger COVID-19 outbreaks.

Design Observational study of all nursing homes in the state of California until 1 May 2020.

Setting The state of California.

Participants 713 long-term care facilities in the state of California that participate in public reporting of COVID-19 infections as of 1 May 2020 and their infections data could be matched with data on ratings and governance features of nursing homes provided by Centers for Medicare & Medicaid Services (CMS).

Main outcome measure The number of reported COVID-19 infections among staff and residents.

Results Study sample included 713 nursing homes. The size of outbreaks among residents in for-profit nursing homes is 12.7 times larger than their non-profit counterparts (log count=-2.54; 95% CI, 1.97 to 3.11; p<0.001). Higher ratings in CMS-reported health inspections are associated with lower number of infections among both staff (log count=-0.19; 95% CI, -0.37 to -0.01; p=0.05) and residents (log count=-0.20; 95% CI, -0.27 to -0.14; p<0.001). Nursing homes with higher discrepancy between their CMS-reported and self-reported ratings have higher number of infections among their staff (log count=-0.41; 95% CI, 0.31 to 0.51; p<0.001) and residents (log count=0.13; 95% CI, 0.08 to 0.18; p<0.001).

Conclusions The size of COVID-19 outbreaks in nursing homes is associated with their ratings and governance features. To prepare for the possible next waves of COVID-19 epidemic, policy makers should use these insights to identify the nursing homes who are more likely to experience large outbreaks.

INTRODUCTION

Nursing homes have been most severely impacted by the COVID-19 pandemic owing to the advanced age and high number of comorbidities of their residents. In Europe, as much as 57% of all deaths related to COVID-19 were at such facilities. In the USA, nursing homes’ residents and staff account for 34% of all COVID-19 fatalities. Infection prevention and control at nursing homes and long-term facilities has therefore become a priority in managing the epidemic.

Given the considerable variation in the prevalence and size of the COVID-19 outbreaks at nursing homes, the objective of this research is (1) to understand why some nursing homes are more susceptible to COVID-19 outbreaks, and (2) to develop predictive models that can identify such nursing homes so that they could be prioritised in efforts to prevent and contain next waves of the epidemic.

METHODS

Patient and public involvement

Patients had no influence on the research questions or outcomes of this research. No patients were involved in the design of this study. We used blind patient files; therefore, no patient recruitment took place. We only used data on the aggregated number of patients with COVID-19 and staff in the nursing homes as reported by the state of California and therefore no personal information of patients was used in this study. Given the
nature of removing all personal information, there is no requirement to disseminate the information to patients.

Data sources and study variables
We collected data from various publicly available sources. The New York Times aggregates and provides data on COVID-19 cases per county. California Department of Public Health (CDPH) provides data on the number of confirmed COVID-19 infections among staff and residents of nursing homes in the state. Centers for Medicare & Medicaid services (CMS) provides data on nursing home characteristics, including their self-reported ratings and CMS health inspections. A description of this data is provided in the next section. Applying the methods suggested by Han et al., we identified the nursing homes with significant discrepancies between their self-reported measures and independent CMS inspections for a consecutive 5-year period. We aggregated the results and used the number of years a nursing home is predicted to be a likely inflator as the overall inflation score for a nursing home. Therefore, an honest nursing home will have an inflation score of 0 while an inflating nursing home can have an inflation score between 1 and 5, with 5 being the most severe. In our dataset, 19.25% of nursing homes were inflating their scores and some of these had a score of 5 indicating that they inflated their scores in all 5 years.

These methods rely on data that are only available for nursing homes in California and therefore, the scope of this study is also limited to nursing homes in California. After cleaning and merging the abovementioned data sources, we analysed a final dataset consisting of 713 nursing homes in California. Details of the data cleaning and merging process are presented in online supplemental appendix 1.

We examined the following outcomes in this study: whether a nursing home has at least one COVID-19 infection among its residents or staff, the number of confirmed COVID-19 infections among its residents and the number of confirmed infections among its staff. We also calculated a fourth outcome that indicates the large outbreaks as the ones in which more than 10 members of staff or residents were infected with COVID-19. This threshold translates to approximately 95th percentile of the number of infected staff. Given that more residents are infected than staff, this threshold translates to 75th percentile of the number of residents.

