ABSTRACT

We describe a simple method for simulating the dynamics of small grains in a dusty gas, relevant to micron-sized grains in the interstellar medium and grains of centimetre size and smaller in protoplanetary discs. The method involves solving one extra diffusion equation for the dust fraction in addition to the usual equations of hydrodynamics. This “diffusion approximation for dust” is valid when the dust stopping time is smaller than the computational timestep. We present a numerical implementation using Smoothed Particle Hydrodynamics (SPH) that is conservative, accurate and fast. It does not require any implicit time stepping and can be straightforwardly ported into existing 3D codes.

Key words: hydrodynamics — methods: numerical — protoplanetary discs — (ISM:) dust, extinction — ISM: kinematics and dynamics

1 INTRODUCTION

Small grains rule the interstellar medium (ISM). Micron-sized dust grains absorb ultraviolet radiation from hot, young stars and re-emit it in the infrared. Understanding how these grains interact with the gas is critical to understanding both the dynamics and thermodynamics of the ISM, and to interpreting observational results which usually assume a fixed gas-to-dust ratio in order to derive physical quantities such as the gas column density.

Modelling such grains presents a severe computational challenge, since small grains are tightly coupled to the gas by the mutual drag force. This presents both a short timescale problem, since the stopping time of the grains is much shorter than the typical computational time, and a short lengthscale problem, since the physical separation between the dust grain population and the gas is much smaller than typical distances in the ISM.

In a recent series of papers (Laibe & Price 2012a,b, 2014a,b,c) we have outlined the limitations associated with modelling dust and gas using the standard two fluid approach, where they are regarded as separate fluids coupled by a drag term. Typically the gas is represented by a set of particles or grid cells, while the dust is represented by a separate set of pressure-less particles coupled to the gas by a drag term. The length and timescale problems discussed above mean that with this approach one needs both infinite spatial and temporal resolution to accurately capture the dynamics of small grains in the limit of perfect coupling (Laibe & Price 2012a; AyliFF et al. 2012). The method is similar to the approach to other multi-fluid systems in astrophysics such as ionised plasmas (Pandey & Wardle 2008), but more general since it can be implemented without any approximations.

In LP14b we derived a Smoothed Particle Hydrodynamics (SPH) algorithm based on the fully general one fluid method and showed that it could accurately capture the dynamics of dust-gas mixtures in both the weakly coupled and tightly coupled limits. For problems involving small grains, however, the full machinery of the one fluid formulation is unnecessary and a much simpler and computationally inexpensive approach is possible, as outlined in Section 3.3 of LP14a. This approximation is accurate when the stopping time, \( t_s \), is less than the Courant timestep (Eq. 115 in LP14a).

Our goal in this paper is to derive a numerical implementation of this much simpler formulation, since there are many situations in astrophysics where the dynamics of small grains is the dominant effect. This includes simulations of galaxies, star formation in the interstellar medium — where small grains control the thermodynamics — and the settling and migration of dust in protoplanetary discs. We summarise the analytic formulation and its applicability in Sec. 3 and tests are presented in Sec. 4. A public version of the ndspmhd code is described as a single fluid moving at the barycentric velocity. In (Laibe & Price 2014a,b) (hereafter LP14a, LP14b) we showed how the equations for a coupled dust-gas system can be reformulated to describe this single fluid mixture without loss of generality, solving both the length and timescale issues and also preventing artificial trapping of dust particles below the resolution of the gas (LP12a, Avillez et al. 2012). The method is similar to the approach to other multi-fluid systems in astrophysics such as ionised plasmas (Pandey & Wardle 2008), but more general since it can be implemented without any approximations.

In LP14b we derived a Smoothed Particle Hydrodynamics (SPH) algorithm based on the fully general one fluid method and showed that it could accurately capture the dynamics of dust-gas mixtures in both the weakly coupled and tightly coupled limits. For problems involving small grains, however, the full machinery of the one fluid formulation is unnecessary and a much simpler and computationally inexpensive approach is possible, as outlined in Section 3.3 of LP14a. This approximation is accurate when the stopping time, \( t_s \), is less than the Courant timestep (Eq. 115 in LP14a).

Our goal in this paper is to derive a numerical implementation of this much simpler formulation, since there are many situations in astrophysics where the dynamics of small grains is the dominant effect. This includes simulations of galaxies, star formation in the interstellar medium — where small grains control the thermodynamics — and the settling and migration of dust in protoplanetary discs. We summarise the analytic formulation and its applicability in Sec. 3 and tests are presented in Sec. 4. (v2.1) implementing the algorithms and with the precise setup of
the test problems is released alongside this paper.1

2 THE DIFFUSION APPROXIMATION FOR DUST

2.1 Continuum equations

2.1.1 General case

In [LP14a] we showed that, to first order in \( \Delta t \), the equations describing the evolution of a dust-gas mixture can be written in the form

\[
\frac{dp}{dt} = -\rho (\nabla \cdot v),
\]

(1)

\[
\frac{dv}{dt} = (1 - \epsilon) f_d + \epsilon f_g + f,
\]

(2)

\[
\frac{de}{dt} = -\frac{1}{\rho} \nabla \cdot [\epsilon (1 - \epsilon) \rho u \Lambda f],
\]

(3)

\[
\frac{du}{dt} = -\frac{P}{\rho_g} (\nabla \cdot v) + \epsilon t_s (\Lambda f \cdot \nabla) u + \Lambda_{\text{heat}} - \Lambda_{\text{cool}},
\]

(4)

where \( \rho \) is the total density of the mixture, \( \epsilon \equiv \rho_d/\rho \) is the mass fraction of dust, \( f \) represents accelerations acting on both components of the fluid while \( f_d \) and \( f_g \) represent the accelerations acting on the gas and dust components, respectively, \( \Lambda f \equiv f_d - f_g \) is the differential acceleration between the gas and dust, \( u \) is the specific thermal energy of the gas, \( P \) is the gas pressure, and \( \Lambda_{\text{heat}} \) and \( \Lambda_{\text{cool}} \) are additional heating and cooling terms, respectively.2

2.1.2 Hydrodynamics

For the simple case of hydrodynamics, the only force is the pressure gradient, giving

\[
\frac{dv}{dt} = -\frac{P}{\rho_g}, \quad f_d = 0,
\]

(8)

and thus

\[
\Delta f = \frac{P}{\rho_g},
\]

(9)

giving Equations[1, 4] in the form

\[
\frac{dp}{dt} = -\rho (\nabla \cdot v),
\]

(10)

\[
\frac{dv}{dt} = -\frac{P}{\rho} + f,
\]

(11)

\[
\frac{de}{dt} = -\frac{1}{\rho} \nabla \cdot (\epsilon t_s \nabla P),
\]

(12)

\[
\frac{du}{dt} = -\frac{P}{\rho_g} (\nabla \cdot v) + \epsilon t_s (\nabla P \cdot \nabla u) + \Lambda_{\text{heat}} - \Lambda_{\text{cool}}.
\]

(13)

These are similar to the usual equations of hydrodynamics in the absence of dust. The only differences are the extra equation that describes the evolution of the dust fraction; the modifications to the thermal energy equation; and the fact that the pressure is related to the gas density only, not the total density (see Sec. 2.1.3 below; this gives the zeroth order effect of a ‘heavy fluid’, as discussed in LP14a).

