Emergent biomarker derived from next-generation sequencing to identify pain patients requiring uncommonly high opioid doses

D Kringle1, A Uitlsch2, M Zimmermann3, J-P Jansen4, W Illias5, R Freynhagen6,7, N Griessinger8, A Kopf9, C Stein9, A Doehring1, E Resch10 and J Lötsch1,10

Next-generation sequencing (NGS) provides unrestricted access to the genome, but it produces ‘big data’ exceeding in amount and complexity the classical analytical approaches. We introduce a bioinformatics-based classifying biomarker that uses emergent properties in genetics to separate pain patients requiring extremely high opioid doses from controls. Following precisely calculated selection of the 34 most informative markers in the OPRM1, OPRK1, OPRD1 and SIGMAR1 genes, pattern of genotypes belonging to either patient group could be derived using a k-nearest neighbor (kNN) classifier that provided a diagnostic accuracy of 80.6 ± 4%. This outperformed alternative classifiers such as reportedly functional opioid receptor gene variants or complex biomarkers obtained via multiple regression or decision tree analysis. The accumulation of several genetic variants with only minor functional influences may result in a qualitative consequence affecting complex phenotypes, pointing at emergent properties in genetics.

INTRODUCTION

Genotyping-based drug therapy decisions are increasingly desired in clinical practice; however, their introduction is still limited. The so far published single functional genetic variants are increasingly perceived as insufficient in providing a genetic diagnosis of clinical phenotypes.1 However, exploitation of the whole genetic information becomes possible overcoming the restricted selection of known variants. Next-generation sequencing (NGS)2 provides unrestricted access to the subjects’ genome.

As the resulting ‘big data’ exceeds in its amount and complexity the classical approaches, the analysis of NGS derived data is an active research topic. It has already led to working solutions (for review, see Nielsen et al.3 and Pabinger et al.4) and new statistical methods for analyzing NGS data are continuously emerging.5–9 However, methods to convert NGS-derived big data into biomarkers are still sparse and solutions exploiting the whole genomic information content for patient classification are still needed. Novel types of classifying biomarkers derived from NGS information are needed, and we report a subsymbolic classifier that uses emergent properties in genetics10 with the potential of self-learned improvement from successively addable genetic and clinical information.

The biomarker was developed based on the clinical problem of extremely high opioid demands by some pain patients without any obvious clinical reason, had been requested because of the perception of uncommonly high analgesic opioid dosing requirements without any obvious clinical reason and explicit denial of an addiction background. Using conversion to oral morphine equivalents (OMEs; for details, see Supplementary Table 1), these patients were divided into two groups with high (≥400 mg day−1 OME; n = 30; mean ± s.d.: 3.04 ± 0.34 log OME) and common (<100 mg day−1 OME; n = 28; ‘controls’; mean ± s.d.: 1.7 ± 0.24 log OME) opioid dosing requirements for chronic pain therapy. Upon written informed consent, a venous blood sample was taken from each patient; the samples were anonymized and sent to our laboratory at the Institute of Clinical Pharmacology in Frankfurt.

Opioid receptor genotyping using NGS

DNA preparation and amplification. Genomic DNA was extracted from 200 μl venous blood on a BioRobot EZ1 workstation applying the blood and body fluid spin protocol provided in the EZ1 DNA Blood 200 μl Kit

DNA NGS and variant identification. The template-positive Ion Sphere Particles were enriched on the Ion OneTouch ES (Life Technologies) and loaded on Ion 316 v2 Chips (500 Mb of expected sequence data output). Sequencing was performed with the Ion (PGM) system using Ion PGM 200 Sequencing Kit v2 (Life Technologies) with the 200-bp single-end run configuration following the manufacturer’s instructions. Using the Torrent Suite software (version 4.4.2; Life Technologies), signal processing, base calling and the generation of unmapped and mapped BAM-files (hg19 reference genomic sequence) were performed. The variant calling (single-nucleotide polymorphisms, multi-nucleotide polymorphisms (MNP), insertions (Ins) and deletions) across the hg19 reference genomic sequence was performed with the Torrent Variant Caller Plugin with following key parameters: minimum allele frequency = 0.1, minimum quality = 10, minimum coverage = 6 and minimum coverage on either strand = 0. The annotation of called variants was done with Ion Reporter software (version 4.2.2; Life Technologies) using VCF files from the Torrent Variant Caller as input. Data quality and coverage checks as well as variant identification were done using the single-nucleotide polymorphism and variation suite software (SVS version 8.3.3 for Linux 64-bit; Golden Helix, Bozeman, MT, USA). The correctness of the genotyping was verified using 10 amplifications of the coding parts of the genes that were completely conventionally sequenced by an independent commercial provider (LGC GMBH, Berlin, Germany).