The independent variables describe the severity of the COVID-19 outbreak in the surrounding area of a nursing home, its governance characteristics, as well as its ratings on quality, staffing and CMS inspections. Table 1 provides detailed description of the study variables. Note that while almost all nursing homes have resident councils, only 20% of nursing homes have existing family councils. We included the existence of family council as a binary variable in our analysis with the contention that it may imply closer coordination and higher engagement with the families of the residents.

Description of CMS' nursing home compare system
The CMS nursing home rating data consist of basic information about nursing facilities such as name, address, phone number and so on, as well as some key features used in our analysis, such as the number of certified beds, whether the nursing home is for-profit or non-profit, whether the nursing home has a family council and so on.

The CMS nursing home rating data serve the CMS nursing home compare system, in which nursing home ratings are generated based on three domains: inspection, staffing and quality measures. The inspection is conducted and reported by CMS-certified inspectors annually. The other two domains are self-reported by nursing homes. The annual inspection investigates areas such as medication management, nursing home administration, environment, food service and residents’ rights and quality of life. The staffing domain is evaluated based on the self-reported CMS Certification and Survey Provider Enhanced Reports staffing data. The two measures used are the total nursing hours and registered nursing hours and are adjusted for case-mix based on the resource utility group case-mix system derived from the minimum data set. The staffing star rating is then updated by the end of the quarter when raw data are collected. Note that with more recent changes, the staffing data reported by nursing homes are subject to validation with nursing homes’ payroll data reported through payroll-based journal. The quality measure rating uses quality measurement criteria, which covers both long-stay terms and short-stay terms. The quality measure star rating is updated by the end of each quarter by using the results from three most recent quarters.

To calculate the star ratings, CMS first assigns an initial star rating to all nursing homes based on their annual inspection results. Nursing homes are then assigned star ratings for the staffing and quality measures domains. The overall star rating is then calculated by considering the inspection rating as the baseline, increasing or decreasing by one star if any self-reported domain satisfies the conditions as follows. Both 4 and 5 stars in staffing rating are qualified for obtaining additional overall star rating, while only 5 stars in quality measure is qualified. Additional conditions apply to nursing homes whose inspection ratings are only 1 star, and for nursing homes which are in the CMS’s special focus facility programme. The overall star rating is lowered by one star if any self-reported domain is 1 star. The overall star rating cannot be more than 5 stars or less than 1 star. Detailed data from CMS on nursing homes are available online.

Statistical analysis
To answer the first research question and understand why some nursing homes are more susceptible to COVID-19 outbreaks, we applied Zero Inflated Bivariate Poisson (ZIBP) regression. The model allows us to examine the effects of nursing homes’ ratings, governance features and their surroundings on the likelihood and size of their COVID-19 outbreaks. Econometric details of the model
### Table 1 Sources and descriptions of the study variables

| Variable                  | Description                                                                 | Source                          | Mean  | SD   | Min  | Max  |
|---------------------------|------------------------------------------------------------------------------|---------------------------------|-------|------|------|------|