2.1.3 Equation of state

The equation set is closed by the usual equation of state specifying the gas pressure \( P \) in terms of the gas density and temperature.

\[
P = (\gamma - 1) \rho u = (\gamma - 1) (1 - \epsilon) \rho u,
\]

(14)

where \( \gamma \) is the usual adiabatic constant.

2.2 Timestepping

The main change when adopting the formulation given above compared to hydrodynamics is the addition of the diffusion equation for the dust fraction. This introduces an additional constraint on the timestep when the diffusion coefficient is large. Assuming an isothermal equation of state \( P = c_s^2 \rho u = c_s^2 (1 - \epsilon) \rho u \) and a constant density, [12] can be written as a simple diffusion equation for \( \epsilon \)

\[
\frac{de}{dt} = \nabla \cdot (\eta \nabla \epsilon),
\]

(15)

where the diffusion coefficient \( \eta \equiv \epsilon t_s c_s^2 \). This implies a stability constraint of the form

\[
\Delta t \ll \Delta t_s \equiv \frac{h^2}{\eta} = \frac{h^2}{\epsilon t_s c_s^2},
\]

(16)
where \( C_0 \) is a dimensionless safety factor of order unity and \( h \) is the resolution length (the smoothing length in SPH). We can rewrite (16) as

\[
\Delta t < C \left( \frac{\Delta t_{\text{Cour}}}{t_s} \right)^2 \Delta t,
\]

(17)

where \( C \) is a constant and \( \Delta t_{\text{Cour}} = C_0 \frac{h}{c_s} \) is the usual Courant condition. This implies that the timestep is constrained when the stopping time is long — the opposite of the usual situation where the timestep is constrained when the stopping time is short. This is the main advantage of using the diffusion approximation — small grains can be integrated explicitly.

Specifically, the diffusion timestep becomes the limiting timestep when

\[
\epsilon_2 > \Delta t_{\text{Cour}}.
\]

(18)

However, this is also the criterion for when the terminal velocity approximation breaks down (see LP14a). This implies that the diffusion approximation becomes inaccurate precisely when the timestep implied by (16) starts to constrain the timestep, because at this point the time-dependence in \( \Delta t \) becomes important. Once this occurs, one should revert to the general formulation given by LP14a where \( \Delta t \) is explicitly evolved, or a two-fluid method. Physically this transition occurs once grains grow beyond a certain size, implying that the stopping time becomes long, or equivalently when one has enough temporal resolution to resolve the timescale on which the differential velocity is changing.

### 2.3 Validity of the diffusion approximation for astrophysics

Under what circumstances is the diffusion approximation valid for astrophysics? Consider a drag force described by the linear Epstein equation (3) for the fusion approximation becomes inaccurate precisely when the diffusion timestep becomes the limiting timestep when

\[
\epsilon_2 > \Delta t_{\text{Cour}}.
\]

This suggests the approximation is valid for grain sizes

\[
x_{\text{grain}} \ll 10^2 \text{cm} \left( \frac{\Sigma}{10^3 \text{g/cm}^2} \right)^{\frac{1}{2}} \left( \frac{P_{\text{grain}}}{1 \text{g/cm}^3} \right)^{\frac{1}{2}}.
\]

(23)

Hence diffusion is a reasonable approximation for grains of \( \sim \text{cm} \) size and smaller in protoplanetary discs. This maximum size is smaller in the outer disc regions, since typically the surface density is inversely proportional to distance from the central star. We examine this experimentally in Section 4.4.

### 3 IMPLEMENTATION IN SMOOTHED PARTICLE HYDRODYNAMICS

#### 3.1 Implementation using two first derivatives

The SPH representation of a more general form of Eqs. (14) have been derived in LP14a and so our first approach is to adopt the same discretisation but with \( \Delta \tau \) prescribed by Eq. (5) giving

\[
\rho_u = \sum_b m_b W_{ab}(h_u),
\]

(24)

\[
\frac{dv_a}{dt} = -\sum_b \left\{ \frac{P_a + q_a^{WV} v_a}{\Omega dP_a} \nabla_a W_{ab}(h_a) + \frac{P_b + q_b^{WV}}{\Omega dP_b} \nabla_b W_{ab}(h_b) \right\} \cdot f_a + f_u,
\]

(25)

\[
\frac{de_a}{dt} = -\sum_b \left\{ \frac{\epsilon_a(1-\epsilon_a) h_{a\alpha}}{\Omega \rho_a} \Delta f_a \cdot \nabla a W_{ab}(h_a) \right\} + \epsilon_a(1-\epsilon_a) h_{a\beta} \Delta f_a \cdot \nabla_b W_{ab}(h_b),
\]

(26)

\[
\frac{du_a}{dt} = \frac{1}{\Omega_{\alpha} (1-\epsilon_a) \rho_a^2} \sum_b m_b \left( P_a + q_{ab}^{WV} \right) (v_a - v_b) \cdot \nabla_b W_{ab}(h_a) + \frac{\epsilon_a f_{ua}}{\Omega_{\rho_a}} \Delta f_a \cdot \nabla_b W_{ab}(h_b),
\]

(27)

where \( W_{ab} \) is the usual SPH kernel (we use the usual cubic spline kernel throughout this paper unless otherwise indicated), \( h \) is the smoothing length, \( \Omega \) is the usual term related to smoothing length gradients

\[
\Omega_{\alpha} \equiv 1 - \frac{\partial h_{\alpha}}{\partial \rho_{\alpha}} \sum_b m_b \frac{\partial W_{ab}(h_a)}{\partial h_{\alpha}},
\]

(28)

and \( h \) is related to \( p \) in the usual manner requiring an iterative procedure to solve Eq. (24) (Price & Monaghan 2004, 2007) and unless otherwise specified we use a ratio of \( h \) to particle spacing of 1.2 (Price 2012). The reader will notice that the first two equations are identical to the usual density summation and momentum equation in SPH. The only differences, mirroring the continuum case (Eqs. (10)-(13), are the addition of the diffusion equation (3) for the dust fraction, the extra terms in the thermal energy equation (27) and the dependence of the pressure on the gas density rather than the total density in the equation of state (14).

The differential force between the fluids implied by our formulation of Eq. (25) is

\[
\Delta f_a = -f_{u\alpha}.
\]

(29)

where

\[
(1-\epsilon_a) f_{u\alpha} = -\sum_b m_b \left\{ \frac{P_a + q_{ab}^{WV}}{\Omega dP_a} \nabla a W_{ab}(h_a) + \frac{P_b + q_b^{WV}}{\Omega dP_b} \nabla b W_{ab}(h_b) \right\}.
\]

(30)
This $\Delta f$, computed as above, is then used to evaluate Equations[26] and [27] requiring a separate loop over the particles.

