Abstract

**Background:** Pulmonary hypertension (PH) occurs in patients with acute respiratory distress syndrome (ARDS); the most severe form comprises acute cor pulmonale (ACP). Here, we investigated the prevalence of PH in patients with ARDS to evaluate its correlation with ACP risk, ARDS severity and central venous pressure (CVP).

**Methods:** We conducted a secondary analysis using data from the MIMIC-III open-source clinical database. The prevalence of PH associated with new-onset ARDS during the first 72 hours after intensive care unit (ICU) admission was investigated; moreover, the association between ACP risk score and PH was validated. We also evaluated the association between elevated CVP (mean CVP >10 mmHg) and PH and other clinical outcomes. **Results:** Among 2,434 patients who met the ARDS Berlin criteria and underwent echocardiography or pulmonary artery catheterization evaluation, a total of 583 (24.0%) patients were diagnosed with moderate or severe PH, of which 418 had low and 165 had high ACP risk. After adjustment for disease/ARDS severity, ACP risk score, and other demographic variables, elevated CVP was independently associated with the occurrence of PH [odds ratio, 2.239 (1.674, 2.993), p<0.005]. Among patients with PH, higher mean CVP was associated with prolonged hospital stay (13.4 vs. 15.2 days, p=0.041) and duration of ventilation (116.5 vs. 150.5 hours, p=0.023). **Conclusions:** Incidence of PH was 24.0% in patients with new-onset ARDS in this retrospective study. Elevated CVP is relevant with higher incidence of PH and worse clinical outcome; these highlighted the importance of hemodynamic monitoring in the management of ARDS.
Acute respiratory distress syndrome (ARDS) is frequently associated with pulmonary hypertension (PH), which is related to increased pulmonary vascular resistance and subsequent right ventricular dysfunction (1). Previous echocardiography (ECHO) (2) or pulmonary artery catheter (PAC) (3,4,5) studies have shown that mild to moderate elevation in mean pulmonary artery pressure (mPAP) occurs in most patients with ARDS. In particular, acute cor pulmonale (ACP), which is the most severe presentation of PH, is associated with a poor clinical outcome; this illustrates the importance of pulmonary hemodynamic assessment by intensivists (6).

Recently, Dessap et al. proposed an ACP risk score that was validated in a prospective cohort of patients with ARDS, that study showed a 22% prevalence of ACP in 752 patients with moderate-severe ARDS (7). Although the importance of ACP identification and prevention is widely accepted in the management of ARDS (6,8), the prevalence, progression, and prognosis of PH associated with ARDS, has not been fully investigated(9). Additionally, scoring criteria have been limited to the field of mechanical ventilation (pneumonia as a cause of ARDS and driving pressure) and gas exchange (PaCO\textsubscript{2} and PaO\textsubscript{2}/FiO\textsubscript{2}) and have not involved any hemodynamic monitoring parameters; notably, CVP has been associated with prognosis in critically ill patients (10, 11, 12) and should be included during the evaluation and identification of PH.

Considering these limitations, we aimed to investigate the prevalence of PH in patients with new-onset ARDS, as well as in subgroups with varying levels of ACP
risk and ARDS severity; moreover, we aimed to evaluate the association between PH and a basic hemodynamic parameter: central venous pressure (CVP). We hypothesized that elevated CVP (mean CVP >10 mmHg) would be independently associated with the risk, severity, and clinical outcome of PH in patients with ARDS.

Methods

Data source

We conducted a secondary analysis using data collected from the MIMIC-III open-source clinical database (version 1.4, released on September 2, 2016), which was developed and maintained by the Massachusetts Institute of Technology (MIT), Philips Healthcare, and Beth Israel Deaconess Medical Center (BIDMC) (13). Information derived from the electronic medical records of 46,476 unique critical care patients admitted to the ICUs at BIDMC between 2001 and 2012 was included in this free accessible database (14). MIMIC-III data are Health Insurance Portability and Accountability Act of 1996 (HIPAA) compliant. Use of the MIMIC-III database was approved by the Institutional Review Boards of BIDMC and MIT, and a waiver of informed consent was granted.

