We propose a new approach based on random matrix theory to calculate the temporal second-order intensity correlation function $g^{(2)}(t)$ of the radiation emitted by random lasers and random fiber lasers. The multimode character of these systems, with a relevant degree of disorder in the active medium, and large number of random scattering centers substantially hinder the calculation of $g^{(2)}(t)$. Here we apply for the first time in a photonic system the universal statistical properties of Ginibre’s non-Hermitian random matrix ensemble to obtain $g^{(2)}(t)$. Excellent agreement is found with time-resolved measurements for several excitation powers of an erbium-based random fiber laser. We also discuss the extension of the random matrix approach to address the statistical properties of general disordered photonic systems with various Hamiltonian symmetries.

Random lasers (RLs) and random fiber lasers (RFLs) are low-coherence optical sources which have stood out over the last three decades due to their potential for applications in fabrication and diverse multidisciplinary fields [1–3]. Their optical feedback stems from the multiple photon scattering in a disordered active medium [4], so differing significantly from the two-mirrors mechanism of the Fabry-Perot type of cavity in conventional lasers. In particular, RFLs are the quasi-one-dimensional version of RLs [5], employing an optical fiber with embedded gain and randomly distributed scattering centers.

RFLs have recently attracted a great surge of interest that led to several new configurations, much improved experimental characterization, and already important applications [1–2]. However, much less is known, both experimentally and theoretically [6–9], about their temporal second-order correlation function, $g^{(2)}(t)$, a central quantity related to the second order coherence degree, photon statistics, and intensity fluctuations [10].

The theoretical challenge to obtain $g^{(2)}(t)$ for RL and RFL systems is significant due to their unique properties. The multimode character of RLs and RFLs combined with the intrinsic stochastic dynamics, a relevant disorder degree in the active medium, with many atoms providing the gain, and a large number of random scatterers substantially hinder the calculation of $g^{(2)}(t)$ for these systems. In this context, standard methods applied [10–12] to conventional lasers are practically unfeasible.

In this work, we propose a novel approach to the calculation of the second-order intensity correlation function $g^{(2)}(t)$ in RLs and RFLs based on random matrix theory (RMT) [13–14]. The entries of a random matrix form a set of usually independent random variables, and earlier studies considered statistical ensembles of Gaussian Hermitian random matrices with either orthogonal, unitary, or symplectic properties [13–14]. The seminal work by Ginibre [15] led to a groundbreaking extension of the random matrix formalism to the non-Hermitian counterpart of such ensembles, thus inaugurating a field that is still quite under development [13–14], with striking complexity, rich mathematical structures, and multiple symmetry classes [16]. The diversity of physical systems approached by non-Hermitian RMT has burst since then [13–14], from classical diffusion in random media [17] to complex-energy gapped topological systems [16], to name a few.

Here we provide the first application of non-Hermitian RMT to a photonic system. The erbium-based RFL used in this work has been considered in earlier studies of photonic complex behavior such as glassy phase with Parisi’s replica symmetry breaking [18], extreme events and Lévy statistics [19–21], and turbulence-like properties [22]. This system was the first to comprise a remarkably large set of $\sim 10^3$ specially designed randomly-distributed phase-error-written fiber Bragg gratings, which act as random scatterers of photons [23]. Trivalent Er$^{3+}$ erbium ions randomly distributed in the fiber provide the gain that generates the feedback for random lasing emission above the RFL threshold. Above threshold a large number ($N \approx 200$) of longitudinal modes interact, spatially overlap, and stochastically compete for gain [18].

