Abstract. Tomato (Lycopersicon esculentum Mill.) root distribution was evaluated by the trench profile wall method at four trickle irrigation regimes (irrigation at soil water potential –10, –20, –40, and –60 kPa) in a 2-year field trial. Total root length intensity (m·m⁻²), final yield (t·ha⁻¹) and fruit size (g/fruit) decreased with decrease in amount of water applied. In both years, tomato water use efficiency (kg·ha⁻¹·mm⁻¹) was significantly lower with irrigation at –10 kPa than with any other irrigation regime studied. The largest proportion of tomato roots, 88% for 1989 and 96% for 1990, was found in the top 40 cm of the soil and rapidly decreased with depth. The high concentration of roots in the 30 to 40 cm layer was attributed to an horizon with high soil bulk density values, immediately below 40 cm, impeding deeper root penetration. Most roots occurred in the emitter area, close to the plant. In rows 1.5 m apart, between 12% and 21% of total root length was found more than 0.5 m from the stem, which may have resulted from the interpenetration of roots from plants of adjoining rows.

Central and southern Portugal has a Mediterranean climate Csa (Köppen), with dry and warm summers (the mean temperature of the warmest month is >22 °C), low relative humidity, and high insolation (Portas et al., 1986). These conditions favor production of vegetable crops such as tomato since precipitation, which adversely affects quality during fruit maturation, is minimal. However, crop water needs are higher than soil water resources and irrigation must be implemented, especially between June and September.

Drip irrigation can be a solution for sandy soils with low water retention, which are typical of most of these areas. Although automation of the drip systems can reduce production costs, the small soil-root volume per plant under drip irrigation can cause plant stress, which in turn can affect yield, if application of water or nutrients is delayed for even short periods of time (Bar-Yosef et al., 1980). The objective of this investigation was to evaluate the effects of different water regimes on root distribution of processing tomato (Lycopersicon esculentum) with automatic drip irrigation.

Materials and Methods

Trials were conducted in 1989 and 1990 on a regosol soil (Typic Quarzipsamments) at the Research Station António Teixeira, in Coruche, which represents about 30% (4000 ha) of the Sorraia Valley area. Soil characteristics and meteorological data during the two years of experimentation are summarized in Tables 1 and 2. Soil water retention curves for the 20 and 60 cm depth are presented in Fig. 1. Wilting point (–1500 kPa) and field capacity (–33 kPa) for the 20 cm depth were 0.031 and 0.20 cm³·cm⁻³, respectively. Soil bulk density was measured in undisturbed samples of known volume (six samples per depth). The experimental design was a randomized block with four irrigation treatments and three replications. The plot sizes were 5 × 13.5 m², with nine rows each. Irrigation was applied when soil water potential reached –10, –20, –40, and –60 kPa, corresponding to 85%, 65%, 55%, and 50% of soil field capacity, respectively. Root data were analyzed as a split plot with the irrigation treatments as main plots and soil depths as subplots. Data were analyzed by year, using analyses of variance and means were separated using Duncan’s multiple range test.

Table 1. Physical and chemical characteristics of the soil.

| Depth (cm) | Texture | Bulk density (g cm⁻³) | Organic matter (%) | pH | P (ppm) | K (ppm) |
|-----------|---------|----------------------|-------------------|----|--------|--------|
| 0–40      | Sand: 92.3 | Silt: 4.3 | Clay: 3.4 | 1.62 | 1.24 | 5.5 | 82.9 | 45.7 |

Soil preparation consisted of an initial 30 to 40 cm deep mouldboard plowing followed by two disc harrow operations to a depth of 10 to 15 cm for seed bed preparation. 'Rio Grande' tomato cultivar was seeded (3 cm depth) in rows 150 cm apart and 10 cm between plants. Soil fertilization in each year was based on soil fertility and plant needs. Before planting, fertilizers as Ca(NO₃)₂•4H₂O, MgSO₄•7H₂O, Ca₃(PO₄)₂ and K₂SO₄, at rates (kg·ha⁻¹) for 1989 and 1990, respectively, N(87,44); P(26,26); K(498, 83); Ca(129,90) and Mg(48,48) were applied, in a band 15 cm directly below the row. For fertilizers supplied with irrigation along the growing season as Ca(NO₃)₂•4H₂O, KNO₃ and H₃PO₄, the rates in kg·ha⁻¹ for 1989 and 1990, respectively, were N(152,226); P(28,26); K(116,485) and Ca(101,55). These fertilizers were previously dissolved using tap water, in a tank connected to the irrigation system. The drip irrigation system was automatically controlled by electric tensiometers placed at the 15 cm depth just below the plants, one for each treatment. All the emitters were located beside the plants and the distance between emitters was 40 cm. The discharge rate was 3 L·h⁻¹ at a pressure of 1.5 kg·cm⁻². For each treatment, irrigation began at plant thinning and terminated when 75% of the fruit were red or orange (ready for commercial harvest).