3.2 Shock-capturing terms

3.2.1 Artificial viscosity

We formulate the artificial viscosity term following the more general algorithm derived in [LP14] but slightly modified to appear as separate $qa$ and $qb$ terms to avoid averaging the kernel gradients, following the formulation of artificial viscosity used in the Phantom code ([Price & Federrath 2010; Lodato & Price 2010]). We use

$$q_{\alpha\beta} = \begin{cases} \frac{1}{2} \rho_a (1 - \epsilon_a) v_{\alpha\beta} (v_{\alpha\beta} \cdot \hat{r}_{ab} - \mathbf{0}) & v_{\alpha\beta} \cdot \hat{r}_{ab} < 0 \\ \mathbf{0} & v_{\alpha\beta} \cdot \hat{r}_{ab} \geq 0 \end{cases}$$

(31)

where $v_{\alpha\beta} \equiv v_a - v_b$ (similarly for $r_{ab}$) and the signal speed $v_{\alpha\beta}$ corresponds to the usual choice for hydrodynamics, i.e.

$$v_{\alpha\beta} = \alpha_a c_a + \beta |v_a \cdot \hat{r}_{ab}|,$$

(32)

where $\alpha \in [0, 1]$ is the linear dimensionless viscosity parameter (in general this can be individual to each particle, e.g. when using the Morris & Monaghan 1997 or Cullen & Dehner 2010 switches) and $\beta$ (typically $\beta = 2$) is the Von Neumann-Richtemyer viscosity parameter.

The $q_{\alpha\beta}$ term and the signal speed involve the jump in total velocity rather than the gas velocity, unlike in [LP14] where only the gas velocity is used. This is both physical and practical: In the terminal velocity approximation the difference

$$\mathbf{r} - v_e \equiv c_t \Delta f,$$

(33)

is small by definition. The practical side is that it we do not know $\Delta f$ prior to the evaluation of Eq. [25] so it is not possible to use the gas velocity directly in the artificial viscosity term without an iterative approach.

3.2.2 Artificial conductivity

We write the artificial conductivity term necessary for correct treatment of contact discontinuities ([Price 2008]), similar to that in [LP14b] giving

$$\left( \frac{d u_a}{d t} \right)_{\text{cond}} = \frac{1}{1 - \epsilon_a} \sum_{b} m_b \left[ \frac{Q_{ab,a} F_{ab}(h_a)}{\Omega \rho^2_a} + \frac{Q_{ab,b} F_{ab}(h_b)}{\Omega \rho^2_b} \right],$$

(34)

where $\nabla_a W_{ab} \equiv F_{ab} \hat{r}_{ab}$ and

$$Q_{ab,\alpha} = \frac{1}{2} \alpha_a \rho_a v_{\alpha\beta} (u_a - u_b),$$

(35)

with $\alpha_a \in [0, 1]$ the dimensionless conductivity parameter and $v_{\alpha\beta} = |v_a \cdot \hat{r}_{ab}|$ ([Price 2008; Wadsley et al. 2008]).

3.3 Conservation properties

Equation [24] manifestly conserves the total mass since the mass of the SPH particles is constant. Similarly it can be straightforwardly verified that the total momentum is conserved, since

$$\frac{d}{d t} \sum_a m_a v_a = \sum_a m_a \frac{d v_a}{d t} = 0,$$

(36)

due to the fact that the resulting double summation is antisymmetric in the particle indices $a$ and $b$. Likewise the total angular momentum is conserved, since

$$\frac{d}{d t} \sum_a m_a r_a \times v_a = \sum_a m_a r_a \times \frac{d v_a}{d t} = 0.$$

(37)

(for more details, see Equation 33 in [Price 2012]). Finally, one may also verify that the total mass of each species is conserved, since

$$\frac{d M_a}{d t} = - \frac{d M_b}{d t} = \sum_a m_a \frac{d e_a}{d t} = 0.$$

(38)

The proof is identical to that given in [LP14] and again results from the fact that the double summation is antisymmetric with respect to the particle indices.

The total energy of the mixture in the terminal velocity approximation is given by [LP14a]

$$E = \int \left[ \frac{1}{2} \rho^2 v^2 + \rho \epsilon^u \right] d V = \int \left[ \frac{1}{2} \rho^2 v^2 + \rho (1 - \epsilon_a) u_e \right] d V.$$

(39)

This is simpler than the full one fluid expression (Eq. 61 in [LP14]) as the term involving $\Delta f^2$ can be neglected. Discretised onto the mixture particles, the energy becomes

$$E = \sum_a m_a \left[ \frac{1}{2} \rho^2 v^2 + (1 - \epsilon_a) u_e \right].$$

(40)

Conservation of energy implies that

$$\frac{d E}{d t} = \sum_a m_a \left[ v_a \cdot \frac{d v_a}{d t} + (1 - \epsilon_a) \frac{d u_a}{d t} - u_a \frac{d e_a}{d t} \right] = 0.$$

(41)

Substituting Equations [25] and [26] in the above, we require for energy conservation that

$$\sum_a m_a (1 - \epsilon_a) \frac{d u_a}{d t} = \sum_a \sum_{b} m_b m_a \left[ \frac{P_a + q^V_{ab,a} v_a \cdot \nabla_a W_{ab}(h_a)}{\Omega \rho^2_a} \right] + \sum_a \sum_{b} m_a m_b \left[ \frac{P_b + q^V_{ab,b} v_b \cdot \nabla_b W_{ab}(h_b)}{\Omega \rho^2_b} \right] - \sum_a \sum_{b} m_a m_b \left[ \frac{u_a (1 - \epsilon_a) v_a f_a}{\Omega \rho a} \right] \Delta f_a \cdot \nabla_a W_{ab}(h_a) - \sum_a \sum_{b} m_a m_b \left[ \frac{u_b (1 - \epsilon_b) v_b f_b}{\Omega \rho b} \right] \Delta f_b \cdot \nabla_b W_{ab}(h_a).$$

(42)

Swapping the summation indices $a$ and $b$ in the second and fourth terms, using the antisymmetry of the kernel gradient $\nabla_b W_{ab}(h_a)$ and collecting terms we have

$$\sum_a m_a (1 - \epsilon_a) \frac{d u_a}{d t} = \sum_a \sum_{b} m_a \left[ \frac{P_a + q^V_{ab,a} (v_a - v_b) \cdot \nabla_a W_{ab}(h_a)}{\Omega \rho^2 a} \right] + \sum_a \sum_{b} m_a \left[ \frac{(1 - \epsilon_a) v_a f_a (u_a - u_b) \Delta f_a \cdot \nabla_a W_{ab}(h_a)}{\Omega \rho a} \right],$$

(43)

from which it is straightforward to verify that, with $du_a/dt$ given by Eq [27] total energy is conserved exactly.

Thus, the approximate version of the one fluid algorithm retains all of the conservation properties of both the original SPH method and the general one fluid approach derived in [LP14].

3.4 Implementation using direct second derivatives

The main disadvantage of the formulation given above is that it requires a third loop over the particles to compute the $de/dt$ term,
3.4.1 Diffusion equation for the dust fraction

We can avoid the extra loop over the particles by discretising the second derivative in Eq. [3] directly, similar to the usual way that dissipative terms are treated in SPH. To do this we assume that viscous forces do not significantly drive the differential velocity between the fluids, i.e. that $\Delta f$ is given by Eq. [9] and therefore that Eq. [3] is given by Eq. [12]. We then discretise Eq. [12] in the usual manner following Cleary & Monaghan (1999):

$$\frac{d\epsilon_a}{dt} = - \sum_b \frac{m_b}{\rho_a \rho_b} \left( D_a + D_b \right) \left( P_a - P_b \right) \frac{\mathbf{F}_{ab}}{\rho_{ab}},$$  \hspace{1cm} (43)

where $D \equiv \epsilon_t$, $\mathbf{F}_{ab} \equiv \frac{1}{2} [ \mathbf{F}_{ab}(h_a) + \mathbf{F}_{ab}(h_b) ]$ and $\mathbf{F}_{ab}$ is defined such that $\nabla \rho_{ab} = \mathbf{F}_{ab} \mathbf{p}_{ab}$. It is straightforward to show that this expression also conserves both the total mass of dust and gas, since the resulting double summation in Eq. [33] is antisymmetric with respect to the particle index.

