Abstract

We present near-infrared spectroscopy of the sporadically active asteroid (6478) Gault collected on the 3 m NASA/Infrared Telescope Facility observatory in late 2019 March/early April. Long-exposure imaging with the 0.5 m Near Earth Environment Monitoring TO5 telescope and previously published data simultaneously monitored the asteroid activity, providing context for our measurements. We confirm that Gault is a silicate-rich (Q- or S-type) object likely linked to the (25) Phocaea collisional family. The asteroid exhibits substantial spectral variability over the 0.75–2.45 μm wavelength range, from unusual blue (s′ = −13.5 ± 1.1% μm−1) to typical red (s′ = +9.1 ± 1.2% μm−1) spectral slope, that does not seem to correlate with activity. Spectral comparisons with samples of ordinary chondrite meteorites suggest that the blue color relates to the partial loss of the asteroid dust regolith, exposing a fresh, dust-free material at its surface. The existence of asteroids rotating close to rotational break-up limit and having similar spectral properties as Gault further supports this interpretation. Future spectroscopic observations of Gault, when the tails dissipate, will help further testing of our proposed hypothesis.

1. Introduction

Cometary-like activity was recently reported on the ~4 km size inner main-belt asteroid (6478) Gault. Tens of millions of kilograms of ejected dust (Hui et al. 2019; Jewitt et al. 2019; Moreno et al. 2019; Ye et al. 2019b) formed a long and thin tail first identified in images collected by the Hawaii ATLAS (Tonry et al. 2018) survey in 2018 December (Smith et al. 2019) and subsequently confirmed by other research groups (e.g., Hale et al. 2019a, 2019b; Jehin et al. 2019; Lee 2019; Ye et al. 2019a). Since then, two additional tails developed (Jewitt et al. 2019), and archival data back to 2013 revealed earlier phases of activity (Chandler et al. 2019), ruling out a single collision as the origin of the activity. The detection of events near aphelion (Chandler et al. 2019) and the absence of detectable gas in the visible spectrum of Gault (Jewitt et al. 2019) imply volatile sublimation is also unlikely to be responsible. On the other hand, signatures of a rotation period of ~2 hr (Kleyna et al. 2019), close to the rotational break-up limit (Pravec & Harris 2000), and the very low velocity of the ejected dust grains (Jewitt et al. 2019; Hui et al. 2019; Kleyna et al. 2019; Moreno et al. 2019; Ye et al. 2019b), indicate that activity may be triggered by rapid spin up due to solar heating (the YORP effect; e.g., Bottke et al. 2006; Vokrouhlický et al. 2015). This remains to be confirmed, as light curves collected so far with various telescopes show very little/no short-term brightness variation (Jewitt et al. 2019; Moreno et al. 2019; Ye et al. 2019b), possibly because the asteroid is embedded in a dust cloud (Licandro et al. 2000). Likewise, Ye et al. (2019b) proposed that activity could be triggered by the merging of a near-contact binary, but currently available light curves do not allow this hypothesis to be validated.

Owing to the lack of spectral measurements before it became active, little is known about the original (pre-outburst) surface composition and taxonomy (Bus & Binzel 2002; DeMeo et al. 2009) of Gault. Dynamically, the asteroid was linked to two overlapping collisional families: Phocaea, which is dominated by S-type asteroids, and Tamara, dominated by low-albedo C-types (Nesvorný 2015; Novaković et al. 2017). Serendipitous observations from the Zwicky Transient Facility (ZTF) survey (Bellm et al. 2019), dating back to 2017, returned optical colors similar to C-type or Q-type asteroids (Ye et al. 2019b; Q-types represent a less-weathered version of the S-type asteroids, e.g., Binzel et al. 2010). Additional color measurements collected during active phases between 2018 December and 2019 March returned similar results (Hui et al. 2019; Jewitt et al. 2019; Ye et al. 2019b). In parallel, spectroscopy over the visible and near-infrared (NIR) wavelength range revealed spectral properties that are consistent with Q-type or S-type asteroids (Sanchez et al. 2019; J. Licandro et al. 2019, private communication), supporting Gault’s membership to the Phocaea collisional family.

In this Letter, we report new spectroscopic measurements of Gault measured in the near-infrared wavelength range between late 2019 March and early April, and near-simultaneous photometry providing context for these measurements.