| Nursing home infected     | Indicates if the nursing home has at least one confirmed case of COVID-19 infection among its staff or residents | CDPH                            | 0.23  | 0.42 | 0    | 1    |
| Confirmed residents       | The number of COVID-19 infections among the residents of nursing homes       | CDPH                            | 1.91  | 7.88 | 0    | 81   |
| Confirmed staff           | The number of COVID-19 infections among the staff of nursing homes           | CDPH                            | 0.41  | 2.19 | 0    | 26   |
| Large outbreak            | Among those nursing homes with at least one infection, indicates if the number of infected staff or residents is more than 10 infections | Authors’ calculation            | 0.31  | 0.46 | 0    | 1    |
| **Severity of COVID-19 epidemic in the surrounding area** |                                                                              |                                 |       |      |      |      |
| County infections per 100K | The rate of COVID-19 infections per 100,000 residents in the county in which the nursing home is located as of 1 May 2020 | New York Times                  | 143.42| 80.07| 0    | 259.8|
| **Governance features**   |                                                                              |                                 |       |      |      |      |
| For profit                | Indicates if the nursing home has a for-profit status                        | CMS                             | 0.86  | 0.35 | 0    | 1    |
| Family council            | Indicates if a family council for the residents exists in the nursing home  | CMS                             | 0.2   | 0.4  | 0    | 1    |
| Certified beds            | The number of beds certified to provide care to Medicare and Medicaid beneficiaries | CMS                             | 98.89 | 54.77| 14   | 769  |
| Occupancy rate            | The ratio of residents to the total number of certified beds                 | Authors’ calculation            | 0.87  | 0.12 | 0.14 | 1    |
| Inflation score           | Counts the number of years in which a significant discrepancy was observed between the self-reported quality measures and CMS-reported health inspections | Authors’ calculation            | 0.32  | 0.81 | 0    | 5    |
| **Ratings**               |                                                                              |                                 |       |      |      |      |
| Quality rating            | Self-reported indicator of quality of services as of 2017                    | CMS                             | 4.59  | 0.87 | 0    | 5    |
| Staffing rating           | Self-reported measure of staffing hours as of 2017. This is based on a combination of registered nurse hours per resident day and the total nursing hours per resident day | CMS                             | 3.41  | 1.13 | 0    | 5    |
| Health inspection rating  | CMS-reported indicator of health inspections ratings as of 2017              | CMS                             | 2.88  | 1.29 | 1    | 5    |

CDPH, California Department of Public Health; CMS, Centers for Medicare & Medicaid Services.
are provided by Walhin. Conventional Poisson models are suitable for modelling count data, while the zero inflated variation of Poisson model is more suitable for modelling count data with excess zeros, especially when excess zeros are generated by a separate processes that could be modelled separately. This leads to a framework that consists of a logit model for estimating the excess zeros in addition to a Poisson count model. ZIBP model is an extension of zero inflated Poisson model and is best suited for situations in which the count data with excess zeros are generated for two outcomes that may be correlated. In cases where the outcome variables are independent, the model reduces to the product of two independent zero inflated Poisson regression models, referred to as Zero Inflated Double Poisson model. In our setting, the two count variables are the number of COVID-19 infections among staff, and residents. These counts include excess zeros since many nursing homes reported no COVID-19 cases, primarily because they are located in areas where at the time of the data collection, had not yet experienced significant surges in COVID-19 cases. These two counts are also correlated since they both happen at the same nursing home and the factors that give rise to them are common at the nursing home level.

Intuitively, we assume that the number of zero’s in the count of infected staff and residents is generated either because the nursing home was in an area that was less infected by the COVID-19 or because it implemented successful prevention procedures to protect its staff and residents. Moreover, we assume that in a nursing home, the number of infected staff covaries with the number of infected residents since they can infect each other and since common infection prevention and control policies apply to both groups. Taking this interdependency into account also alleviates the concerns over the possible impact of omitted variables in our model. In this context, because of the close proximity of residents and staff, the same variables that could affect the number of infections among one group would most likely also impact the number of infections among the other group. The covariance coefficient captures this interdependency in outcomes. As a sensitivity analysis, we also report the results of Zero Inflated Double Poisson regression. In this model, the counts of infections among staff and residents are assumed to be independent from each other. We use NLMIXED procedure in SAS software to estimate our models. Note that we have provided access to both the data and the SAS code for this analysis.

To answer the second research question and identify the nursing homes with the highest risk of COVID-19 outbreaks, we used our models to predict the probability of experiencing an infection and compared their performance with common machine learning techniques, namely neural networks (NN) and support vector machine with radial basis function (SVM-RBF) kernel. Since our problem has a highly nonlinear structure, advanced machine learning models such as NN and SVM that do not rely on data structure assumptions may provide a flexible and desired solution. The target variable in each model is equal to 1 if at least one patient or staff reported to be infected. The prediction features include nursing home governance features such as occupancy rate, number of certified beds, whether a family council presents, whether the nursing home is for profit or not and inflation score evaluated from past years. The nursing homes’ health inspection rating, staffing rating and quality rating are also included. The machine learning models are implemented in Python V.3.7 with 70% data training and 30% data testing. The entire dataset is used to plot the lift chart. We also measured the performance of our models in predicting the nursing homes with highest risks of experiencing large outbreaks with more than 10 infections.