3.4.2 Harmonic vs. arithmetic mean

In the original Cleary & Monaghan (1999) paper (see also Monaghan 2005) it was suggested to use the harmonic mean instead of the arithmetic mean of the diffusion coefficient, i.e.

$$\frac{d\epsilon_a}{dt} = - \sum_b \frac{m_b}{\rho_a \rho_b} \left( 4 D_a D_b \right) \left( P_a - P_b \right) \frac{\mathbf{F}_{ab}}{\rho_{ab}},$$  \hspace{1cm} (44)

with the motivation being that this better handles the case where the diffusion coefficient $D$ is discontinuous. However, we found this could give incorrect results. Imagine the dust confined to a layer such that $\epsilon_t = 0$ for some particle, a, outside the layer, with $\epsilon_t \neq 0$ for particles inside the layer. In this case the harmonic mean is zero for every pair involving particle $a$ since $d\epsilon_a/dt = \frac{1}{\epsilon_t}$ is always zero. Thus it is impossible for the layer to move into the region where $\epsilon$ was initially zero, which is clearly incorrect (consider for example a discrete layer of dust descending under gravity). With the arithmetic mean we find no such problem and it is easy to prove that the formulation is correct for example with a procedure similar to the one we use in Appendix [A].

3.4.3 Thermal energy equation

In order to conserve energy, the corresponding expression for $d\epsilon_a/dt$ when using Equation [43] for $d\epsilon_a/dt$ is given by

$$\frac{d\epsilon_a}{dt} = \frac{1}{\rho_a (1 - \epsilon_a) \alpha_a} \sum_b m_b (P_a + q_{ab}) \left( v_a - v_b \right) \cdot \nabla_a W_{ab}(h_a)$$

$$= \frac{1}{2 \Omega_a (1 - \epsilon_a) \rho_a} \sum_b m_b \left( u_a - u_b \right) \left( D_a + D_b \right) (P_a - P_b) \frac{\mathbf{F}_{ab}}{\rho_{ab}},$$  \hspace{1cm} (45)

At first sight the second term is a rather strange one and it is not at all clear that this should translate to the correct physical term in Eq. [24]. Yet, amazingly, it does — the proof is given in Appendix [A]. Hence there is no disadvantage in using this alternative formulation with respect to conservation properties. The shock capturing terms remain the same as in Section [3.2].

3.4.4 Choice of smoothing kernel

Although the formulation of second derivatives in SPH using the kernel gradient (43) is now more than 30 years old (Brookshaw 1985), and while it is clearly better than using $\nabla^2 W$ directly, to our knowledge there has been no systematic investigation of the best kernel to use in order to compute a second derivative. In particular, on the dust settling test in Section [4.4] we found that using (43) with the cubic spline could give quite noisy results. Hence for this test we instead adopted the $M_6$ quintic kernel instead (see Sec. [4.4]). While this results in a more accurate estimate, it is also more expensive due to the larger kernel radius. Hence a more systematic investigation of suitable kernels for second derivatives in SPH would be valuable here. For example, in LP12 we found double-hump shaped kernels to be an order of magnitude more accurate compared to standard kernels for computing the drag terms in the two fluid method at no additional cost.

3.4.5 Two first derivatives vs. direct second derivatives

To our knowledge there exists no systematic study on whether it is better to compute second derivatives in SPH directly or using two consecutive first derivatives (though see Watkins et al. 1996). In principle both approaches yield a second order approximation provided that the particles are well ordered, and in the context of implementing physical viscosity terms in SPH both approaches have been advocated (e.g. Flebbe et al. 1994, Watkins et al. 1996, Español & Revenge 2003, Lodato & Price 2010), with only Watkins et al. (1996) suggesting that the two first derivatives approach is more accurate. By comparing our two implementations in Sec. [4.2] we effectively compare both approaches. We find only small differences between the two approaches in terms of the overall accuracy, with the main advantages being that the direct second derivatives approach is both faster and easier to implement.

4 NUMERICAL TESTS

A key issue in developing numerical codes for dust-gas mixtures is that there are few simple test problems that can be used to benchmark the algorithm. We have partially resolved this issue by deriving the analytic solution for linear waves in such a mixture (Laibe & Price 2011) and showing that the solution for a shock

---

3 While Cleary & Monaghan (1999) proposed the harmonic mean, there is no detailed comparison between the two choices in their paper and the only proof that the harmonic mean correctly represents the second derivative, apart from the numerical tests in their paper, involves a Taylor-series approximation where the harmonic mean reduces to the arithmetic mean.
in the limit where $\Delta v \to 0$ is the same as for the hydrodynamic case but with a modified sound speed $c_{\text{spec}} = \sqrt{\gamma K}$ (Miura & Glass 1982). The dustybox solution (Laibe & Price 2011) is not relevant to this paper since we have already assumed that $\Delta v$ has reached its asymptotic value by using the terminal velocity approximation. Hence, we use the dustywave and dustyshock problems to benchmark our algorithm. Our exploration of the diffusion approximation for dust suggested a new test problem with a simple analytic solution, which we describe in Sec. 4.3.

4.1 Dustywave

In dustystep wave problem, we solve for the propagation of a linear wave in a dust-gas mixture. We set up the problem in 1D as in our previous papers (LP12a, LP12b, LP14b), using $\rho_{d0} = \rho_{g0} = 1$ (i.e. $\rho_d = 2$ and $\epsilon_d = 0.5$) with a sinusoidal perturbation to the velocity and density of the mixture particles $v(x) = v_0 \sin(2\pi x)$ and $\rho(x) = \rho_0 [1 + \delta \rho_0 \sin(2\pi x)]$, with amplitude $v_0 = \delta \rho_0 = 1 \times 10^{-4}$, with a corresponding thermal energy perturbation given by $\delta u = u_0 = \rho_0 \rho_0^2 \delta \rho_0$. An adiabatic set of state is used with $\gamma = 5/3$ and the thermal energy is set so that the initial sound speed $c_s = 0$. We use 100 SPH particles in the domain $x \in [0, 1]$.

There is a fundamental inconsistency in the dustywave initial conditions when using the terminal velocity approximation because the setup of the problem and hence the analytic solution assumes that $\Delta v_0 = 0$. By definition in the terminal velocity approximation we have $\Delta v = t \Delta v_0$, which is non-zero. Hence the solution even at $t = 0$ is not identical to the full one fluid case. However, these differences become smaller at large drag and at later times.