2. Spectroscopy

2.1. Observations and Data Reduction

Spectroscopic observations were conducted on two different nights with the 3 m NASA Infrared Telescope Facility (IRTF) located on Maunakea, Hawaii. We used the SpeX NIR spectrograph (Rayner et al. 2003) combined with a 0.8 × 15 arcsec
We provide the mean modified Julian date (MJD), instrument, air mass, heliocentric ($r_H$) and topocentric ($\Delta$) distances, and phase angle ($\alpha$) of the asteroid.

Table 1

| UT Date     | Mean MJD | Instrument | Air Mass | $r_H$ (au) | $\Delta$ (au) | $\alpha$ (deg) |
|-------------|----------|------------|----------|------------|---------------|----------------|
| 2019 Mar 31 | 58573.398553 | SpeX      | 1.09–1.33 | 2.30        | 1.44          | 16.0           |
| 2019 Apr 8  | 58581.293721 | SpeX      | 1.05–1.06 | 2.28        | 1.48          | 18.9           |
| 2019 Mar 23 | 58565.910038 | NEEMO T05 | 1.52–1.62 | 2.32        | 1.41          | 12.9           |
| 2019 Mar 24 | 58566.849897 | NEEMO T05 | 1.45–1.47 | 2.31        | 1.41          | 13.3           |

| 2019 Apr 02 | 58575.847994 | NEEMO T05 | 1.38–1.41 | 2.29        | 1.45          | 16.9           |
| 2019 Apr 04 | 58577.821224 | NEEMO T05 | 1.36–1.37 | 2.29        | 1.46          | 17.7           |
| 2019 Apr 24 | 58597.834428 | NEEMO T05 | 1.39–1.46 | 2.24        | 1.61          | 23.7           |
| 2019 Apr 26 | 58599.782625 | NEEMO T05 | 1.27–1.30 | 2.24        | 1.63          | 24.1           |

Note. The only asteroid class defined by negative spectral slope is the B-type, but this class usually shows very little or no absorption features in the NIR. Here, the silicate absorption bands clearly indicate that the spectrum is compositionally similar to the S-complex, although it is bluer than the vast majority of S-type and Q-type asteroids (DeMeo et al. 2009).

Figure 1. Spectral measurements of (6487) Gault acquired on UT 2019 March 31 (blue) and UT 2019 April 8 (brown), compared to a previous measurement of (25) Phocaea (orange; from the SMAX spectral database). All spectra are normalized to 1 at 0.8 μm. The orange, green, and blue regions indicate the mean (±1σ) spectral regions of S-type, Q-type, and B-type asteroids, respectively, from DeMeo et al. (2009).
(6478) Gault from the orbital plane of the asteroid (plane-crossing date: UT 2019 March 24).

Gault was blue during the two half-observing sequences. A 1D spectrum from each half sequence, and composite images at the sequence midpoint, extracted from the SMASS database must have only affected the exposures of Gault, which seems highly unlikely. To rule out this hypothesis, we divided our full sequence of spectral images at the sequence midpoint, extracted a 1D spectrum from each half sequence, and confirmed that Gault was blue during the two half-observing sequences.

3. Photometry

3.1. Observations and Data Reduction

Nearly simultaneously to our spectroscopic observations, images of the asteroid were collected using the 0.5 m telescope near Earth Environment Monitoring (NEEMO) T05 (RiDK900 f/7 manufacture) equipped with a FLI ProLine16803 4k × 4k camera (Birlan et al. 2018, 2019). NEEMO T05 is a relatively compact telescope with a field of view of about 47 × 47 arcmin installed inside the Astronomical Institute of the Romanian Academy (IAU code 073). 120 s long exposures with 2 × 2 binning were measured in the non-filtered mode, meaning that the full 0.36–0.93 μm wavelength range of the light was being recorded. Observing circumstances are summarized in Table 1.

The images were calibrated using flat and dark calibration files. Composite images built from shifted images centered on the asteroid are shown in Figure 2. Differential aperture photometry was performed on the individual images with the MaximDL software, using up to five reference stars with a signal-to-noise ratio that is greater than 100 for photometric calibration. We used an aperture of 4″ and a sky annulus of 3″, with a 2″ gap between the two. Magnitudes of our reference stars were retrieved from the eight-filter (Johnson B and V and Sloan u, g, r, i, z, and Z) AAVSO Photometric All-Sky Survey (APASS; Henden et al. 2015). We used Johnson V-band magnitudes for calibration, which covers the closest spectral range to the non-filtered mode of the instrument. However, we acknowledge that the spectral response of our CCD sensor does not perfectly match Johnson V, thereby introducing a systematic error in our measurements. Finally, individual measurements taken on the same night were averaged together.