Patients

All patients in the database were screened. The inclusion criteria in this study were as follows: (1) adults (≥18 years of age) at ICU admission, with complete medical records including available CVP measurement records during the first 72 hours after ICU admission; (2) ICU stay ≥72 hours; and (3) Berlin definition criteria for ARDS.
were met at the time of ICU admission. The ARDS definition included: acute onset, \( \text{PaO}_2/\text{fraction of inspired oxygen (FiO}_2\) of \( \leq 300 \text{ mmHg}\), bilateral infiltrates on chest radiograph, and absence of heart failure. Mild, moderate, and severe ARDS were classified on the basis of the \( \text{PaO}_2/\text{FiO}_2\) ratio \( (15)\). For patients with multiple ICU stays, only data related to the first ICU admission were considered.

**ACP risk score**

According to the study reported by Dessap et al. \( (7)\), we calculated the ACP risk score based on the medical records (average values) during the first day after ICU admission; this included four variables: pneumonia as a cause of ARDS, driving pressure \( \geq 18 \text{ cmH}_2\text{O}\), \( \text{PaO}_2/\text{FiO}_2\) ratio \( < 150 \text{ mmHg}\), and arterial carbon dioxide partial pressure \( \geq 48 \text{ mmHg}\). For this study, driving pressure was defined as the difference between plateau pressure and positive end-expiratory pressure (PEEP).

**Outcome**

The primary outcome was moderate or severe PH, as defined by either diagnosis in the ECHO report or mPAP measured by PAC (moderate PH: mPAP between 30 and 45 mmHg; severe PH: mPAP \( > 45 \text{ mmHg}\) \( (5, 16)\). Pulmonary artery pressure (systolic and mean PAP) estimation by echocardiography was based on the measurement of tricuspid regurgitation peak velocity, which is a classic and widely accepted method in PH estimation, and mean PAP by Echo was calculated from the estimated systolic PAP\( (16)\). Only ECHO or PAC evaluations performed during the first 72 hours after ICU admission were considered when assessing evidence of PH. If both results were
available and the grades were inconsistent, the PAC measurement was used as the decisive outcome. Enrolled patients without any available PAC or ECHO evaluations were considered to be non-PH subjects. Other clinical outcomes were recorded, including 28-day mortality, ICU stay, hospital stay, vasopressor duration, and ventilation duration.

**Statistical analysis**

Data are expressed as the mean ± standard deviation, median with interquartile range, and proportions (absolute and relative frequencies), as appropriate. Student’s t-test or the Mann–Whitney test was used to compare continuous variables, while the χ² test or Fisher’s exact test was used to compare proportions. All statistical analyses were performed by using the IBM® SPSS® Statistics version 24 (SPSS Inc., Chicago, IL, USA). A p value of <0.05 was considered to indicate a statistically significant difference.

Mean CVP level during the first 72 hours after ICU admission was used to categorize the patients into two groups: ≤10 mmHg and >10 mmHg, which comprised patients of low and high CVP groups, respectively (11). To assess the independent effect of high mean CVP level on outcome (moderate or severe PH) in patients with ARDS, we performed a multivariate logistic regression regarding the association between elevated mean CVP and occurrence of PH after adjustment on the basis of relevant illness severity variables, which comprised demographic characteristics; ICU type; admission type; Simplified Acute Physiology Score II (SAPS II); Sequential Organ
Failure Assessment (SOFA); and ACP risk score at admission and whether lung
protective ventilation (LPV) strategy was followed. To further investigate the
association of the elevated mean CVP and severity of PH, we also compared the
proportions of various degrees of PH among subgroups of patients with varying levels
of ACP risk and ARDS severity.

Results

Basic characteristics

Among the 46,476 ICU patients and 61,532 ICU admissions in the MIMIC-III v1.4
databases, 7,823 patients met the ARDS Berlin criteria at ICU admission and 2,434
patients with ARDS stayed in the ICU for >72 hours. Among these 2,434 patients,
1,824 underwent ECHO evaluation and 958 received PAC evaluation, as illustra-
ted in Figure 1. According to the reports of ECHO and average mPAP from PAC evaluation
during the first 72 hours after ICU admission, 583 patients with ARDS were
diagnosed with moderate or severe PH (PH group), while 1,851 patients exhibited no
evidence, or had borderline/mild degree of PH (non-PH group). SAPS and SOFA
scores at admission, as well as the proportion of patients for whom the LPV strategy
was followed, were comparable between PH and non-PH groups. The severity of
ARDS showd an opposite trend with incidence of PH.

