Abstract

Background: DYT1 early-onset generalized dystonia is a neurological movement disorder characterized by involuntary muscle contractions. It is caused by a trinucleotide deletion of a GAG (ΔGAG) in the DYT1 (TOR1A) gene encoding torsinA; the mouse homolog of this gene is Dyt1 (Tor1a). Although structural and functional alterations in the cerebellum have been reported in DYT1 dystonia, neuronal morphology has not been examined in vivo.

Methodology/Principal Findings: In this study, we examined the morphology of the cerebellum in Dyt1 ΔGAG knock-in (KI) mice. Golgi staining of the cerebellum revealed a reduction in the length of primary dendrites and a decrease in the number of spines on the distal dendrites of Purkinje cells. To determine if this phenomenon was cell autonomous and mediated by a loss of torsinA function in Purkinje cells, we created a knockout of the Dyt1 gene only in Purkinje cells of mice. We found the Purkinje-cell specific Dyt1 conditional knockout (Dyt1 pKO) mice have similar alterations in Purkinje cell morphology, with shortened primary dendrites and decreased spines on the distal dendrites.

Conclusion/Significance: These results suggest that the torsinA is important for proper development of the cerebellum and a loss of this function in the Purkinje cells results in an alteration in dendritic structure.

Introduction

Dystonia is a neurological syndrome characterized by involuntary contractions of both agonist and antagonist muscles of affected regions that cause twisting and abnormal movements or postures [1]. DYT1 dystonia is a genetically determined form of generalized early-onset dystonia, with an age of onset between childhood and adolescence. Symptoms usually first affect the lower limbs and eventually progress to the entire body [2]. DYT1 dystonia is caused by a trinucleotide deletion of a GAG (ΔGAG) codon in the DYT1 (TOR1A) gene, which results in the loss of a glutamic acid residue in the C-terminal region of the torsinA protein [3]. We previously generated Dyt1 ΔGAG knock-in (KI) mice, a mouse model of DYT1 dystonia, showed impairments of motor coordination and balance in the beam-walking test and hyperactivity in the open-field test [4]. The function of torsinA is largely unknown, but it is a member of the AAA+ ATPase superfamily and is believed to have a chaperone-like function [5,6,7,8,9,10].

Biochemical and cellular studies show that torsinA localizes to the endoplasmic reticulum [6], protects against oxidative stress, and prevents protein aggregate formation [5,7,8,9]. In situ hybridization studies have also revealed that torsinA mRNA is highly expressed in the dopaminergic neurons of the substantia nigra pars compacta, granule and pyramidal neurons of the hippocampus, Purkinje and dentate nucleus neurons of the cerebellum, and cholinergic neurons of the neostriatum [11,12]. Furthermore, ultrastructural studies of the striatum of humans and macaques have revealed an association of torsinA immunostaining with small vesicles within axons and presynaptic terminals forming symmetric synapses [13].

Growing evidence suggests that the structural and/or functional abnormalities in the cerebellum could be involved in the pathogenesis of dystonia. Brain imaging studies have revealed structural grey matter changes in the cerebellum of patients with upper limb dystonia [14], cervical dystonia, and blepharospasm [15,16]. Increased activation of the cerebellum in the patients with DYT1 dystonia carriers and alterations in the olivo-cerebellar pathway of patients with primary focal dystonia have been reported [17]. Furthermore, there are several reports showing that trauma to the cerebellum or cerebellar atrophy can cause dystonia [18,19]. In a genetically dystonic rat that harbors a mutation in the...
gene caytaxin, cerebellectomy eliminates the motor symptoms and rescues the juvenile lethality [20,21]. Electronic lesions of dorsal portions of the lateral vestibular nuclei (dLV), which receive input from the Purkinje cells, are associated with the greatest improvement in this rat [22]. The Purkinje cells send the major inhibitory signal from the cerebellum to the deep cerebellar nuclei, which is mediated by the neurotransmitter γ-aminobutyric acid (GABA). Pharmacological disruption of the cerebellar signaling is also shown to induce dystonia in mice [23]. Lastly, the tottering mouse, which has a recessive mutation of a calcium channel gene, shows ataxia and paroxysmal dystonia, but this phenotype can be eliminated by surgical removal of the cerebellum or introduction into a Purkinje cell-specific degenerative background [24,25].