3.2. Photometric Light Curve

Additional photometric measurements collected by other teams between 2019 January and May were used to complement our data set. We used published data from the Xinming Observatory (Hui et al. 2019) graciously provided by the authors upon request, as well as measurements from the moving object detection system of the ZTF survey made available by Ye et al. (2019b) on the Minor Planet Center website.

All photometric measurements were converted to absolute magnitudes to account for the changing geometry of the asteroid. Observed magnitudes were reduced to heliocentric and geocentric distances rH = 1 au and Δ = 1 au, and then corrected for phase angle using Equation (2) in Hui et al. (2019) for the compound (asteroid+tail) phase function. We used Bowell et al. (1989)’s phase function for the asteroid, and Schleicher et al. (1998)’s for dust in the tail. Ye et al. (2019b) derived Hg,r = 14.81 ± 0.04 and Hg,r = 14.31 ± 0.01 for the asteroid based on pre-outburst photometric measurements of Gault from the ZTF survey assuming G = 0.15. Here, we recalculated Hg,r and Hg,t from the same data for G = 0.23, which is typical for S-complex asteroids (e.g., Pravec et al. 2012). We find Hg,r = 14.88 ± 0.04 and Hg,t = 14.38 ± 0.01 which, converted to Johnson magnitudes using equations from Tonry et al. (2012), translates to Hg,B = 15.39 ± 0.06,
$H_n,V = 14.64 \pm 0.04$, $H_n,R = 14.17 \pm 0.04$. Finally, all absolute magnitudes were converted to a common Johnson $V$-band filter using average colors in the photometric data set.

The resulting light curve is shown in Figure 3: the asteroid brightness decreased from its phases of activity in late 2018/early 2019 up to the first half of 2019 March. Transient brightening then occurred in March, peaking UT March 24 ($JD = 2,458,566.5$), which coincides with the moment when the Earth crossed the orbital plane of the asteroid (one of the asteroid orbital nodes). This indicates that brightening likely originated from the increased presence of dust in the orbital plane of the asteroid rather than an outburst, which is supported by the fact that no new tail subsequently appeared.

No additional magnitude change indicative of an outburst is detected afterward.

### 4. Possible Origins for Spectral Variability

To further investigate the origin of NIR spectral variability in Gault, we searched for additional spectroscopic measurements collected by other research groups. Sanchez et al. 2019 and J. Licandro et al. (2019, private communication) measured red spectral slopes that are slightly more neutral than our second spectrum from UT 2019 April 8. B. T. Bolin et al. (2019, private communication), on the other hand, derived a blue spectral slope of $s^\prime = -9 \pm 5\% \, \mu m$ from broadband $JHK$ photometry that is consistent with our first spectroscopic
observation on UT 2019 March 31. This measurement was acquired about 50 days earlier than ours, implying that Gault underwent at least two distinct events of spectral bluing. Taken as a whole, these data sets do not reveal any correlation of NIR spectral slope with absolute magnitude (Figure 3); therefore, color does not appear to relate to the level of activity. Spectral bluing in particular does not coincide with local brightness minima or maxima, making it difficult to relate to either the surface or the tail of the asteroid.

Various active comets are known to exhibit similar large-amplitude spectral variability in the optical, from blue to red colors, on temporally short timescales (e.g., Weiler et al. 2003; Ivanova et al. 2017; Luk’yanyk et al. 2019). The origin of variability in these objects remains unclear. Many different processes have been invoked, from the sublimation of icy grains, to physical and compositional variations of the emitted dust particles. In active S-type asteroids, the hypothesis of ice sublimation can likely be rejected. In our current understanding of the solar system formation and evolution, these objects accreted below the snow line (Vernazza & Beck 2017), seemingly ruling out the presence of volatiles in their interior and, therefore, in the emitted dust. This is reinforced in the case of Gault by the lack of detectable gas in its visible spectrum (Jewitt et al. 2019) and the morphology of the tails that argue against sublimation as the driven mechanism for activity (Ye et al. 2019b). Alternative hypothesis are as follows.

A. Rayleigh scattering: Non-geometrical scattering by optically thin particles has often been invoked as origin of the blue color of cometary comae. However, while small particles certainly dominate by number in tails of active objects before being dispersed by solar wind, Jewitt (2015) argued that large grains should always dominate the scattering cross section. In the case of Gault, this is further supported by the large average particle size (\(d \sim 100\ \mu m\)) derived from morphological analysis of the tails (Jewitt et al. 2019; Kleyman et al. 2019; Moreno et al. 2019; Ye et al. 2019b), implying that they do not contain a preponderance of Rayleigh scatterers.