In accordance with the method proposed by Dessap et al. (7), we extracted the
pneumonia-associated ARDS patients as well as the average of driving pressure,
$\text{PaCO}_2$, and $\text{PaO}_2/\text{FiO}_2$ ratio during the first 24 hours after ICU admission; we also
calculated the ACP risk score for each patient. Patients with ACP risk score ≥2 were considered to have a high risk of ARDS-associated PH; the proportions of these patients in the non-PH and PH groups were 20.0% and 28.3%, as shown in Table 1. The group of patients with high ACP risk scores showed an increased number of instances of PH, compared with that in the group with low ACP risk scores (165/536 vs. 418/1898, 30.8% vs 22%).

**Mean CVP level and outcome**

During the first 72 hours after ICU admission, 583 patients were diagnosed with moderate or severe PH (moderate: 534; severe: 49). After adjusting for age, gender, ethnicity, admission type, admission ICU type, SAPS II and SOFA scores at admission, ARDS severity, ACP risk score, and whether the LPV strategy was unfollowed, mean CVP >10 mmHg remained significantly associated with the diagnoses of moderate or severe PH in patients with ARDS, as shown in Table 2.

We also compared the other main ICU outcomes, which included 28-day mortality, length of ICU stay, length of hospital stay, and duration of vasopressor and ventilation usage, between groups of patients who exhibited PH, with or without mean CVP >10 mmHg (Table 3). The results showed that prolonged hospital stay time (13.4 vs. 15.2 days, p=0.041) and ventilation duration (116.5 vs. 150.5 hours, p=0.023) were required for patients with ARDS who exhibited PH and higher mean CVP level; however, differences in 28-day mortality (27.8% vs. 22.7%), ICU stay duration (8.1 vs. 9.3 days), and vasopressor duration (42.4 vs. 69.8 hours) were not statistically
significant between the two groups.

**Subgroups and sensitivity analysis**

Because the ACP risk score and ARDS severity may reflect the potential risk of PH in patients with ARDS, we investigated the associations between mean CVP level and PH prevalence among different subgroups after stratification by ACP risk score and ARDS severity, as shown in Figure 2. The results showed that the incidence and severity of PH were lower in patients with ARDS who exhibit mean CVP ≤10 mmHg than in patients with ARDS who exhibit mean CVP >10 mmHg among most subgroups stratified by ACP risk [0 points: 29 (11.6%) vs. 125 (22.2%), p<0.005; 1 point: 28 (14.2%) vs. 236 (26.6%), p<0.005; 2 points: 11 (14.1%) vs. 121 (32.4%), p=0.001; ≥3 points: 4 (23.5%) vs. 29 (42.6%), p=0.175] and ARDS severity [mild: 25 (13.4%) vs. 92 (12.7%), p=0.019; moderate: 30 (12.0%) vs. 267 (14.0%), p<0.005; severe: 17 (16.0%) vs. 152 (31.1%), p=0.001].

Multivariable regression analysis also confirmed that in the low or high ACP risk subgroups, sepsis or non-sepsis subgroups, and LPV followed or not subgroups, the significant effect of mean CVP >10 mmHg on PH morbidity remained in patients with ARDS, as illustrated in Figure 2.

**Discussion**

ARDS is a clinical condition characterized by acute hypoxemic respiratory failure. In recent years, intensivists have progressively recognized the significance of circulatory failure in ARDS, which is caused by pulmonary vascular dysfunction (PVD) and may
eventually cause ACP (1). Several studies have indicated that ACP is common in patients with moderate-to-severe ARDS; moreover associated with increased mortality in patients with ARDS (4,6,7,17,18). As noted in the Introduction of the present paper, Dessap et al. proposed a risk prediction model to identify high risk factors of developing ACP; notably, they observed a 22% prevalence rate of ACP within 3 days from the diagnosis of ARDS in the group with high ACP risk (7).