RESULTS

Study sample

During the data cleaning and merging process, 493 nursing homes were eliminated from our final sample, either because their names were not matching across different datasets, or their ratings information is not available from CMS, or because their COVID-19 infections are not reported by CDPH. To ensure that the final sample is random and our results are not biased, we compared the eliminated nursing homes with the ones in the study sample. The results of two sample t-tests and logistic regression are presented in online supplemental appendix 1. None of the observed governance factors affect the chance of being included in the sample. Among the remaining variables, while the difference with regards to quality ratings and county infections per 100,000 is statistically significant between the two groups, their magnitude is small and serve to make our estimates more conservative.

Study sample included 713 nursing homes in California. As reported in table 1, as of 1 May 2020, 23% of the study sample reported at least one COVID-19 infection among either their staff or residents. Of those, 31% experienced large outbreaks with more than 10 infections among either their staff or residents. The geographic spread of COVID-19 infections in California nursing homes is graphically presented in the online supplemental appendix 1.

Preventing COVID-19 infections

According to the model selection criteria reported in table 2, the ZIBP model provides a better fit as its Akaike information criterion (AIC), Bayesian information criterion (BIC), and −2log likelihood are all smaller than those of Zero Inflated Double Poisson model. We therefore report the estimates of the ZIBP model in the text. The coefficients in the first panel of table 2 represent how the log odds of experiencing an infection changes with one unit of increase in the corresponding predictor. As reported in the first panel of table 2, the only variables...

Fit statistics

| −2 log likelihood | 4422.7 | 4561.7 |
| AIC | 4484.7 | 4621.7 |
| BIC | 4626.4 | 4758.8 |

Note: The coefficients in the first panel represent how the log odds of experiencing an infection changes with one unit of increase in the corresponding predictor. The coefficients in the second and third panels represent how the expected log count of the infections changes for each unit increase in the corresponding predictor.

AIC, akaike information criterion; BIC, bayesian information criterion.

with statistically significant impact on the chance of COVID-19 outbreaks at nursing homes are their size and the rate of infections per 100 000 residents at the county in which they are located. For both variables, a one-unit of increase is associated with a 1% increase in the odds of experiencing at least one COVID-19 infection.
health inspection rating is associated with a sizeable decrease in the number of infections among both staff and residents. One unit of increase in CMS-reported health inspection ratings is associated with a 17% and 18% decrease in the expected number of infections in staff and residents, respectively. A one-unit improvement in staffing rating is associated with a 25% decrease in the number of infections among residents. Note that better staff rating is highly dependent on higher ratio of staff to residents and the higher number of staff per resident would allow nursing homes to control infections more efficiently among their residents. While the observed associations between ratings on health inspections and staffing with the number of infected staff and residents were expected, the association between self-reported quality ratings and the number of infections is the opposite of our expectations. One unit of increase in self-reported quality ratings is associated with, respectively, 49% and 14% increase in infections among staff and residents. This finding is aligned with the emerging stream of research that shows nursing homes embellish their self-reported quality ratings and therefore these ratings may not always indicate better quality of care for residents. Our final variable, inflation score, quantifies the discrepancy between the self- and CMS-reported ratings. The higher the discrepancy, the more likely it is that the nursing home is overstating their quality measures. With a one-unit increase in such discrepancy, the expected number of infections among staff and residents increases by 51% and 14%, respectively.

**Controlling COVID-19 outbreaks**

The coefficients in the second and third panels of table 2 represent how the expected log count of the infections changes for each unit increase in the corresponding predictor.

As reported in the second and third panels of table 2, the expected rate of infections among staff and residents increases with the size of the nursing home. This indicates that the severity of COVID-19 epidemic in the surrounding area increases the chance of experiencing at least one infection at the nursing homes.

While the size of outbreaks among residents is about 12.7 times higher in for-profit nursing homes, the size of outbreak among staff in for-profit nursing homes is not statistically different from non-profit ones. This is in line with prior empirical research that has repeatedly shown that for-profit nursing homes are inferior in many aspects of care quality.