Data analysis
Opioid receptor genotype differences between patients with high opioid dosage and controls were analyzed using the single-nucleotide polymorphism and variation suite software (SVS version 8.3.3 for Linux 64-bit; Golden Helix), the R software package (version 3.0.2 for Linux; http://CRAN.R-project.org/) and the Matlab numerical computing environment (version 8.3.0.532, MathWorks, Natick, MA, USA). The analyses are described briefly in the following; more detailed descriptions are provided in the Supplementary Materials.

Assessment of group differences in single opioid receptor variant or haplotype frequencies. A first analysis employed the classical approach to pharmacogenetic analyses consisting of χ² statistics with an α-level of 0.05 corrected for multiple testing according to the conservative criterion of Bonferroni. The dominant hereditary model (DD, Dd versus dd, where D denotes the minor allele and d the wild-type allele) was applied. In addition, haplotypes identified in silico via the minimizing historical recombination algorithm were analogously assessed. To observe statistical power, only variants found at a frequency of >10% were included.

Assessment of combined genotypic group classifiers. Further analysis addressed combinations of genetic variants employing two classical methods comprising stepwise regression analysis and classification and regression tree (CART) analysis. In addition, advanced approaches at complex genetic group classifiers were used. As above approaches implicitly assumed homogeneity within the two patient cohorts, cluster analysis was used to reveal subgroups within each cohort. For this analysis, data were preprocessed to obtain the genotypes at each locus that could be expected by chance, which were obtained as the group size weighted means across all patients, separately for each variant. Subsequently, for each variant and patient the directed deviations were calculated as the difference between the actual observation and the above calculated expectation. These deviations were submitted to cluster analysis using the Ward algorithm and the Jaccard distance calculated as 1 – Jaccard coefficient, the latter being identical to the percentage of nonzero values that differ. In a final step, these clusters served for the training of a k-nearest neighbor (kNN) classifier with k = 3. Furthermore, the distance function was optimized by selection of the most informative variables using computed ABC analysis that identified those genetic variants that promised to provide the best distinction between the two patient groups based on the difference in absolute group means of the number of rare-type alleles.

RESULTS
Group differences in single opioid receptor variant frequencies. Nucleotide information was completely available and sequencing runs met the standard requirements. The average throughput was 540 mega-bases, using 316 sequencing chips, which is within the upper third of the expected sequencing output according to the manufacturer’s instructions, and the average chip loading was 71%, meeting the all expected assay quality parameters criteria.

NGS identified 152 variants in opioid receptor genes in the whole study population (Figure 1). A number of 100, 42, 3 and 7 variants were located in the covered sequences of the OPRM1, OPRK1, OPRD1 and SIGMAR1 genes. Group differences in the allelic frequencies were analyzed for 77 gene loci where variant alleles were found in at least 10% of the patients. This resulted in a corrected α-level of 0.000649351 as the upper limit for acceptance of a significant difference (Figure 2). A P-value below this limit resulted for the group frequency comparisons of the Chr6:154451812-single-nucleotide variation (SNV) in the μ-opioid receptor gene OPRM1 (P = 0.00049, α-corrected P = 0.038) and for the Chr8:54147491-SNV in the k-opioid receptor gene OPRK1 (P = 0.00027, α-corrected P = 0.021), whereas a few other variants in the μ-opioid receptor gene, that is, Chr6:154444346-Ins (uncorrected P = 0.0169), Chr6:154452687-MNP (uncorrected P = 0.036) and Chr6:154567863-SNV (uncorrected P = 0.0174), merely displayed differences at an uncorrected significance level and were therefore rejected.