Nevertheless, further studies have enhanced the understanding of pulmonary hemodynamics in ARDS; thus, ACP should not be regarded as the sole clinical outcome of PVD evaluation (9). Instead, moderate to severe PH has been designated for early recognition and intervention before the onset of ACP. In the present study, we investigated the prevalence of PH associated with new-onset ARDS during the first 72 hours after ICU admission. The ACP risk model was validated, and the prevalence of PH was found to be significantly higher in the group of patients with ARDS who exhibited high ACP risk than in those with low ACP risk (30.8% vs. 22.0%). Our results indicate an increased incidence of PVD associated with ARDS and support the use of ACP risk score as a sign of more generalized PH, rather than for the extreme manifestation of ACP.

The evaluation of right heart dysfunction plays a critical role in the development of PH associated with ARDS (18). Therefore, in this study, CVP, which is the most convenient and direct method for right-heart monitoring, was used for the evaluation and prognosis of PH associated with ARDS. After adjustment for disease/ARDS severity, ACP risk score, and other demographic variables, we showed that elevated
mean CVP (>10 mmHg) was independently associated with the occurrence of PH in patients with ARDS during the first 3 days after ICU admission. Based on the data-driven analysis on MIMIC III v1.4, our result highlights the critical role of CVP assessment in the evaluation and treatment of ARDS. Analysis of patients with PH showed that patients with lower mean CVP had better clinical outcomes. Subgroup analysis of patients with varying degrees of ACP risk score and ARDS severity also showed that the incidence and severity of PH was lower in patients with ARDS who exhibited mean CVP of ≤10 mmHg.

Elevated CVP(ECVP) occurs frequently in critical care settings (19) and may be caused by several conditions, such as heart failure, pericardial disease, and especially as a surrogate of intravascular volume. However, recent studies have challenged the validity of ECVP in critical care settings. An ECVP might indicate an impediment to the venous return and microcirculatory blood flow as well as accompanying lung edema. ECVP may work as a preliminary indicator of increased pulmonary vascular resistance or right ventricular dysfunction, which was crucial during the development of PH.

It is noteworthy the initial SAPS and SOFA scores were comparable between PH and non-PH groups and the proportions of patients employing LPV were both < 40%. The use of LPV was introduced in the 2000s and was widely accepted, because it specifically lowered the incidence of ventilation-induced lung injury and mortality in ARDS. Multiple studies, however, showed the reality in clinical settings was not satisfactory, considering the obvious underuse of the LPV strategy (20, 21, 22).
Therefore, in this real-world study, we did not restrict subjects into strict LPV strategy, in order to more clearly evaluate the current status of PH and the use of ACP risk score. Our results did not indicate whether following LPV was independently associated with PH after adjustment; this may partially be because the \( \text{PaO}_2/\text{FiO}_2 \) ratio and driving pressure were already included in the ACP risk score. Therefore, we suggest that ACP risk evaluation should not be limited to patients with ARDS who followed the LPV strategy.

Our study has several limitations. First, this study is limited by its retrospective nature and the source of data used. Therefore, no causal relationships could be established among CVP, PH and mortality. Additionally, CVP records, ECHO reports, and PAC results could only be assessed in patients who underwent the corresponding evaluation after ICU admission. Thus, the associations of CVP (or other variables) with PH may be overemphasized in such situations. Additionally, further investigation is needed regarding whether early CVP-targeting intervention, which consists of fluid management and cardiac optimization, may affect the incidence of PH and other clinical outcomes in patients with ARDS. Second, prone position ventilation has been proven to be associated with an improved oxygenation level and lowered risk of ACP in patients with ARDS. Nevertheless, considering the lack of uniform standards of such therapy, we did not include this indicator in the study. Thus, further investigation is needed to determine whether prone position ventilation may lower the risk of PH in patients with ARDS who exhibit a high risk of ACP.