Occupancy rate, which represents the ratio of the number of patients to the number of certified beds of a nursing home, is associated with a lower rate of infections among staff such that a 1% increase in occupancy rate decreases the expected count of infections among staff by 2.4%.

Among the three different ratings, the CMS-reported health inspection rating is associated with a sizeable decrease in the number of infections among both staff and residents. One unit of increase in CMS-reported health inspection ratings is associated with a 17% and 18% decrease in the expected number of infections in staff and residents, respectively. A one-unit improvement in staffing rating is associated with a 25% decrease in the number of infections among residents. Note that better staff rating is highly dependent on higher ratio of staff to residents and the higher number of staff per resident would allow nursing homes to control infections more efficiently among their residents. While the observed associations between ratings on health inspections and staffing with the number of infected staff and residents were expected, the association between self-reported quality ratings and the number of infections is the opposite of our expectations. One unit of increase in self-reported quality ratings is associated with, respectively, 49% and 14% increase in infections among staff and residents. This finding is aligned with the emerging stream of research that shows nursing homes embellish their self-reported quality ratings and therefore these ratings may not always indicate better quality of care for residents. Our final variable, inflation score, quantifies the discrepancy between the self- and CMS-reported ratings. The higher the discrepancy, the more likely it is that the nursing home is overstating their quality measures. With a one-unit increase in such discrepancy, the expected number of infections among staff and residents increases by 51% and 14%, respectively.

**Improving the quality reporting system**

CMS could solve these discrepancies and improve the reporting process by implementing better inspection and auditing strategies. Figure 1 shows how the number of infections among staff and residents could be compressed had the self-reported quality measures by nursing homes were truly reflecting their quality of care.

Given the importance of ratings for nursing homes, with a reliable rating system with no discrepancy between self-reported and CMS-reported measures, nursing homes would strive to elevate their ratings through actual improvements in their quality of care. As shown in the upper panel of figure 1, compared with the current system, lower number of predicted infections among staff would have been more frequent under an improved rating system such that predicted average number of infections among staff would have decreased from 1.85 to 1.52, which is equal to 17.6% fewer total infections across the staff of all nursing homes. As shown in the lower panel of figure 1, the same effect is observed for nursing home residents. Had self-reported quality ratings were truly reflecting the quality of care, the expected number of infections among residents of nursing homes would have reduced from 8.67 to 8.15 which is equal to 5.8% fewer total infections across the residents of all nursing homes.

Finally, the sizeable covariance estimate (0.68; 95% CI 0.54 to 0.87; p=0.1) indicates that the number of infected staff is not independent from the number of infected...
residents. This observation empirically confirms our expectation of dependency between the count of infections in staff and residents such that nursing homes with high number of infected staff also have high number of infected residents. This finding was expected as residents and staff are in close contact with each other and once infections occur among the members of one group, it would be very difficult to prevent them in the other group. More importantly, common infection control procedures implemented by nursing homes would apply to both groups and prevent infections among both groups. Note that as discussed earlier, according to all the model selection criteria, the ZIBP performs better than its competitors. This is not surprising since it has the advantage of modelling and adjusting for the correlation between the count of infections among staff and residents. In the online supplemental appendix 1, we provide further empirical details on the correlation between the number of infections among residents and staff.

**Identifying nursing homes with highest chance of COVID-19 infections and outbreaks**

Figure 2 compares the lift of the ZIBP model with those of NN and SVM-RBF. We use lift as a measure for the ability of the model at predicting or classifying cases with respect to random selection. Lift shows how much better our model works compared with a random selection model. The first 50 nursing homes are zoomed in at the top right corner of the figure. The ZIBP model’s performance is comparable with the common NN and SVM-RBF methods. For the first 50 nursing homes, the rate of true positives of ZIBP model is between 2.45 and 2.73 times higher than that of a random selection model. The area under the curve for ZIBP, NN and SVM-RBF models is respectively 0.68, 0.73 and 0.62.

Figure 3 presents the lifts of the ZIBP model in identifying the nursing homes with large COVID-19 outbreaks among those that have confirmed at least 10 infections. For the first 50 nursing homes, ZIBP correctly identifies nursing homes with large outbreaks among staff between 1.3 and 3.9 times better than a random selection model. The model’s performance for predicting large outbreaks among residents for the first 50 nursing homes is 1.5–2.1 times better than a random selection model.