All opioid receptor genetic variants previously proposed as modulating opioid requirements (Table 1) failed to display significant group differences with respect to their allelic frequencies. For example, the variant T at OPRM1 118 G allele was found in 9 patients requiring high opioid doses and in 13 controls (uncorrected P = 0.589). However, none of the variants identified in this classical analysis provided an acceptable accuracy for the assignment of a patient to either group (51.5 ± 2% and 51.4 ± 5%) and the diagnostic sensitivities of these markers were also low (Table 3). Furthermore, a total of 24 different genetic variants carried only by pain patients who received very high opioid doses but not by any of the control patients provided an immediate biologically plausible cause for reduced or absent opioid receptor function (Table 2).
Predictions using combined genetic markers obtained with classical approaches

An only moderate improvement of the opioid receptor genetics-based group classification performance was obtained using classical assessments of combined genotypic group classifiers. Stepwise regression analysis identified, based on the \( P < 0.05 \) inclusion and \( P > 0.1 \) rejection criteria, \( n = 6 \) opioid receptor variants, that is, Chr6:154443510-SNV, Chr6:154449106-Ins, Chr6:154450991-MIX, Chr6:154451812-SNV, Chr8:54147491-SNV and Chr8:54155452-SNV, as suitable components of a combined genotypic classifier for the

Figure 1. Overview of the opioid receptor genetic pattern of the present patients (\( n = 30 \) and 28 pain patients with high and average opioid dosage, respectively). The denominations of gene loci where variants have been detected is given at the bottom of the figure. (Top) Bar plot of the frequency of carriers of single-nucleotide polymorphisms (SNPs), with bar lengths indicating the percentage of patients carrying a variant allele (either heterozygously or homozygously); bars in the upper direction (yellow) show the high opioid patients (\( n = 30 \)) and bars directed toward the bottom (dark gray) show the controls (\( n = 28 \)). (Bottom) Matrix plot of the occurrence of variants (columns) per patient (lines; color coding is white: wild type, yellow: heterozygous, red: homozygous rare allele), separated by gaps for the two groups of patients and for the four opioid receptor genes (OPRD1, OPRM1, OPRK1 and SIGMAR1) from the left to the right; the codes at the right are the patient's codes left in the figure for potential data validation purposes). For better visibility, the variants are numbered and the abscissa details are given in an enlarged version in the Supplementary Materials (DetailedAbscissa_Figure1.pdf).
present group assignment. A linear regression model using these alleles performed with an average accuracy of 61.7 ± 6% on the 100 randomly drawn test data sets (Table 3). A decision tree classifier constructed with the CART algorithm used \( n = 12 \) opioid receptor variants, that is, Chr6:154360483-SNV, Chr6:154414666-SNV, Chr6:154439865-SNV, Chr6:154442128-SNV, Chr6:154443510-SNV, Chr6:154450065-SNV, Chr6:154450991-MIX, Chr6:154450996-MNP, Chr6:154451812-SNV, Chr8:54147491-SNV and Chr8:54155452-SNV. The prediction of group assignment using this decision tree performed with an average accuracy of 74.4 ± 4% on the 100 randomly drawn test data sets (Table 3).

Predictions using advanced approaches at complex genetic group classifiers
A Ward clustering using the Jaccard distance on all genetic markers led to clusters of \( n = 5 \) each in both the high opioid patients and the controls. The \( k \)NN classifier was trained with the pattern of each cluster per group that resulted in a number of typical patterns given by the number of clusters per patient group. Each of the 100 randomly drawn test data sets was compared in the high-dimensional data space with the obtained complete genotypes according to the Jaccard distance, and the case was assigned to that cluster to which the majority of its three neighbors belonged. The performance of this classifier on the test data resulted in an accuracy of 74.4 ± 7% matching that of the CART-derived classifier (Table 3). This result could be improved by eliminating those genetic markers that only introduced noise into the classifier. ABC analysis revealed that the genetic information contained at 34 loci in opioid receptor genes suffices for accurate group assignment to either patients with high opioid dosage or controls (Figure 3). With these markers, three clusters were identified for the control group, whereas four clusters appeared in the high opioid group. The performance of this \( k \)NN classifier on the test data, obtained as described in the previous paragraph, resulted in an accuracy of 80.6 ± 4% (Table 3).

