ABSTRACT

BACKGROUND AND PURPOSE: Objective and quantitative data to define cerebellar vermis and/or brain stem hypoplasia in children are lacking. Our aim was to provide MR imaging biometric references for the cerebellar vermis and brain stem from a large cohort of children with normal cerebellums.

MATERIALS AND METHODS: The MR imaging data were retrospectively selected from our hospital data base from January 1, 2014, to December 31, 2017. All MR imaging examinations of children between 1 day and 15 years of age, including midline sagittal sections, were included. Children with a clinical history or MR imaging abnormalities that may affect the posterior fossa were excluded. We manually measured four 2D parameters: vermian height, anterior-posterior diameter of the vermis, anterior-posterior diameter of the midbrain-pons junction, and anterior-posterior midpons diameter. The inter- and intraobserver agreement was evaluated.

RESULTS: Seven hundred eighteen children were included (372 boys and 346 girls), from 1 day to 15 years of age. Normal values (third to 97th percentiles) were provided for each parameter. The vermis parameters showed a rapid growth phase during the first year, a slower growth until the fifth year, and finally a near-plateau phase. The brain stem parameters showed more progressive growth. The intra- and interobserver agreement was excellent for all parameters.

CONCLUSIONS: We provide reference biometric data of the vermis and the brain stem using simple and reproducible measurements that are easy to use in daily practice. The relevance of these 2D measurements should be further validated in diseases associated with cerebellar abnormalities.

ABBREVIATIONS: APD-MP = anterior-posterior diameter at the midbrain-pons junction; APD-P = anterior-posterior midpons diameter; APD-V = anterior-posterior diameter of vermis; H-V = vermian height; ICC = intraclass correlation coefficient

The important role of the cerebellum in nonmotor functions has been confirmed in recent studies performed in healthy subjects. In this setting, the diagnosis of cerebellar hypoplasia is essential, particularly in children with mental retardation in whom impairment in cerebellar cognitive functions is frequently observed. Cerebellar hypoplasia has been further associated with impairment in reasoning, spatial recognition, language, timing of the speech, and disorders of personality.

Even if different methods of volumetry and segmentation have already been reported in the literature, the interpretation of the vermis as normal or pathologic in daily routine is only based on subjective criteria. Because morphologic variations and changes occur throughout infancy, this subjective approach may be inappropriate to state the normality of the vermis or to claim the diagnosis of vermian hypoplasia, which is defined as a small, harmonious vermis with fissures of normal width. Pons hypoplasia has been also described in association with vermis abnormalities in specific syndromes such as pontocerebellar hypoplasia.

To our knowledge, no reference data have been published that can be easily used in daily practice to define vermis or pons hypoplasia. The aim of our study was to provide reference biometric data of the vermis and brain stem from a large cohort of children with normal cerebellums and brain stems to increase the accuracy of MR imaging for the diagnosis of vermis and/or pons hypoplasia.
MATERIALS AND METHODS

Population

The protocol has been approved by our institutional review board. Given the retrospective nature of the study, informed consent from the parents was not required. The MR imaging data were nonconsecutive cases selected retrospectively from our hospital data base from January 1, 2014, to December 31, 2017.

MR imaging examinations of children between 1 day and 15 years of age, including midline sagittal sections from 2D or 3D T1- or T2-weighted sequences, were included. All children in the present study had no self- or parent-reported clinical history of cognitive disorders or mental illness that could have a potential impact on the cognitive status and cerebellum alteration. We also excluded all patients with a history or symptoms that may be responsible for or associated with cerebellar abnormalities: prematurity (birth at <37 weeks of amenorrhea according to the World Health Organization), metabolic disorder, neuropsychological disorder, hypoxic pathology, cerebellar syndrome, autistic syndrome, axial hypotonia, delayed acquisition, posterior fossa pathology, and posterior fossa or midline malformation. All MR images were reviewed by a board-certified pediatric neuroradiologist to ensure that there were no posterior fossa abnormalities. Mass effect, signal abnormalities, vermian or pons hypoplasia, atrophy, and other midline malformations were sought, and if present, the corresponding data were excluded. The MR imaging data that did not allow precise measurements because of unsatisfactory quality were also excluded.