The numerical solution is shown after 4.5 wave periods in Figure 1 showing the gas and dust velocities (filled and open circles, respectively). As in LP14b we have reconstructed the gas and dust velocities on each particle from the barycentric variables, i.e. $v_g \equiv v - e \Delta v$ and $v_d \equiv v + (1 - e) \Delta v$. The left Figure shows the results using the two first derivatives approach (Sec. 3.1) while the right Figure shows the results using the direct second derivatives version (Sec. 3.2) in each case compared to the analytic solution from LP11. There is no distinguishable difference between the two approaches. The solution in the regime where the terminal velocity approximation is valid ($K \gtrsim 100$ and $0 \lesssim t \lesssim 0.01$) is within a few percent of the analytic solution. There is a conspicuous phase error at lower drag ($K \lesssim 10$ and $0 \lesssim t \lesssim 0.1$), but in part caused by the inconsistency in the initial conditions, which becomes worse as $t$ becomes larger, and in part because this is where the terminal velocity approximation breaks down. Nevertheless the general behaviour in terms of the damping of the wave at intermediate drag is captured despite the inapplicability of the approximation in this regime. The behaviour at even lower drag ($K \lesssim 1$; not shown) is incorrect; here the wave remains damped when using the terminal velocity approximation whereas the damping should decrease as the coupling tends to zero. Hence the full one fluid approximation should be used in this regime (e.g. LP14b), as we argued in Sec. 3.2.

Figure 2 shows the solution for the density perturbation. Importantly, the analytic solution for density in the dustywave problem quickly becomes nonlinear, particularly when the drag is weak. This can be seen by considering the limit of no drag: Assuming the dust is not submitted to any external force we have

$$v(t) = v(t = 0) = v_0 \sin(kx_0),$$

implying

$$x(t) = x_0 - v_0 \sin(kx_0) t.$$  

Hence, from mass conservation, the dust density is given by

$$\rho_d(t) = \rho_{d0}(x_0) \left( 1 - v_0 k \cos(kx_0) t \right).$$  

This result is physically consistent with the initial velocity profile: grains are depleted at $x = \pm \pi$, pile up at $x = 0$ and maintain a constant density at $x = \pm \pi/2$ (zero net flux of particles). In particular, density fluctuations become of the order of the background on a typical time $v_0/k^2$ and the analytic solution of the dustywave problem from LP11 cannot be applied anymore. It should be noted however that the velocities remain small and still agree with the solution of the linear problem. Hence, we have computed the reference solution in Fig. 2 using a high-resolution (5000 particle) simulation with our fully general one fluid algorithm LP14b; whereas in Fig. 1 we used the linear solution from LP11 (both methods produce indistinguishable results for the velocity field).

Since there is no inconsistency in the density in the initial conditions, the solution using the diffusion approximation is more accurate for the densities than for the velocities ($L_2$ error of 0.06 at $K = 100$ and 0.006 at $K = 1000$), though still becomes inaccurate ($L_2$ error $\gtrsim 0.5$) for $K \lesssim 10$. As with the velocities, there is no difference between the two implementations (compare left and right panels in Figure 2), indicating that any inaccuracies are due to the physical approximation rather than the numerical scheme itself.

4.2 Dustyshock

The dustyshock problem at strong drag was one of the most difficult problems to solve using a two fluid approach due to the resolution requirement $h \lesssim c_s t$, that leads to overdamping of the solution if not satisfied (LP12a). We have already shown in LP14b that this spatial resolution requirement is unnecessary when using a general one fluid formulation, although the drag still imposes a prohibitive timestep constraint, meaning that an implicit timestepping scheme (albeit a fairly simple one) is still necessary. Figure 3 shows that with our present method we can capture the high-drag dustyshock solution using explicit timestepping without any timestep constraint other than the usual Courant condition, and without any particular spatial resolution requirements.

We set up the problem as usual, following the standard Sod (1978) shock tube with conditions in the gas for $x \leq 0$ given by $(\rho_g, v_g, P) = (1.0, 0.0, 1.0)$ and for $x > 0$ given by $(\rho_g, v_g, P) = (0.125, 0.0, 0.125)$. We assume a constant dust fraction in the initial conditions $\epsilon_d = 1$, using 569 particles (corresponding to a particle spacing of $\Delta x = 0.001$ for $x \leq 0$, an adiabatic equation of state with $\gamma = 5/3$ and a drag coefficient $K = 1000$. In this regime the solution corresponds to the usual hydrodynamic solution with a modified sound speed (red lines in Figure 3). In this respect we are testing only the ability of the algorithm to recover the zeroth order effect of a heavy fluid (see LP14b), which from the results in Figure 3 can be seen to be true.

As previously there is very little difference between the two implementations (comparing left and right panels) except that the direct second derivatives approach (c.f. Section 3.2) produces slightly less noise in the pressure profile across the contact discontinuity. While this can be important for some problems (see e.g. Price 2008), such a minor difference is not enough to prefer this discretisation over the two first derivatives approach. However, given that the direct second derivatives algorithm is also significantly faster it may be preferred on this basis.
A fast algorithm for small grains in SPH 7

Based on Equation (15) we present a new test for dust–gas mixtures with a simple analytic solution. This consists of the steady diffusion of an overconcentration of dust. To set up the problem we consider a uniform density box with $p = \rho_0 = 1$ and an isothermal equation of state $P = c_s^2 \rho g$ with $c_s = 1$. In this case the dust diffusion can be described by Equation (15). For the diffusion parameter we assume that the stopping time is a constant (this is equivalent to assuming an Epstein-like drag where $t_s = \rho_{\text{grain}} c_s^2 / (p c_s)$ is constant).

4.3 Dusty diffusion

4.3.1 Analytic solution

The exact solution can be obtained by solving the equation

$$\frac{de}{dt} = \nabla \cdot (e \tilde{\eta} \nabla), \quad (49)$$

where $\tilde{\eta} \equiv t_s c_s^2$ is a constant. We solve this by assuming spherical symmetry, i.e.

$$\frac{de}{dr} = \tilde{\eta} \frac{d}{dr} \left( r^2 \frac{de}{dr} \right), \quad (50)$$

for which there are several known analytic solutions, including the general time-dependent solution

$$e(r, t) = A \left| 10 \tilde{\eta} t + B \right|^{\frac{3}{2}} - \frac{r^2}{10 \tilde{\eta} t + B}. \quad (51)$$
Figure 3. Results of the dustyshock test with a large drag coefficient, \( K = 1000 \), comparing the use of two first derivatives to compute the dust diffusion (left) with the direct second derivative discretisation of the diffusion term (right). In both cases the numerical solutions agree with the analytic solution valid in the limit of infinite drag (solid red line), although the pressure is smoother across the contact discontinuity when the diffusion term is computed directly. The advantage of the present scheme compared to the full one fluid approach (LP14b) is that we have used explicit time-stepping. We also avoid the punitive \( h < t_\varepsilon c_s \) resolution requirement associated with the two fluid formulation (LP12b). 569 SPH particles were used.

Figure 4. Dust fraction as a function of spherical radius in the 3D dust diffusion test at \( t = 0.0, 0.1, 0.3, 1, 3 \) and 10 (top to bottom) from simulations using \( 50 \times 58 \times 60 \) particles. The numerical solution, projecting all particles in \( r \), is given by the black dots and may be compared to the analytic solution given by the red lines. The left panel shows the solution with two first derivatives, while the right panel uses the direct second derivative.