The above mentioned theoretical difficulties are circumvented in the statistical approach of RMT. By combining the semiclassical stochastic dynamics driven by the non-Hermitian Hamiltonian of the erbium-based RFL with the universal statistical properties of Ginibre’s non-Hermitian Gaussian random matrix ensemble with
the upper incomplete gamma function. A striking feature of the complex matrix elements, and \( \Gamma(z,x) \) where \( N \) complex plane is universally cubic as \( s \rightarrow 0 \) in all three Ginibre ensembles (with orthogonal, unitary or symplectic properties) \([13, 14]\).

\[
P(s) \sim s^{3}e^{-\pi s^{2}/(16s^{2})},
\]

with maximum near the mean level spacing \( \langle s \rangle \). This contrasts with their Hermitian counterparts, whose nonuniversal distributions \( P(s) \sim s^{3}e^{-\pi s^{2}/(16s^{2})} \) indicate level repulsion degree given by the respective Dyson index \( \beta = 1, 2, 4 \) \([13, 14]\), where \( \gamma = \Gamma((\beta + 2)/2)/\Gamma((\beta + 1)/2) \) and \( \Gamma(z) \) is the gamma function.

The fluctuations in the time series of intensities of optical spectra of the Er\(^{3+}\)-based RFL can thus be modelled by a stochastic dynamics governed by a non-Hermitian random matrix. The Heisenberg equation of motion for \( \alpha_{\lambda} \) yields

\[
\frac{d\alpha_{\lambda}}{dt} = i[\hat{H}, \alpha_{\lambda}] + S + \xi_{\lambda}.
\]

In a semiclassical context, operators \( \alpha_{\lambda}^{\dagger}(t) \) and \( \alpha_{\lambda}(t) \) are replaced in \( \hat{H} \) by their complex expected values, i.e., we now work with the functional \( \hat{H}[\alpha_{\lambda}^{\dagger}, \alpha_{\lambda}] \) instead of the operator \( \hat{H}[\alpha_{\lambda}^{\dagger}, \alpha_{\lambda}] \). Further, the noise can be made uncorrelated (white) through a proper choice of basis transformation, \( a_{\nu}(t) = \sum_{\lambda} T_{\nu\lambda} \alpha_{\lambda}(t) \). The stochastic semiclassical dynamics of \( a_{\nu}(t) \) is then driven by a system of coupled equations with uncorrelated (white) noise \( \xi_{\nu} = \sum_{\lambda} T_{\nu\lambda} \xi_{\lambda} \).

For excitation powers near the threshold in the random lasing regime, higher-order nonlinear terms in \( \hat{H} \) are perturbatively negligible if compared to the quadratic term with random couplings \( g_{\lambda\lambda'} \):

\[
\hat{H}[\alpha_{\lambda}^{\dagger}, \alpha_{\lambda}] = -\sum_{\lambda\lambda'} g_{\lambda\lambda'}^{*} \alpha_{\lambda}^{*} \alpha_{\lambda'} + \mathcal{O}(\langle \alpha_{\lambda}^{*} \alpha_{\lambda} \rangle^{2}),
\]

where \( g_{\lambda\lambda'} \) displays nonzero off-diagonal elements due to the openness of the RFL. In this regime the set of coupled differential equations for \( a_{\nu}(t) \) presents stationary solution \( a_{\nu}(t \rightarrow \infty) \) satisfying

\[
\sum_{\nu' \neq \nu} \tilde{g}_{\nu\nu'} a_{\nu'}(\infty) + \tilde{g}_{\nu\nu} a_{\nu}(\infty) + S_{\nu} = 0,
\]

with \( \tilde{g}_{\nu\nu'} = \sum_{\lambda\lambda'} T_{\nu\lambda} g_{\lambda\lambda'} T_{\nu'\lambda}^{-1} \) and \( S_{\nu} = \sum_{\lambda} T_{\nu\lambda} S_{\nu} \). The normal modes have the form \( \tilde{a}_{\nu}(t) = \tilde{a}_{\nu}(\infty) + A_{\nu} e^{i\omega_{\nu}t} \), where \( \omega_{\nu} \equiv \omega_{n} + \gamma_{n} \) denotes the random complex eigenvalues of the non-Hermitian matrix \( \tilde{g}_{\nu\nu'} \).