MR Imaging Analysis

All acquisitions were performed on a 1.5T MR imaging scanner (Ingenia; Philips Healthcare, Best, the Netherlands). Midline sagittal sections were obtained from 2D sagittal T1- or T2-weighted sequences or reconstructed from 3D T1-weighted sequences (section thickness, ≤3 mm).

All measurements were performed by a board-certified neuroradiologist. Simple 2D measurements were manually performed on a sagittal section passing through the midsagittal plane and were defined as follows: 1) The height of the vermis (H-V) was the largest craniocaudal diameter of the vermis; 2) the anterior-posterior diameter of the vermis (APD-V) was the largest anterior-posterior diameter of the vermis passing through the tip of the V4; 3) the anterior-posterior diameter of the midbrain-pons junction (APD-MP) was measured perpendicular to the major axis of the brain stem passing through the midbrain-pons junction; and 4) the anterior-posterior midpons diameter (APD-P) was measured perpendicular to the major axis of the brain stem passing through the middle of thepons (Fig 1).

To evaluate the interobserver reproducibility, a second senior neuroradiologist performed the measurements independently on a sample of 50 children randomly selected. Each radiologist was unaware of the results obtained by the other one. Moreover, to evaluate the intraobserver reproducibility, the first reader repeated the measurements on the same sample after 1 month.

Statistical Analysis

We first assessed the intra- and interobserver reproducibility of measurements of the cerebellar vermis by calculating the intraclass correlation coefficient (ICC) and using the Bland-Altman method on a random sample of 50 patients. The ICCs were estimated using a 2-way random-effects model (absolute agreement), and 95% confidence intervals were obtained using bootstrap methods (2000 bootstrap samples). ICC values <0.5, between 0.5 and 0.75, between 0.75 and 0.9, and >0.90 were interpreted as poor, moderate, good, and excellent reproducibility. According to the Bland Altman method, we calculated the mean bias as well as the limits of agreement between readers. The remaining data analyses were performed on the overall study sample to provide age-specific reference intervals (“normal ranges”) for each age class.
and one of the methods recommended by the World Health Organization (WHO). The values of APD-MP were similar in both sexes. As shown in Table 4, the intraobserver agreement was excellent for each parameter, with an ICC ranging from 0.916 to 0.994. The interobserver agreement was good to excellent, with an ICC ranging from 0.846 for APD-P to 0.981 for H-V. Intra- and interobserver agreement did not significantly differ for measurements performed on T1 or T2 images (On-line Table 2).

**DISCUSSION**

Our study used a simple method, easily reproducible in daily practice in a large cohort of children with normal vermes and brain stems. Findings showed an important growth of the vermian parameters during the first year, while the brain stem demonstrated similar values in both sexes. As shown in Table 4, the intraobserver agreement was excellent for each parameter, with an ICC ranging from 0.916 to 0.994. The interobserver agreement was good to excellent, with an ICC ranging from 0.846 for APD-P to 0.981 for H-V. Intra- and interobserver agreement did not significantly differ for measurements performed on T1 or T2 images (On-line Table 2).
parameters grew gradually. The values of these parameters were higher in boys except for APD-MP, for which the values were similar in both sexes.

To our knowledge, this is the first reference biometric data for the vermis and the brain stem in children. Previous studies assessed normal MR imaging biometric data of the posterior fossa in the fetus,7,16-18 and quantitative methods have already been used to diagnose vermis hypoplasia, but no MR imaging biometric data of the normal cerebellum and brain stem have been reported before. Makris et al9 described a surface-based parcellation of the human cerebellar cortex and provide cerebellar surface and volumetry from 10 volunteer subjects with a good-to-excellent reproducibility. This method integrated automated and semiautomated and manual procedures using postprocessing software. Joyal et al19 suggested measuring the area of the vermis from a single midsagittal section, but reproducibility has not been studied. In addition, both studies were performed in the adult population, and their methodology is not easy to apply in daily practice. Our 2D measurements have the advantage of being highly reproducible, easy, and fast to perform. An interactive tool derived from the biometric models has been created and is available on-line (http://ci2c.fr/vermis.php) to facilitate its application.