Despite these findings, few studies have sought to examine the potential role of the Purkinje cells in the pathogenesis of DYT1 dystonia and other dystonias. In this study, we examined the morphology of the cerebellum in Dyt1 ΔGAG knock-in (KI) mice. Golgi staining of the cerebellum of KI mice revealed a reduction in the length of primary large dendrites and a decrease in the number of spines on the distal dendrites of Purkinje cells. Since it has been reported that the ΔGAG mutation causes a reduction of torsinA in the striatum and the entire brain [26,27,28], we sought to determine if this phenomenon was mediated by a loss of function of the Dyt1 gene only in Purkinje cells (Dyt1 pKO) of mice. We previously reported the making of Dyt1 loxP mice [29]. In the present study, we produced Dyt1 pKO mice by crossing the Dyt1 loxP mice with Pcp2-cre mice, which restricts lox-mediated recombination to Purkinje cells [30]. We found that the Purkinje cells in the Dyt1 pKO mice have a similar morphology to that of the KI mice, with shortened primary large dendrites and decreased spines on the distal dendrites.

**Results**

**Golgi staining of Purkinje cells in KI mice**

To examine the morphological structures of the Purkinje cells in KI mice, we used Golgi staining of cerebellar sections. First, the sizes of the Purkinje cell soma were measured and no significant difference was found between the KI and control (CT) mice (means ± standard errors; CT: 100±2.22%; KI: 99.19±1.35%; p>0.05, Figure 1A–1B). However, the length of the large primary dendrite in the KI mice was approximately 20% shorter than those in the control mice (CT: 100±7.84%; KI: 80.13±2.95%; p<0.01, Figure 1C). Furthermore, the number of spines in the quaternary dendrite branch of KI mice was approximately 27% percent less than those in control mice (CT: 100±1.93%; KI: 73.11±2.17%; p<0.01, Figure 1D–1E). These results suggest the important role of torsinA in the dendritic structure and morphology of Purkinje cells.

**Generation of the Purkinje-cell specific Dyt1 conditional knockout (Dyt1 pKO) mice**

To examine whether the morphological alterations in the KI mice was caused by a loss of torsinA function in Purkinje cells, we generated a Purkinje cell specific knockout of the Dyt1. Dyt1 loxP mice [29] were crossed with a line of mice with the cre recombinase gene driven by the promoter of Pcp2, a Purkinje cell-specific gene [30]. Mice double heterozygous for both the Dyt1 loxP and Pcp2-cre were then crossed with Dyt1 loxP homozygous mice to derive Dyt1 pKO mice and their control littermates (Figure 2A). Genotyping for Dyt1 pKO and control littermates was performed by multiplex PCR (Figure 2B). We confirmed Purkinje cell specific knockout of Dyt1 by in situ hybridization. TorsinA mRNA was highly expressed in the Purkinje cells in control littermates (Figure 2C.1). In contrast, torsinA mRNA was not detected in Purkinje cells in Dyt1 pKO mice (Figure 2C.2), suggesting Dyt1 was specifically knocked out in the Purkinje cells.