Figure 5. Cross section of the dust density in the \( z = 0 \) plane in the 3D dust diffusion test at \( t = 0, 1 \) and 10 (left to right).

where \( A \) and \( B \) are arbitrary constants. We use this solution to verify our numerical scheme by solving only the diffusion equation via either Equations (26) and (30) or Equation (43) with the particle positions fixed (for this problem only).

4.3.2 Results

We set up the problem in 3D with \( 50 \times 58 \times 60 \) particles set on a uniform close-packed lattice in the domain \( x, y, z \in [-0.5, 0.5] \). The positions of the \( y \) and \( z \) boundaries are adjusted slightly to ensure periodicity of the lattice across the boundary (the particle spacing in \( x, y \) and \( z \) is \( \Delta p, \sqrt{3} \Delta p/2 \) and \( \sqrt{6} \Delta p/3 \) respectively, where \( \Delta p = 0.02 \)). We use an isothermal equation of state, setting \( c_s = 1 \) and \( t_\varepsilon = 0.1 \) such that \( \tilde{\eta} = 0.1 \), and set the initial dust fraction using

\[
\epsilon(r, 0) = \epsilon_0 \left[ 1 - \left( \frac{r}{r_c} \right)^2 \right].
\]
consistent with Equation [51] with \( B = \varepsilon_0 r_e^2 \) and \( A = \varepsilon_0 B^2 \). We set \( \varepsilon_0 = 0.1 \) and \( r_e = 0.25 \).

Figure 6 compares the numerical solution to the analytic solution, while Figure 5 illustrates the general behaviour of the solution. The solution with Equation [48] right panel of Fig. 4 is excellent \( L_2 \) error \( \leq 5 \times 10^{-4} \) for \( r < 0.2 \), apart from the physical deviation from the self-similar solution due to the transition to constant rather than negative \( \varepsilon \) at the outer radius. The solution with using Equations [46] and [47] (left panel) is also good, but shows some low amplitude oscillations that develop from the propagation of the ‘kink’ in the initial epsilon profile. These oscillations are worse at lower resolution (they can be smoothed out by adding some artificial dissipation in \( \varepsilon \) but the solution is still not as good as using Equation [48]).

Figure 5 quantifies these results with a convergence study using 8\(^3\), 16\(^3\), 32\(^3\) or 64\(^3\) particles arranged on a cubic lattice. We show the \( L_2 \) error computed by splash [Price 2007] from particles with \( r < 0.2 \). While in both cases the convergence is second order \( \sim (\Delta x)^2 \), it can be seen that the direct second derivatives approach gives results more accurate by a factor of 5 at any given resolution. Our results with both schemes when employing \( \varepsilon \) instead of \( \varepsilon \) (Appendix B) are worse by a factor of \( \sim 2 \), again with a similar preference for the direct second derivatives approach. Thus while it is clear that all of our proposed numerical schemes correctly discretise the diffusion equation, we find the discretisation using Equation [48] to be more accurate for this problem.

### 4.4 Dust settling in a protoplanetary disc

Our final test is drawn from our intended application, namely the dynamics of small grains in protoplanetary discs.

#### 4.4.1 Setup

We simplify the problem by considering only the vertical settling of grains in the \( r-z \) plane. That is, we set up particles in a two dimensional cartesian box with an acceleration in the ‘vertical’ (z) direction given by

\[
\alpha_z = -\frac{GM}{(R_0^2 + z^2)^{3/2}},
\]

where we assume code units such that \( GM = 1 \) and set \( R_0 = 5 \) as a constant. The boundary conditions are periodic in the horizontal (x) direction and free in the vertical direction. We use an isothermal equation of state \( P = c_s^2 \rho \) where the sound speed \( c_s \) is set such that the aspect ratio \( H/R_0 = c_s^2/(\Omega_0 R_0) = 0.05 \), where \( \Omega_0 \equiv \sqrt{GM/R_0^3} \). The orbital time is therefore \( t_{orb} = 2\pi/\Omega_0 \approx 70 \) in code units. We set particles of equal mass initially on a uniform hexagonal lattice in the domain \( x \in [-0.25, 0.25] \) and \( z \in [-3H, 3H] \). We specify the particle separation in the \( x \) direction to be either 16, 32, or 64, resulting in \( 16 \times 56 = 856 \) particles at the lowest resolution, \( 32 \times 111 = 3552 \) particles at medium resolution and \( 64 \times 222 = 14028 \) at the highest resolution.

We then stretch the particle distribution to match the equilibrium density profile using the method described in [Price 2004] where the \( z \) position of each particle is determined by solving the root finding problem

\[
f(z) = \frac{M(z)}{M(z_{\text{max}})} - \frac{(z_\text{0} - z)}{z_{\text{max}} - z_{\text{min}}} = 0,
\]

where \( M(z) = \int_{\text{min}}^z \rho(z')dz' \), \( z_\text{0} \) is the initial position of the particle and we set

\[
\rho(z) = \rho_0 \exp[-z^2/(2H^2)].
\]

We set the mass of each particle equal to \( M(z_{\text{max}}) \) divided by the number of particles in the domain, consistent with the desired density profile. Equation [55] is a slight approximation (fourth order in \( z/H \); e.g. [Laibe et al. 2012]) but this is unimportant since we relax the particles into a hydrostatic equilibrium anyway, as described below.

We set up the simulation initially with only gas and run the calculation to \( t = 1000 \) in code units (i.e. \( \sim 14 \) orbits) with both artificial viscosity and an artificial damping term of the form

\[
\left( \frac{dv}{dt} \right)_{\text{damp}} = -f_{\text{damp}} v,
\]

where \( f_{\text{damp}} = 0.03 \) in order to allow the distribution to relax to equilibrium. We then add dust to the simulation, assuming a dust-to-gas ratio of \( \rho_d/\rho_g = 0.01 \) by setting the dust fraction using

\[
\varepsilon \equiv \frac{\rho_d}{\rho} = \frac{\rho_d/\rho_g}{(1 + \rho_d/\rho_g)}.
\]

We then evolve the simulation for a further 50–100 orbits.

To give the problem physical meaning we consider a distance unit of 10AU (such that \( R_0 = 5 \) corresponds to 50AU), a mass unit of \( 1M_\odot \) and the time unit set such that \( G = 1 \) in code units. This implies an orbital time of \( 2\pi/\Omega_0 = 353 \) years. A midplane density \( \rho_0 \) of \( 10^{-3} \) in code units then corresponds to \( \sim 6 \times 10^{-13} \) g/cm\(^3\), giving a disc surface density \( \Sigma = 55 \) g/cm\(^2\). We adopt a linear Epstein drag prescription, defining the stopping time according to Eq. [20]

\[
\tau_\text{damp} = 1.35 \times 10^{-3} \left( \frac{s_{\text{grain}}}{1\text{mm}} \right) \left( \frac{\rho_{\text{grain}}}{3\text{g/cm}^3} \right) \left( \frac{\rho}{\rho_0} \right)^{-1}.
\]