Data about the growth of the cerebellum during childhood are scarce. During fetal life, the cerebellum has a long period of development that makes it particularly vulnerable to prenatal disorders, including genetic or metabolic diseases, toxins, or infections.20-22 In early stages, perturbations of the expression of genes involved in cerebellar patterning or abnormal proliferation and migration produce a wide spectrum of abnormal phenotypes from agenesis to minor abnormalities such as hypoplasia or abnormal cerebellar foliation. The fastest development is observed for the vermis and the cerebellum in comparison with other brain structures in the third trimester of pregnancy.17 Their growth is multiplied by 2 between the 20th and the 35th week of development.23 As the proliferation and migration of granular cells continue during the first postnatal months, the last granular cell migration occurs in humans at about 18 months of age. In line with previous studies suggesting further proliferation and neuronal migration in the cerebellum during the postnatal period,20,24,25 our data show the persistence of a rapid growth of the vermis during the first year of life.

Cerebellar hypoplasia has been described in many conditions associated with mental retardation.3-5,26 In this setting, morphologic variations may disclose underlying structural and functional impairment of cerebellar structures potentially involved in cognitive functions. Advanced MR imaging techniques such as DTI-based tractography have emphasized the anatomic relationship between the cerebellum and the other structures of the central nervous system involved in nonmotor functions,27 especially dentato-thalamo-cortical fibers and fibers connecting the cerebellum to visuospatial, cognitive, and memory-related areas, in healthy

**FIG 2.** Smoothed curves of the different parameters (H-V, APD-V, APD-P, APD-MP) by age and sex.
FIG 3. Reference intervals (third, 50th, 97th) for the different parameters (H-V, APD-V, APD-P, APD-MP). The values of APD-MP are similar in both sexes.

Table 4: Inter- and intraobserver agreement for cerebellar vermis and brain stem parameters

| Parameter | Intraobserver Agreement | Interobserver Agreement |
|-----------|-------------------------|-------------------------|
|           | Mean Bias | 95% Limits of Agreement | ICC (95% CI) | Mean Bias | 95% Limits of Agreement | ICC (95% CI) |
| H-V       | 0.156     | 0.869, 1.181 | 0.994 (0.982–0.998) | −0.302 | −2.129, 1.525 | 0.981 (0.948–0.991) |
| APD-V     | 0.332     | 1.831, 2.494 | 0.941 (0.878–0.970) | 0.242 | −2.851, 3.335 | 0.893 (0.799–0.948) |
| APD-P     | 0.100     | −1.161, 1.361 | 0.916 (0.854–0.953) | 0.088 | 1.704, 1.880 | 0.846 (0.674–0.944) |
| APD-MP    | 0.052     | −0.729, 0.833 | 0.988 (0.978–0.994) | 0.188 | −1.238, 1.614 | 0.959 (0.918–0.978) |
Furthermore, in children with cerebellar hypoplasia, impairment of cerebellar white matter tracts has been observed in preliminary studies. These structural data have been strengthened by functional MR imaging studies exploring the anatomofunctional segmentation of the cerebellum. These studies highlighted a limbic area corresponding to lobules VI and VII, left lateralization of the activation on visuospatial tasks, right activation in linguistic and working memory tasks, and activation of the anterior lobes in language articulation, whereas the posterior lobules were activated in silent language.

Our study has some limitations. First, our study population consisted of nonconsecutive cases examined retrospectively. We acknowledge that while effort was made to exclude children with posterior fossa abnormalities, we included children with pathologies that could potentially affect the cerebellum despite a macroscopically normal appearance on MR imaging. For children older than 6 years of age, our results should be confirmed by larger trials imaging strictly healthy children. Although measurements have been performed on different MR images, this feature did not significantly affect their reliability. Finally, our global measurements do not allow detecting a focal cerebellar hypoplasia involving a single lobe or lobule. Further studies are necessary to confirm the accuracy of our biometric data when applied to the evaluation of children with vermian hypoplasia and other posterior fossa abnormalities.

CONCLUSIONS

We provide reference biometric data of the vermis and the brain stem using simple and reproducible measurements that are easy to use in daily practice. Our results show a more important growth of the vermian parameters during the first year of life, while the brain stem parameters grow gradually. The relevance of these 2D measurements should be further validated in diseases associated with cerebellar abnormalities responsible for developmental disorders of so-called higher cerebellar functions.