**Golgi staining of Purkinje cells in Dyt1 pKO mice**

To examine whether the Dyt1 pKO mice recapitulate the dendritic morphology of the KI mice, we performed Golgi staining on cerebellar sections from Dyt1 pKO mice at approximately 8 months old. Similar to the KI mice, no significant difference in the size of the Purkinje cell soma in Dyt1 pKO mice compared to control mice was observed (CT: 100±3.20%; Dyt1 pKO: 94.27±2.92%; p>0.05, Figure 3A–3B). Furthermore, the length of the large primary dendrite in the Dyt1 pKO mice was approximately 37% shorter than those in control mice (CT: 100±5.65%; Dyt1 pKO: 63.36±1.73%; p<0.001, Figure 3C). Lastly, the number of spines in the quaternary dendrite branch of the Dyt1 pKO mice was approximately 33% less than those in control mice (CT: 100±3.45%; Dyt1 pKO: 67.36±2.2%; p<0.01, Figure 3D–3E). These results suggest that torsinA plays an important role in the Purkinje cell dendritic development.

To examine whether the morphological alteration in Purkinje cells was developmentally regulated, we analyzed the Purkinje cells in Dyt1 pKO mice at 2–3 months old. No significant difference in the size of the Purkinje cell soma in Dyt1 pKO mice was observed compared to control mice (CT: 100±3.71%; Dyt1 pKO: 98.01±2.52%; p>0.05). There was also no significant difference in the length of the large primary dendrite in Dyt1 pKO mice compared to control mice (CT: 100±3.81%; Dyt1 pKO: 90.68±3.37%; p>0.05). However, the number of spines in the quaternary dendrite branch of the Purkinje cells in Dyt1 pKO mice was reduced compared to control mice (CT: 100±3.79%; Dyt1 pKO: 93.47±0.85%; p<0.001). The results suggest that the spine numbers reduced in advance of the reduction of the length of the large primary dentrite by the loss of torsinA function in the Purkinje cells.

**Discussion**

First, we examined the morphology of Purkinje cells in the cerebellum in KI mice. We found that the primary large dendrites of the Purkinje cells in KI mice were significantly shorter than that of wild type mice and there was a marked reduction in the number of spines. Next, to determine if this morphological change was mediated by a cell-autonomous effect of loss of torsinA function, we generated a line of mice in which torsinA was conditionally knocked out only in Purkinje cells. The Dyt1 pKO mice showed a similar decrease in the length of primary large dendrites and a reduction in the number of spines. The results also suggest that the spine numbers reduced in advance of the reduction of the length of the large primary dendrite by the loss of torsinA function in the Purkinje cells. These results suggest that torsinA plays an important role in the development of the cerebellum, and that a loss of this function in the Purkinje cells results in a cell autonomous effect leading to an alteration in dendritic structure. If the same alterations are present in patients with DYT1 dystonia, this change in synaptic associations between the parallel fibers and the Purkinje cells may contribute to the pathogenesis of the dystonic symptoms.

Growing evidence suggests that structural and functional abnormalities in the brain could be involved in the pathogenesis of dystonia [14,15,16,31]. However, neuronal morphology of the cerebellum has not been examined in vivo. A recent report suggests that DYT1 dystonia is a neurodevelopmental disorder involving...
Anatomical studies have proposed an interaction between the cerebellum and the basal ganglia through a disynaptic pathway originating in the cerebellum and projecting to the striatum via the thalamus [33]. A deficiency in this connectivity was identified in patients with DYT1 human carriers [34]. Additionally, rats that have undergone a hemicerebellectomy were found to have a complete loss of striatal long-term depression (LTD) [35], which was also compromised in mutant human torsinA transgenic mice [36]. Since the Purkinje cells are the sole output from the cerebellum, the abnormal function of Purkinje cells, as represented by our results, may be responsible for the change in striatal LTD in mutant torsinA animals.