#### 4.4.2 Setting of millimetre grains

We first perform a series of tests with a grain size of \( s_{\text{grain}} = 1 \) mm, chosen as a balance between the regime where the diffusion method is applicable and where it is still possible to obtain a solution in a reasonable time with the two fluid method. For the setup above...
Figure 7. Settling of mm dust grains in a 2D (r-z) vertical section of a protoplanetary disc at $R_0 = 50$ AU (assuming $H/R = 0.05$; so $H_0 = 2.5$ AU) using $32 \times 111$ mixture particles. The plot shows dust density as a function of time. The top row shows the results using our new dust diffusion method. The solution may be compared to that obtained with the full one fluid formulation from Laibe & Price (2014b) (middle row) and with the two fluid formulation Laibe & Price (2012a,b) (bottom row; uses $32 \times 111$ particles in both gas and dust). Our new method requires half the number of particles compared to the two fluid approach and is 50 times faster.

this is at the limit of where the diffusion method is applicable, and indeed we found that Eq. [16] controlled the timestep, indicating that the time dependence of the differential velocity has started to become important. In LP12a we showed that it was necessary to satisfy $h \leq c_s t_s$ to avoid overestimating the drag. For 1mm grains our two fluid calculations violate this criterion by a factor of $\sim 9, 4.5$ and 2.25 at the midplane at low, medium and high resolution, respectively, but do not appear to show overdamping. Loré-Aguilar & Bate (2014) found that the resolution problem is not as severe when the dust-to-gas ratio is low, suggesting that $h \leq \epsilon c_s t_s$ is a more precise resolution criterion.

Figure 7 shows the dust density in the medium resolution calculations at intervals of ten orbital periods using three different methods. The top row shows the results with our new method em-
Computing this solution required approximately 50 times more cpu time than the diffusion method.

All three methods produce dust settling on a comparable timescale, with only minor differences in the numerical solutions. A more detailed comparison is given in Figure 8, showing the dust density on all particles as a function of $z$ at the same times as those shown in Figure 7. The main noticeable difference is that the two fluid solution contains more noise in the particle distribution. This is because the dust is modelled as a separate set of particles that feel no mutual repulsion, compared to the one fluid case where the dust distribution benefits from the regular arrangement of the mixture particles. The approach with direct second derivatives (top row) produces a slightly over-smoothed solution compared to the the two first derivatives approach (second row) — with the latter giving results that are indistinguishable from the full one fluid method (third row), showing that the diffusion approximation is indeed accurate in this regime.

A major difference between the one fluid methods and the two fluid method is that resolution is tied to the total mass rather than the dust mass. This is evident in Figure 8 where the two fluid method (bottom row) can be seen to better capture the “wings” in the dust density at high latitudes. We quantify this further in Figure 9 with a resolution study of the same problem performed in 1D to avoid the particle noise in the two fluid approach. Settling means that after some time the dust covers a much smaller region of the domain than the gas, so the one fluid formulations under-resolve the dust mass. This is evident in Figure 8 where the two fluid solution contains more noise in the particle distribution. This point is discussed in LP14b mainly as an advantage to the one fluid case where the dust density is comparatively less well resolved.

In obtaining our results with the diffusion approximation, we
found a few caveats to the numerical algorithm we derived in Section 3. First, we found it necessary with both to use the $M_h$ kernel for this problem to obtain a smooth and accurate solution (this kernel extends to 3h instead of 2h and so better approximates the Gaussian). To avoid particle pairing occurring at high latitudes with the quintic we set the ratio of smoothing length to particle spacing to 1.0 instead of 1.2, equivalent to using a mean neighbour number of 28.3 in 2D (see Price 2012). The second caveat was that the dust fraction becomes negative around the edge of the collapsing dust layer in both of our implementations (and also with the full one fluid method). This arises because of the exact conservation of the mass in the algorithm, which causes a slight overshoot at the discontinuity. In order to smoothly handle this we derived an alternative approach (Appendix B) which guarantees a positive dust fraction, but we found it to give less accurate results than the method employing $\epsilon$ (c.f. Sec. 4.3). Instead, we found that the most effective way of solving this was to simply set the dust fraction to zero on particles where it had become negative. This slightly violates the exact conservation of the dust mass, but the error is small ($\sim 10^{-5}$ in $\epsilon$ with the quintic) and it is a small price to pay for stability of the algorithm.

4.4.3 Setting with different grain sizes

Finally, we demonstrate the ability of the diffusion method to simulate small grains in a protoplanetary disc by performing a series of calculations varying the grain size from 0.1$\mu$m to 1mm. Grain sizes below 1mm are difficult to simulate with the two fluid technique because of the punitive spatial and temporal resolution requirements (LP12a, LP12b). With the general one fluid method presented in LP14b the limitation on the spatial resolution is removed, because we are no longer modelling the separation between fluids with physically separate resolution elements, but it is still necessary to use implicit timestepping. Yet these grains are important in protoplanetary discs as they control much of the thermal radiation.

Figure 10 shows the results of a series of medium resolution ($32 \times 111$) calculations of dust settling for different grain sizes, shown after 50 orbits at $R_0$. We used only explicit timestepping, and for grain sizes smaller than 1mm the timestep was constrained only by the Courant condition. The different settling behaviour of the different grain populations in discs is clearly evident, with the micron and sub-micron grains remaining stuck to the gas at high latitudes, the millimetre grains settling effectively to the midplane and the 100 micron and 10 micron grains having partially settled.

Being able to accurately and efficiently simulate single-size small grains in discs in this manner is the first step towards modelling an evolving grain population self-consistently.

5 DISCUSSION AND CONCLUSIONS

We have derived and implemented a numerical scheme for describing the dynamics of small dust grains coupled to a gas, using Smoothed Particle Hydrodynamics, in the limit where the stopping time is short compared to the computational timestep. This requires solving one additional diffusion equation as well as the usual equations of hydrodynamics slightly modified by some additional terms. We derived two implementations, one where the diffusion equation is computed using two first derivatives (Section 3.1) and one where direct second derivatives were employed (Section 3.4). We found only minor differences between the two approaches on the test problems we tried. Given this, we recommend the direct
second derivatives approach (Sec. 3.4), which is both simpler and faster because it does not require an extra loop over the particles.

As discussed in Sec. 2.2, the terminal velocity approximation or, as we prefer, the “diffusion approximation for dust”, is valid when the stopping time is less than the computational timestep. The simple way to guarantee this validity in practice is to ensure that the diffusion timestep (Eq. 16) is not constraining the timestep, otherwise the more general one fluid approach implemented in LP14b where the time dependence of $\Delta t$ is kept should be used instead. In this sense the method we have described is complementary to both the full one fluid approach (LP14b) and the two fluid approach (LP12c). The main difference is that the other methods need implicit timesteps when the grain size is small ($t_s < \Delta t$), whereas this method requires implicit timesteps when the grain size is large ($t_s > \Delta t$), but this is where the approximation breaks down anyway.

Finally, we considered only one grain size at a time in this paper. We have recently generalised our one fluid formulation to describe an arbitrary number of grain populations all within a single fluid mixture (LP14c). Our next step will be a numerical implementation of this more general formulation, including the simplification to a diffusion approximation, as well as modelling the evolution of the grain population including growth and fragmentation.