DISCUSSION
The present analysis showed that patterns of opioid receptor genotypes indeed provide a basis for the high opioid dose occasionally observed in pain patients. However, this was obtained using a ‘self-learning subsymbolic high-dimensional classifying biomarker’. That is, in machine learning a classifier is called symbolic if it can in principle answer the question of why a given data set has been assigned to a particular group; however, it is in principle not possible to get a reason for a particular classification. The presently used \( k \)NN classifier belongs to this type of algorithms. Its functioning is like an associative memory. For a given case the classifier searches its data base of already learned correct classifications in order to find those cases that are most similar to the given data set.\(^{15}\) If a data set has been classified successfully to its proper class, the data base of the classifier can be enhanced with this data set and classification (‘machine learning’). In analogy to the

subsymbolic/symbolic concept in machine learning we define a subsymbolic biomarker as a pattern of markers, here represented by the genetic changes, where (1) none of the markers needs to be directly related to any known biological function/process or a cellular component, although this is not excluded; and (2) the sequence of marker changes is not important, that is, the marker does not retrieve its classificatory value by its place in a sequence such as a nucleic or amino acid sequence in genes or proteins. In contrast, a symbolic biomarker would represent a genetic change that can be directly related to a biological function/process or a cellular component. However, if the pattern of the subsymbolic biomarkers is observed in an organism, it can be connected to biological function processes or a cellular component. This points at emergent properties in genetics.10

A subsymbolic high-dimensional classifying biomarker uses subsymbolic biomarkers and subsymbolic classifiers in order to decide between different biological conditions/classes/clusters. It is called self-learning, if successfully classified data are added to the knowledge base of the classifier. This can be called a ‘self-learning subsymbolic high-dimensional classifying biomarker’ (Figure 4). The present information from 30+28 patients can be successively enlarged by adding further patients. In the case that a new opioid receptor genotype pattern will be correctly identified by comparison with the present information from these 58 patients, the biomarker would be successful. In the opposite case, a wrongly classified genotype pattern can be implemented into the present data basis and new ABC marker sets. Jaccard distances can be computed to improve further diagnoses by a continuously developing system. Thus, the biomarker can ‘learn’.

One of the keys to the success of the classification was the accounting for the heterogeneity of the patients. Beyond the main phenotype of high opioid dosage, the present patients were indeed a heterogeneous group. They had been submitted to our pharmacogenetic counseling mostly without further details of the clinical background except for a few cases such as those presented. Therefore, patients have different diseases underlying the pain. The high opioid doses may be accidental as most patients were sent from University tertiary care centers where the physicians were more inclined to raise the opioid doses, whereas in the periphery, the same patients might have been labeled as
Machine-learned pharmacogenetic biomarker
D Kringel et al

Figure 3. Identification of those genetic variants that promised to provide the comparatively best distinction between the two patient groups. The bar plot shows the absolute group size standardized differences of the occurrence of each variant between the two patient groups. The 34 bars left of the solid vertical line indicate the genetic variants found by a computed ABC analysis (right upper part of the figure) to provide a statistically valid set of markers to be included in a complex biomarker. At the upper right corner is the ABC plot14 of the cumulative distribution function of the additional fraction of the absolute group differences in allelic numbers (solid curved line). In addition, ABC plots of the identity distribution, \( x_i = \text{constant} \) (dotted line, that is, each genetic variant occurs at the same number in each group), and of the uniform distribution in the data range (dotted line, that is, each variant allele had the same chance to occur) are shown. Compared with the latter distributions, the solid curved line clearly indicates a highly unequal distribution of the group differences in the numbers of variant alleles.

Further marks in this plot consist of a light grey and a darker grey star denoting the so-called Pareto and BreakEven points, respectively. The Pareto point \( A (A_x, A_y) \) is the point at the smallest distance (left oblique black line) to the ideal point at \( xy \) where the effort would be zero to obtain the whole yield. The BreakEven point \( B (B_x, B_y) \) marks the point on the ABC curve where its slope, \( dY/dE \), equals 1, that is, the so-called profit gain \( dABC \) equals 1. Beyond that point, more information can only be gained with inadequately high efforts. The ABC analysis comes from economical informatics and, in the present context, aims at identifying the most informative genetic variant for group classification by dividing the 152 variants into 3 distinct subsets. Set A should contain the ‘critical few’, that is, those elements that allow obtaining a maximum of yield with a minimal effort.14 Set B comprises those elements where an increase in effort is proportional to the increase in yield. In contrast, set C contains the ‘trivial many’, that is, those elements that are not worth to be considered a biomarker. As a result, set A was used to establish a subsymbolic classifying biomarker.

opiod resistant already at doses below 400 mg OME per day and therefore not included into this analysis. An opioid resistance might indeed apply to one of the presented patients as discussed below. Thus, the heterogeneity of opioid-treated pain patients is a clinical reality and has to be considered in a successful biomarker. Here, a self-learning biomarker provides an ideal basis.