In the semiclassical approach the RFL intensity reads

\[
I(t) = \sum_{\nu} |\tilde{a}_{\nu}(t)|^{2}.
\]

By calculating the temporal second-order intensity correlation function,

\[
g^{(2)}(t) = \frac{(I(t + t')I(t'))}{(I(t'))^{2}},
\]

with averages taken over a time interval much larger than the system’s relevant time scales, we obtain \( g^{(2)}(t) \) in the
convenient form,

$$g^{(2)}(t) = 1 + \sum_n b_n \cos(x_n t - \varphi_n)e^{-y_n t} + \sum_n c_n e^{-2y_n t},$$

with prefactors $b_n$ and $c_n$ and phases $\varphi_n$ arising from the modes overlapping integrals at distinct times in Eq. (6). In the GinUE ensemble, eigenvalues and level spacings are distributed as in Eqs. (1) and (2), respectively. This result for $g^{(2)}(t)$ generally applies to RL and RFL systems comprising even quite distinct time scales. Indeed, the time scales that emerge from the Hamiltonian eigenvalues are naturally set from the fit of the experimental data to Eq. (7) together with Eqs. (1) and (2). For higher excitation powers the addition in Eq. (4) of a fourth-order term with random couplings between a large number of modes leads to a renormalized second-order coupling and Eq. (7) remains approximately valid.

The experimental data of the Er\textsuperscript{3+}-based RFL are fit to Eq. (7) for several excitation powers. Notably, the eigenvalue statistics and universal features of the level repulsion also set the main time scales of $g^{(2)}(t)$.

The experimental data of the Er\textsuperscript{3+}-based RFL are fitted below to Eq. (7) for several excitation powers. The stability of the pump source contrasts with the periodic behavior responsible for the photonic Floquet phase transitions and perturbations in the random matrix properties of GinUE ensemble, compared to its Hermitian counterpart [13, 14].

FIG. 1. (a) Experimental setup of the Er\textsuperscript{3+}-based RFL showing (1) the CW pump laser, (2) optical spectrum analyzer (OSA), (3) wavelength division multiplexer (WDM), (4) RFL, (5) coupler, (6) InGaAs photodetector, (7) oscilloscope, and (8) spectrometer. (b) Spectral profiles below ($P/P_{th} = 0.9$) and above ($P/P_{th} = 1.3$) the RFL threshold. (c) Intensity signal (black; light gray in the printed version of the article) and second-order correlation function $g^{(2)}(t)$ below (in both online and printed versions) of the Er\textsuperscript{3+}-based RFL for $P/P_{th} = 4.0$ with effectively Q-switched pulses of nearly same periods, as shown by symbols + at the maxima. The intensity was displaced in time so its first maximum coincides with that of $g^{(2)}(t)$. (d) Homogeneous intensity fluctuations of the pump source.
introduce the parametrization consistent with cubic degree level repulsion, Eq. (2), and \( \Delta n \) eigenvalues set by theoretical analysis in the random matrix approach. We define the nearest-neighbor level spacing in an ordered eigenvalues set by \( s_n = (\Delta x_n^2 + \Delta y_n^2)^{1/2} \), where \( \Delta x_n = x_{n+1} - x_n \) and \( \Delta y_n = y_{n+1} - y_n \). To generate a sequence of \( N \) eigenvalues \( \omega_n \) with level spacing distribution consistent with cubic degree level repulsion, we follow a procedure analogous to [34]. We conveniently introduce the parametrization \( \Delta x_n = 2\pi(1 + \delta_n)/T \) and \( \Delta y_n = \kappa(1 + \gamma_n) \), with \( \kappa = 2\pi((s)T/2\pi^2 - 1)^{1/2}/T \), \( |\delta_n| \ll 1 \) and \( |\gamma_n| \ll 1 \), so that the random spacings \( s_n \) are given by small fluctuations around the mean \( s \).

Also, as the prefactors and phases in Eq. (7) depend on the random eigenvalues \( \{\omega_n\} \), we associate a weight proportional to \( \rho(\omega_n) \), Eq. (1), with each term in the sums in (7). In this parametrization \( T \) gives the average temporal separation between consecutive maxima in \( g^{(2)}(t) \), whereas \( \kappa \) governs its long-t envelope exponential decay. So we set a noteworthy link between the universal properties of the level spacing and eigenvalue statistics in the random matrix ensemble and the main time scales of the second order correlation function of the RFL.