APPENDIX A: PROOF THAT EQUATION [45] IS A DISCRETE FORM OF EQUATION [4]

Here, we prove that the expression obtained for the second term in Eq. [45] by enforcing the conservation of energy, namely

\[
\frac{1}{2(1 - \varepsilon_c)\rho_b} \sum_b \frac{m_b}{p_b} (u_a - u_b)(D_a + D_b)(P_a - P_b) \frac{F_{ab}}{|r_{ab}|},
\]

is indeed a discrete form of the corresponding term in Eq. [4] i.e.

\[
\frac{\varepsilon_s}{P_b} \nabla P \cdot \nabla u.
\]

We proceed, following [Price 2012], by identifying \(-2F_{ab}/|r_{ab}|\) as equivalent to the second derivative of a (new) kernel function, i.e.

\[
\nabla^2 Y_{ab} \equiv -2F_{ab}/|r_{ab}|.
\]

It may be shown straightforwardly that this new kernel \(Y_{ab}\) indeed satisfies the normalisation conditions appropriate to the kernel second derivative (see [Price 2012] for more details). We can then take the Laplacian of the standard SPH summation interpolant with this kernel, i.e.

\[
A_a \equiv \sum_b m_b \frac{A_{ab}}{p_b} Y_{ab},
\]

to give

\[
\nabla^2 A_a \equiv \sum_b m_b \frac{A_{ab}}{p_b} \nabla^2 Y_{ab}.
\]

By writing (A1) in the form

\[
\frac{1}{4\pi \rho_b^2} \sum_b \frac{m_b}{p_b} (u_a - u_b)(D_a + D_b)(P_a - P_b) \nabla^2 Y_{ab},
\]

we can then use (A5) to translate the various terms. Expanding (A6) we have

\[
\frac{1}{4\pi \rho_b^2} \sum_b \frac{m_b}{p_b} (P_a u_a D_a - P_a u_b D_a + P_a u_a D_b - P_a u_b D_b - P_b u_a D_a + P_b u_b D_a - P_b u_a D_b + P_b u_b D_b) \nabla^2 Y_{ab}.
\]

Translating each of the terms in turn using (A5) gives

\[
\frac{1}{4\pi \rho_b^2} \left[ P_a D \nabla^2 1 - P_a \nabla^2 u - P_a \nabla^2 D - D \nabla^2 (P_u) - P_u \nabla^2 (P D) + \nabla^2 (P a D) \right].
\]

Expanding the \(\nabla^2 (ab)\) terms using the vector identity

\[
\nabla^2 (ab) = a \nabla^2 b + 2(\nabla a \cdot \nabla b) + b \nabla^2 a,
\]

and expanding the last term using

\[
\nabla^2 (P a D) = a D \nabla^2 P + P D \nabla^2 u + P a \nabla^2 D + 2D(\nabla P \cdot \nabla D) + 2D(\nabla P \cdot \nabla u) + 2P(\nabla D \cdot \nabla u),
\]

we find, upon simplification that (A8) reduces to simply

\[
\frac{1}{4\pi \rho_b^2} \left[ 4D(\nabla P \cdot \nabla u) \right].
\]

Hence, (A6) and so (A1) is a discrete form of

\[
\frac{D}{P_b} (\nabla P \cdot \nabla u) = \frac{\varepsilon_s}{P_b} \nabla P \cdot \nabla u.
\]

QED.

APPENDIX B: ENFORCING POSITIVITY OF THE DUST FRACTION

While the usual SPH density summation enforces positivity of the total density, in the one fluid approach there is no constraint on the positivity of the dust fraction, being simply evolved via a differential equation. We found during our testing of the algorithm (Section 4.4) that this can occur in practice, even though we conserve the total dust mass. An simple example is where \(\varepsilon\) is non-zero on only a fraction of the particles and zero on others, implying an infinite gradient in \(\varepsilon\) at the discontinuity surface, which as the dust front evolves can lead to negative \(\varepsilon\) on the particles that initially had zero. It should be noted that however that these errors are small and kernel dependant (i.e. of order \(10^{-5}\) with a quintic kernel). We discuss other possible solutions in Section 4.4, but here present one such solution, which is to evolve the quantity

\[
s = \sqrt{\rho_0 \varepsilon},
\]

instead of \(\varepsilon\). We can enforce the same conservation of dust mass but with a guaranteed positivity of the dust fraction since

\[
\varepsilon_u = \frac{s^2}{\rho_0}.
\]
B1 Continuum equation

In terms of $s$, the local equation for dust mass conservation is

$$\frac{ds}{dt} = \frac{\rho}{2s} \nabla \cdot \left[ s^2 \left( 1 - \frac{s^2}{\rho} \right) \Delta v \right] - \frac{s}{2} \nabla \cdot v. \quad (B3)$$

where as previously $d/dt$ is the convective derivative using the barycentric velocity. For the case of hydrodynamics (Section 2.1.2) where $\Delta v = t_s \nabla P / [(1 - s^2/\rho)\rho]$, we can simplify this to

$$\frac{ds}{dt} = \frac{\rho}{2} \left[ \nabla \cdot \left( s \left( 1 - \frac{s^2}{\rho} \right) \Delta v \right) + \frac{1 - s^2}{\rho} \Delta v \cdot \nabla s \right] - \frac{s}{2} \nabla \cdot v. \quad (B4)$$

B2 SPH implementation with two first derivatives

Conservation of the total dust mass implies

$$\frac{d}{dt} \left( \sum_a m_a s_a^2 \rho_a \right) = 0, \quad (B5)$$

giving

$$2 \sum_a m_a s_a \frac{ds_a}{dt} = \sum_a m_a \frac{d\rho_a}{dt} s_a^2. \quad (B6)$$

To enforce Eq. (B6) we compute the evolution of $s_a$ according to

$$\frac{ds_a}{dt} = -\frac{\rho_a}{2} \sum_b m_b s_b \left( \frac{1 - s_b^2/\rho_b}{\Omega_b \rho_b^2} \Delta v_a \cdot \nabla_s W_{ab} (h_a) \right) + \frac{1 - s_b^2/\rho_b}{\Omega_b \rho_b^2} \Delta v_b \cdot \nabla_s W_{ab} (h_a) \right) + \frac{s_a}{2\rho_a \Omega_a} \sum_b m_b (v_a - v_b) \cdot \nabla_s W_{ab} (h_a). \quad (B7)$$

The first term of the right-hand side of Eq. (B7) corresponds to the first two terms (i.e. inside the brackets) of the right-hand side of Eq. (B3) in the continuous limit (note the factor $s_b$ inside the SPH summation). The contribution of this term to the left-hand-side of Eq. (B6) is zero as it leads to a double summation of an antisymmetric term with respect to the indices $a$ and $b$. The second term of the right-hand-side of Eq. (B7) corresponds to the $\nabla \cdot v$ term of Eq. (B3) and provides the right hand-side of Eq. (B6), which can be seen by differentiating the SPH density summation (24) with respect to time.

B3 SPH implementation with direct second derivatives

We can also construct a method evolving $s$ but with direct second derivatives. Here we discretise Eq. (B4) using

$$\frac{ds_a}{dt} = -\frac{\rho_a}{2} \sum_b m_b s_b \left( D_a + D_b \right) \frac{P_{ab}}{P_{ab}}, \quad (B8)$$

where $D \equiv s^2 t_s/\rho$ as previously. It is straightforward to show that this is indeed a discretisation of (B4) using the method described in Appendix A. The average density is required in the denominator in order to conserve the total dust mass, which can be verified by substituting (B8) into (B6).