B. Size variation of the emitted dust grains: S-complex bodies are associated to ordinary chondrite (OCs) meteorites (Nakamura et al. 2011). Fresh (unweathered) samples of OCs usually display rather neutral or slightly red NIR spectra. Like other meteorite types (e.g., Cloutis et al. 2011, 2012), OCs further exhibit a trend of increasing spectral slope with increasing grain size: the coarser the grains, the more neutral the spectrum (Figure 4). We are not aware, however, of any spectrum of OC grains as blue as Gault on UT 2019 March 31. In particular, no matching spectrum of grained samples of OCs could be found in the RELAB spectral database of meteorites (Pieters & Hiroi 2004).

C. Partially cleaned surface: Dust-free slabs of OC meteorites provide the closest spectral analogs to the asteroid blue spectrum (Figure 4), opening the possibility that a fresh blocky material exposed by the outbursts is responsible for the blue color. Considering the fact that a red spectrum was measured at minimum brightness on UT 2019 April 8, when dust from the tail was only marginally contributing to the flux, the removal of the dust regolith must have been only partial on Gault, resulting in a spectrally heterogeneous surface. If this hypothesis is correct, then additional Q-type bodies rotating close to break-up should exhibit the same blue spectral slope as Gault, as the result of recent centrifugal ejection of their dust regolith. Indeed, some asteroid pairs, bodies that are suspected to be rotationally disintegrated asteroids (Pravec et al. 2010), often present fresh spectral slopes (Polishook et al. 2014). A search for blue Q-type asteroids in the SMASS/MITHNEOS spectral database (Binzel et al. 2019) reveals

\[\text{Table 2} \]

Blue Q-type Asteroids from the SMASS Database

| Number      | Designation | \(D^b\) (km) | \(P^c\) (hr) | Note |
|-------------|-------------|--------------|--------------|------|

| 2013 XY8    | unknown     | 0.03         | 0.06         |       |

Notes.

\(a\) Diameter.
\(b\) Rotation period.
\(c\) From Warner et al. (2009).

Figure 5. Spectral comparison between Gault (blue) and additional blue-slope Q-type asteroids from the SMASS database (black; see Table 2). The presence of fast rotators among these objects supports the hypothesis of fresh dust-free surfaces as the origin of blue color among Q-type asteroids: (68063) 2000 YJ66 has a rotation period \(P = 2.1\) hr, which is close to the spin barrier. 2013 XY8 is a 30 m size extreme rotator with \(P = 3.6\) minutes unable to sustain any dust regolith.
six bodies (Figure 5), two of which are fast rotators near or beyond the spin limit (Table 2). The most extreme case is a 30 m size boulder with a 3.6 minute long rotation period. We acknowledge, however, that many other S-types that are not blue are also found near break-up speeds, implying that substantial regolith loss does not always happen on these objects. The heterogeneous (partially cleaned) surface hypothesis therefore appears to us the most credible explanation for spectral variability and transient bluing of Gault. One possible flaw comes from the lack of spectral variability during our ∼50 minute long sequences of spectroscopic observations. This is hardly reconcilable, in the case of an heterogeneous body, with the rotation period of ∼2 hr proposed for Gault (Kleyna et al. 2019).

5. Summary

We present new NIR spectroscopic observations and imaging of the newly active S-complex (Q- or S-type) asteroid (6478) Gault. Combining our data set with similar observations from other research groups, we showed that the asteroid exhibits substantial spectral variability, from very blue ($\alpha' = -13.5 \pm 1.1\% \mu m^{-1}$) to red ($\alpha' = +9.1 \pm 1.2\% \mu m^{-1}$) spectral slope over the 0.75–2.45 $\mu m$ spectral range, that does not seem to correlate with activity. Spectral comparisons with samples of OC meteorites and other blue Q-type asteroids in the SMASS database suggest that the asteroid surface partially lost its dust regolith during the outburst events, thereby exposing a fresh blocky material at its surface. Future spectroscopic observations when the tails dissipate will help confirming or ruling out this hypothesis.

We thank the anonymous referee for a careful reading of the manuscript and constructive remarks. This work is based on observations collected at the Infrared Telescope Facility, which is operated by the University of Hawaii under contract NNH14CK55B with the National Aeronautics and Space Administration. M.M. and F.D. were supported by the National Aeronautics and Space Administration under grant No. 80NSSC18K0849 issued through the Planetary Astronomy Program.