Figure 1. Purkinje cells in Ki mice. (A) A representative Purkinje cell trace (left). A representative Purkinje cell from CT and Ki mice at 40× magnification (right). (B) There was no significant difference in size of the Purkinje cell soma between CT and Ki mice. (C) However, the large primary dendrite of the Purkinje cells in the Ki mice was significantly shorter than those in CT mice. (D) Next, the quaternary dendrite branch of CT and Ki mice was examined at 100× magnification. (E) The number of spines on the quaternary dendrite branch in the Ki mice was significantly reduced compared to CT mice. Scale bars in Panel A represent 10 μm. Scale bars in panel D represent 1 μm. doi:10.1371/journal.pone.0018357.g002
The Purkinje cells play an important role in motor coordination and motor learning by integrating two types of excitatory inputs: climbing fibers and parallel fibers. Climbing fibers originate from the inferior olivary nucleus and convey the motor signals to the parallel fibers. Parallel fibers are the T-shaped axons of cerebellar granule cells, and convey the sensory and motor information carried through the pontocerebellar and spinocerebellar mossy fiber pathways. It is also known that the parallel fiber-Purkinje cell (PF-PC) synapse plays an important role in the adaptive learning process [37]. Glutamate receptor δ2 subunit (GluRδ2) is selectively expressed in the Purkinje cells of the cerebellum [38]. Impairment of motor coordination, Purkinje cell synapse formation, and cerebellar LTD was reported in GluRδ2 mutant mice [39]. GluRδ2 mutant mice were unable to stabilize PF-PC synapses and resulted in a reduction in the number of PF-PC synapses along with impaired CF synapse elimination [40]. We previously reported motor deficits in KI mice [4] and in this study found morphological alterations of Purkinje cells in KI mice. The results suggest that functional alterations of the cerebellum may associate with the pathogenesis of DYT1 dystonia.

Furthermore, torsinA is known to interact with kinesin 1 [41], a motor protein involved in cellular transport and the cytoskeleton.

![Figure 3. Purkinje cells in Dyt1 pKO mice.](image-url)
of the cell. In vitro studies have shown that suppression of kinesin leads to decreased neurite extension in hippocampal neurons [42]. Furthermore, in human neuroblastoma cells, it was shown that overexpression of mutant torsinA also leads to decreased neurite extension [43]. A decrease in neurite extension possibly through kinesin could explain the decrease in primary dendritic length. In addition to the shortened primary dendrite length, however, the KI mice also showed a decrease in spine number. This decrease in neurite extension would not explain the decrease in number of spines. Recent reports have shown that overexpression of mutant human torsinA in Drosophila results in altered synaptic morphology at the neuromuscular junction [44]. It is, therefore, likely that this decrease in spine number results in altered synaptic plasticity, possibly leading to decreased parallel fiber connectivity.

Lastly, we have created a novel Purkinje cell-specific knockout of Dyt1 to compare its morphology to the KI and wild-type mice. Several genetic studies suggest that a loss-of-function of torsinA contributes to the pathology of dystonia [28,29,45]. We have found the Dyt1 pKO mice replicates the KI dendritic morphology of Purkinje cells, in that they have decreased primary dendrite length and decreased spine number. These findings suggest that the ΔGAG mutation in the KI mice results in a loss of function of torsinA and provide further evidence of the important role of torsinA in the cerebellum.

In conclusion, these results add to the growing body of evidence of the importance of the cerebellum in the pathogenesis of dystonia and this being the first reported morphological alteration in the cerebellum. Furthermore, these results suggest that torsinA plays an important role in the regulations of dendritic length and spine number in the cerebellum. Finally, the ΔGAG mutation in the Dyt1 may result in a loss of function of torsinA in the Purkinje cells. These findings will further the understanding of the pathophysiology that underlies not only DYT1 dystonia but also possibly other neurological movement disorders.