**DISCUSSION**

Staff and residents of nursing homes constitute the largest demographic of COVID-19 fatalities in the USA. However, nursing homes have not been uniformly impacted by the epidemic; some have not experienced even a single infection while some others have been devastated by COVID-19 fatalities. To prepare for the possible next waves of the epidemic, it is critical to uncover the underlying reason of such variation and to explore the nursing homes’ features that are associated with higher chance and size of outbreaks.

The aim of this research was to understand how publicly available data on nursing homes can explain the significant variation in the chance and size of COVID-19 infections at nursing homes, and to also develop predictive models that can identify the nursing homes with the highest chance and size of outbreaks.

Our results indicate that COVID-19 outbreaks are more likely to happen at larger nursing homes and those with higher rate of COVID-19 infections in the surrounding area. These factors have been shown to be associated with higher probability of experiencing infections by other researchers as well.29

Those with better staffing and health inspection ratings are more successful in controlling the outbreaks. The association between staffing levels and likelihood of having COVID-19 infections among both staff and residents has been reported by other researchers as well.30

Interestingly, higher self-reported quality ratings are associated with larger size of outbreaks. This counterintuitive result could further evidence that nursing homes exaggerate their self-reported quality measures. Higher
discrepancy between self-reported measures and CMS-reported health inspections was associated with larger COVID-19 outbreaks.

The size of the outbreaks among residents is significantly higher in for-profit nursing homes which have been previously shown to also be of poorer quality in various aspects of care. 19–22

There is a complex relationship between the main variables in our models. For-profit Nursing Homes generally have lower nurse staffing, more deficiencies, larger in size and have a greater likelihood of inflating their ratings. 31 32 It is therefore not surprising that they were found to be more likely to have larger numbers of COVID-19 infected residents and staff.

The model developed in this research can correctly identify the nursing homes that are more likely to experience an infection or are at the highest risk of an outbreak.

The insights of this research help policy makers to identify the nursing homes with the highest probability and size of COVID-19 outbreaks. This will allow them to prioritise such nursing homes in their efforts to control the epidemic. Such efforts could entail devoting more resources towards nursing homes with significantly higher risk or when feasible, temporarily transferring patients to different nursing homes to control the spread of the virus.

Our results show that our ZIBP model outperforms SVM and that the predictive ability of the NN is only modestly better than ZIBP model. That is, the application and comparison of these machine learning models with the results of the ZIBP model confirms that not only the ZIBP model can explain the relationship between various independent variables and COVID-19 infections at nursing homes, but it also offers competitive predictive performance.

An important takeaway from this research is the importance of data collection and transparency. Our research was made possible because of the availability of key information on COVID-19 infections in nursing homes in the USA and publicly available data such as ownership, size, staffing and key performance measures. Access to such data is invaluable in both understanding and taking preventive action to curb the COVID-19 infections in nursing homes. As such we hope that other industrialised nations take necessary steps to collect and disseminate such information to protect and safeguard the vulnerable residents in long-term care facilities.

This work leaves several areas for future research. First, given the variation in testing at different nursing homes, the number of confirmed infections may be undercounting the actual number of infections and therefore a more reliable measure would be the number of fatalities associated with COVID-19. Second, should temporal data become available, researchers can study growth curves of infections or deaths among staff and residents and examine their interlinked effects on each other. Third, should national data become available, we can test our contentions using a much larger sample at the national level. This would increase the external validity and generalisability of our findings. Finally, when data from other states and other time become available, we can include a spatial random effect in the model to account for spatial dependencies between the infections at different nursing homes.

One of the limitations of the study is that its data on nursing homes’ features are collected in 2017 which is over 2 years prior to the outbreak. Although more recent data were available on the time of the study, the variable ‘inflation score’ had to be adopted from the 2017 data. We should also note that 86% of California nursing homes are for-profit and these nursing homes were probably more likely to under-report their infection rates and deaths than other nursing homes for fear of losing residents and revenue. 33