In conclusion, in this retrospective study using a large intensive care database, we
investigated the prevalence of PH in patients with new-onset ARDS and validated the use of ACP risk score to predict the incidence of PH. We also confirmed independent associations between elevated CVP and both higher incidence of PH and worse clinical outcome; these findings highlight the importance of hemodynamic evaluation in the identification and management of ARDS.

| ARDS severity       |       |       |       |
|---------------------|-------|-------|-------|
| Mild, n (%)         | 613 (25.2%) | 496 (26.8%) | 117 (20.1%) |
| Moderate, n (%)     | 1,227 | 930 (50.2%) | 297 (50.9%) |
| Severe, n (%)       | 594 (24.4%) | 425 (23.0%) | 169 (29.0%) |

ACP risk score: 0.9±0.8, 0.9±0.8, 1.1±0.8, 0.412
ACP risk score ≥2, n (%): 536 (22.0%), 371 (20.0%), 165 (28.3%), <0.005

Mean CVP, mmHg: 13.0±3.7, 12.5±3.6, 14.3±3.8, 0.083

Outcome

| 28 days mortality, n (%) | 429 (17.6%) | 293 (15.8%) | 136 (23.3%) | <0.005 |

| Length of ICU stay, day [IQR] | 7.3 [4.4, 6.9 [4.2, 12.9]] | 9.2 [5.4, 17.2] | <0.005 |

| Length of hospitalization, day | 13.9 [9.1, 13.6 [8.9, 21.8]] | 15.0 [9.9, 26.1] | <0.005 |
Treatment received

|                | Duration of vasopressor, hours [IQR] | Duration of ventilation, hours [IQR] |
|----------------|--------------------------------------|--------------------------------------|
|                | 45.5 [18.1, 99.3]                    | 96.8 [33.0, 234.3]                   |
|                | 40.3 [16.1, 84.8]                    | 85.7 [24.5, 207.7]                   |
|                | 68.0 [24.6, 164.2]                   | 149.4 [59.0, 284.5]                  |

Results are presented as mean (standard deviation), median [interquartile range (IQR)], or n (%).
Table 2 Multivariate analysis between patients with and without pulmonary hypertension in patients with adult respiratory distress syndrome

| Variable                      | Unadjusted OR | Adjusted OR | 95% CI       | p    |
|-------------------------------|---------------|-------------|--------------|------|
| Age                           | 1.007         | 1.009       | [1.001, 1.017] | 0.026 |
| SAPS II (per 1 point)         | 1.020         | 1.008       | [0.998, 1.019] | 0.128 |
| SOFA (per 1 point)            | 1.093         | 1.050       | [1.003, 1.097] | 0.037 |
| ARDS severity (per 1 grade)   | 1.295         | 1.012       | [0.849, 1.208] | 0.892 |
| ACP score (per 1 point)       | 1.349         | 1.335       | [1.160, 1.537] | <0.005 |
| LPV strategy unfollowed       | 0.961         | 0.989       | [0.796, 1.229] | 0.922 |
| Condition                                      | OR    | CI    | p value |
|------------------------------------------------|-------|-------|---------|
| Mean CVP > 10mmHg                              | 2.422 | 2.239 | <0.005  |
| History of chronic pulmonary disease            | 1.223 | 1.091 | 0.460   |
| History of pulmonary circulation disease        | 2.706 | 2.433 | <0.005  |

* Adjusted for age, gender, ethnicity, admission type, and admission ICU type.

OR, odds ratio; CI, confidence interval; SAPS II, Simplified Acute Physiology Score II; SOFA, Sequential Organ Failure Assessment; ARDS, acute respiratory distress syndrome; ACP, acute cor pulmonale; LPV, lung protective ventilation; CVP, central venous pressure. p values <0.05 are shown in bold.
Table 3 Main clinical outcomes in subgroups with mean central venous pressure ≤10 mmHg and mean central venous pressure >10 mmHg in patients with moderate or severe pulmonary hypertension

| Characteristics                  | Mean CVP≤10mmHg (n = 72) | Mean CVP>10mmHg (n = 511) | p value |
|----------------------------------|----------------------------|----------------------------|---------|
| 28 days mortality, n (%)         | 20 (27.8%)                 | 116 (22.7%)                | 0.340   |
| Length of stay in ICU            | 8.1 [5.0, 14.0]            | 9.3 [5.5, 17.9]            | 0.113   |
| Length of stay in hospital       | 13.4 [9.5, 20.2]           | 15.2 [10.0, 26.8]          | 0.041   |
| Duration of vasopressor, hour    | 42.4 [13.6, 120.0]         | 69.8 [28.6, 169.6]         | 0.099   |
| Duration of ventilation, hour    | 116.5 [47.7, 252.6]        | 150.5 [60.5, 295.3]        | 0.023   |