Materials and Methods

Animals

All experiments were carried out in compliance with the USPHS Guide for Care and Use of Laboratory Animals and approved by the Institutional Animal Care and Use Committee at the University of Alabama at Birmingham with Animal Protocol Number 10009510. All experiments were performed by investigators blind to the genotype of the mice. Dyt1 loxP mice were generated as previously described [29]. To generate the Purkinje cell-specific knockout, Dyt1 loxP mice were first crossed with Ppna2-cre mice [30]. The double heterozygous mice were then crossed with Dyt1 loxP homozygous mice to derive Dyt1 pKO mice and their control littermates. Genotyping for Dyt1 pKO and control littermates was performed by multiplex PCR using F (5’-ATTCCAAAAATGTGTGCATAGCCAGG-3’) and T (5’-CTACAGTGCGCCGTAATGTGGG-3’) primer sets [29] for Dyt1 loxp and creA (5’-ATCTCCCGGTATGGAA-CTCCAGGCGG-3’) and creB (5’-CACCTCAGTTAGAAAAATGCC-GATG-3’) primer sets for cre [46]. KI mice were prepared and genotyped as previously described [4]. Mice were housed under a 12-h-light/dark cycle with ad libitum access to food and water.

In Situ Hybridization

Purkinje-cell specific knockout of torsinA was confirmed by in situ hybridization. To prepare the Digoxigenin (DIG)-labeled probe, a DNA fragment corresponding to 3’-UTR of Dyt1 was amplified by PCR with a primer sets of Dyt1insitu2 (5’-CACCAAGCTGCACTACGCTTGA-3’) and Dyt1insitu3 (5’-GAAAAGCTTCTATATTTAAGGACC-3’) and Dyt1 DNA plasmid template. The amplified PCR fragment was then ligated into a pGEM-T Easy vector (Promega). Next, the construct was transformed in E. coli JM109 competent cells (Promega) and single colonies were isolated. An appropriate clone that had the DNA fragment in the correct direction was confirmed by PCR using T7 and Dyt1insitu3 primer sets. The plasmid DNA was purified and cut with the restricted enzyme NotI. The DNA fragment was purified and dissolved in diethyl pyrocarbonate (DEPC)-treated water. DIG-labeled probe for Dyt1 was prepared by using digoxigenin RNA labeling kit with the SP6 promoter (Roche Applied Science, Indianapolis, IN). In situ hybridization to sagittal sections of the cerebellum was performed as previously described [47].

Golgi staining

Adult KI mice (CT: n = 4; KI: n = 7, approximately 8 months old), Dyt1 pKO mice (CT: n = 3; Dyt1 pKO: n = 3, approximately 8 months old), and another batch of Dyt1 pKO mice (CT: n = 4; Dyt1 pKO: n = 4, 2–3 months old) were used in this experiment. After mice were deeply anesthetized with pentobarbital (1 ml/kg, intraperitoneally), the cerebellum was quickly removed and prepared for Golgi staining using the FD Rapid Golgi Stain Kit (FD NeuroTechnologies, Ellicott City, MD). After staining, the cerebellum was frozen with dry ice and sectioned parasagittally (150 μm) using a sliding microtome (Histoslide 2000, Reichert-Jung). The sections were then mounted on slide, dehydrated with xylene and then cover-slipped with permount (Fisher Scientific). Images of individual Purkinje cells were captured using a Nikon ECLIPSE E800 M microscope with a 40X Plan Fluor objective lens. The size of each Purkinje cell soma and the length of the large primary dendrite (5 to 16 cells from each mouse) were measured using ImageJ software (NIH, Ver. 1.42 g). Quaternary dendrite branches from the soma as shown in Figure 1A were chosen at random and the spines were counted. The numbers of spines located on randomly selected quaternary dendrite branches (5 to 16 cells from each mouse), 10 μm in length, were counted manually using a 40x and 100x Plan Fluor objective lens and a 10x CIHU ocular lens. The size of Purkinje cell soma, the length of the large primary dendrite, and the spine numbers were measured by an investigator blind to the genotypes and the data were analyzed by another investigator.

Statistical analysis

The area (μm²) of each Purkinje cell soma and the length of the large primary dendrite (μm) were measured and the data were normalized to control mice and expressed as percentage. The number of spines were counted and normalized to that of control mice. All results were analyzed using Student’s t-test. Significance was assigned by a P-value less than 0.05.