However, although the subsymbolic biomarker successfully classified the patients, the question remained of how genetic changes of no singular identifiable major molecular consequence can nevertheless underlie the phenotype. A possible explanation may be the above-mentioned emergent properties in genetics10 to which the biomarker pointed. Specifically, we hypothesize that from the accumulation of several genetic variants that mostly provide only small quantitative modulations of gene transcription, a qualitative genetic change can emerge toward a substantially more or less efficiently transcribed gene that then gains the phenotypic consequences that were not produced by any single variant alone.

Indeed, molecular knowledge about members of the ‘A’ set of the ABC analysis (Figure 3) supports this hypothesis, and this will be illustrated by two examples. The Chr6:154451812-SNV, and various further variants that occurred only in patients receiving high analgesic opioid doses (not shown), is noncoding: yet, it is known that such variants can affect mRNA splicing, stability and structure, resulting in a reduced transcriptional efficiency.16,17 Indeed, genome-wide association studies yielded that besides mutations in the coding regions of genes, even mutations in noncoding and intergenic regions can be associated with diseases.18 These changes can affect the function of proteins, change the cellular response to therapeutic targets and can explain the different responses of individual patients to medications.19 Furthermore, the Chr8:54147491-SNV variant (c.438G>T) changes the codon ATA, which translates to isoleucine, to codon ATC, which also translates to isoleucine. Although apparently this mutation does not lead to an alteration in the primary polypeptide sequence, that is, it is synonymous, this kind of mutation is now widely acknowledged to be able to cause changes in protein expression, conformation and function.20 Recent genetic and biomedical studies have identified multiple mechanisms that provide an indication of the means by which synonymous mutations can affect physiological changes and consequently influence disease.21

A synonymous substitution might produce changes in the phenotype by affecting splicing that in consequence can lead to a shortened mRNA and subsequently a nonfunctional protein.21,22 Moreover, synonymous mutations might alter the mRNA stability, leading to faster degradation and reduced protein expression.23,24 Another possibility of how synonymous mutations may influence protein levels is affecting translation elongation. The relative synonymous codon usage (RSCU) value represents the local translation elongation rates and is directly linked with protein expression, as the speed of translation is often important for accurate protein folding. For example, a negative ΔRSCU value...
the hypothesis of a general weakening of the endogenous opioid system, mainly but not exclusively μ-opioidergic, that was caused by the accumulation of genetic variants. This may have finally rendered the patient as nearly ‘opioid resistant’, directly because of a reduced activity of exogenous μ-opioid agonists and indirectly also owing to a disturbed opioidergic system. Alternatively, as the subsymbolic nature of the biomarker involves that its classification performance cannot be definitely assigned to one of its components, it could turn out that the main contributors to the successful classification are variants in the OPRM1 gene. This is also well within the possibility of a self-learning classifier that, as explained above, by successively re-evaluating and modifying its composition, may still evolve toward a OPRM1 variant-based classifier. In that case, the association with a reduced activity of mainly μ-opioid receptor agonists would become straightforward. This analysis showed that opioid receptor genotyping, consistent with biological plausibility, has the potential to provide the desired predictively of particular (clinical) phenotypes as demonstrated with high opioid dose demands in pain patients. This may be obtained with a novel type of biomarker, called ‘self-learning subsymbolic high-dimensional classifying biomarker’. A self-learning biomarker offers an ideal basis to account for the heterogeneity of patients as it uses flexible patterns for the prediction. This is a novel concept of biomarkers and it is not limited to the present clinical diagnostic tasks. Related to this concept, results of the analysis can also be taken as evidence for emergent properties in genetics.10