Figure 3(a) shows the eigenvalue density \( \rho(\omega) \) in the complex plane, Eq. (1), using the relation \( |\omega|^2/\sigma^2 = 4\pi^2/T^2\sigma^2 \), where \( T = 74.0 \) \( \mu s \) and \( \sigma = 5.88 \times 10^5 \) \( s^{-1} \). Figure 3(b) displays the probability distribution \( P(s/\langle s \rangle) \) of normalized nearest-neighbor level spacings \( s / \langle s \rangle \) in the Ginibre ensemble, Eq. (2), with average \( \langle s \rangle = 8.51 \times 10^4 \) \( s^{-1} \). Figure 3(c) shows in black circles the experimental data of one measurement of \( g^{(2)}(t) \) near the threshold, \( P/P_{th} = 1.6 \), and the fit to the model result (7) in dash-dotted green lines. The model fit value \( T = 74.0 \mu s \) compares nicely with the experimental measure \( T_{exp} = 74.3 \mu s \). The remaining fitting parameters are \( b_n = 9.22 \times 10^{-5}, c_n = 2.31 \times 10^{-6}, \) and \( \varphi_n = 0.1 \) in order to keep the fitting procedure as simple as possible, we assume that the dependence of \( b_n, c_n, \) and \( \varphi_n \) on the eigenvalues is not too strong and thus effectively work with only one value for each of these three families of parameters). We also consider \( N = 200 \) as the number of modes of the Er\( ^{3+} \)-based RFL, which was determined using the speckle contrast technique [18]. These values imply a time constant \( \kappa^{-1} \sim 120 - 300 \) \( \mu s \) consistent with the lifetime range [35] of the active state of Er\( ^{3+} \) ions in the random lasing regime of the CW pumped Er\( ^{3+} \)-based RFL. Indeed, the observed time scales depend on the Er\( ^{3+} \) dynamics in the system, so that the typical millisecond Er\( ^{3+} \) time scale can be in fact lowered to the range of a few hundreds of microseconds when the system operates in the laser regime above threshold, in agreement with our estimates.

Finally, we display in Figs. 4(a) and 4(b) the results for intermediate and high excitation powers, \( P/P_{th} = 2.4 \) and \( P/P_{th} = 4.0 \), respectively. As before, a good comparison is found between the periods: \( T = 48.0 \mu s \) and \( T_{exp} = 48.2 \mu s \) in Fig. 4(a), while \( T = 47.4 \mu s \) and \( T_{exp} = 47.5 \mu s \) in Fig. 4(b). In particular, the pulse repetition rate \( (x T^{-1}) \) increases monotonically with \( P \), in agreement with results on a random Q-switched fiber laser [32].

In conclusion, in this work we have proposed a new approach to the problem of calculating the second-order intensity correlation function in RL and RFL systems, with application to an Er\( ^{3+} \)-based RFL. It is difficult to overstate the benefits that the RMT approach can bring to photonic systems exhibiting some kind of disorder. Rather than working with a huge set of (virtually unfeasible to determine) disordered mode couplings in the photonic Hamiltonian, the statistical RMT approach takes advantage of the eigenvalue statistics, eigenvector correlators, level spacing density, and repulsion degree, among other features.

The symmetry properties of each photonic system may guide the proper statistical ensemble to adopt. Thus, a
FIG. 4. Measurements (black) of the second order correlation function \( g^{(2)}(t) \) of an Er\(^{3+}\)-based RFL for (a) intermediate \( (P/P_{th} = 2.4) \) and (b) high \( (P/P_{th} = 4.0) \) excitation powers. Model results (dash-dotted green), Eq. (7), show nice agreement with the experimental data.

diversity of general disordered photonic systems including RLs and RFLs, described by orthogonal, unitary or symplectic Hamiltonian random matrices, either Hermitian or non-Hermitian, with real, complex or quaternionic elements and multiple symmetry classes [13–16], can in principle have their statistical emission and further photonic properties addressed by the RMT approach.

We thank the support from CNPq, CAPES, FACEPE, and Instituto Nacional de Fotônica (Brazilian agencies).