Fruits were harvested in all the plants of six rows (5 m long) for each plot, when 85% to 90% of fruit were red or orange, for both years. Fruit were counted and weighed for total yield and medium fruit size determination.
At harvest, three profiles per treatment and replication were opened using the trench profile method (Böhm, 1976) to characterize tomato rooting patterns. A layer of soil that averaged 5 mm in thickness was washed from a smoothed 1.5-m-wide wall and, then, a metal frame with grids (5 × 5 cm) was laid against the profile wall. The length of roots exposed by washing was estimated by counting the number of 5-mm-long roots in each grid area (Böhm, 1976). The profile wall was located at a distance of 5 cm from the base of a tomato plant, perpendicular to the row, and extended deeper than the rooting depth. The second and third profiles were made in the

Fig. 3. Root distribution of tomato at different irrigation regimes: –10 kPa (a); –20 kPa (b); –40 kPa (c); –60 kPa (d) (1 point = 5 mm visible root length at the profile wall). Drip emitter located beside plant is indicated by ●, 1990.

Table 3. Total root length intensity (m·m⁻²), yield (t·ha⁻¹), mean fruit size (g/fruit), and water-use efficiency (WUE) (kg·ha⁻¹·mm⁻¹) for each irrigation regime.

*ETR = irrigation + precipitation – drainage.
same trench and 40 cm beyond the previous profile, next to another plant-emitter situation. Assuming that one root unit is 0.005 m long, since 5 mm of soil has been washed away from a 1.5 × 1-m² area, a total count of N units in the whole profile corresponds to a root length per unit of ground surface equal to (N × 0.005)/(1.5 × 0.005). So, root length per unit of soil surface area, root length intensity (m·m⁻²), was estimated as follows:

\[
\text{Root length intensity (m·m}^{-2}) = \frac{N}{1.5}
\]

where \(N\) = number of points (1 point = 5 mm visible root length).

Rooting intensity pictographs were made by placing dots on gridded paper in positions that corresponded to actual exposed root locations. The same procedure was used for the second year. The number of dots for each grid area corresponds to average values of all the counts made in the same position for each treatment (Figs. 2 and 3).

### Results and Discussion

Total root length per unit of soil surface area was significantly different between irrigation treatments in both years (Table 3).

### Table 5. Rooting pattern along the soil profile by irrigation regime.

| Depth (cm) | Irrigation treatment | Root length intensity (m·m⁻²) |
| --- | --- | --- |
| 0–10 | –10 KPa | 362.3 | 303.3 | 283.0 | 283.0 | 163.7 |
| 10–20 | –20 KPa | 349.3 | 320.7 | 255.3 | 255.3 | 129.7 |
| 20–30 | –40 KPa | 365.0 | 311.0 | 248.7 | 248.7 | 94.3 |

| 60–70 | 12.7 | 13.7 | 23.3 | 23.3 | 4.0 |
| 70–80 | 20.0 | 2.3 | 24.3 | 24.3 | 2.7 |
| 80–90 | 10.0 | 0.3 | 16.3 | 16.3 | 0.0 |
| 90–100 | 3.3 | 0.0 | 8.0 | 8.0 | 0.0 |

In 1989, root length was not significantly different (irrigation at –10 vs. –40 kPa of soil water potential) with values of about 1400 m·m⁻². Total root length for irrigation at –20, –40, and –60 kPa were 86%, 85%, and 33% respectively of total root length at irrigation at –10 kPa. For the second year only the treatment with irrigation at –60 kPa was significantly different, with 1796 m·m⁻² of root length intensity as compared with about 2500 m·m⁻² for the other treatments. The rates of total root length for 1990, and for irrigation at –20, –40, and –60 kPa were respectively 97%, 98%, and 71% of total root length obtained with irrigation at –10 kPa. Final yield, fruit size and root growth in both years increased as irrigation increased (Table 3). Although the increase from –20 to –10 kPa did not raise significantly total yield, the mean fruit size (g/fruit) was significantly higher with irrigation at –10 kPa. A similar increase in fresh fruit yield with increased irrigation water had been reported by Bar-Yosef et al. (1980). The water use efficiency (total yield/real evapotranspiration ETR) (Table 3) in the first year increased with water applied from irrigation at –60 kPa (234 kg·ha⁻¹·mm⁻¹) to irrigation at –20 kPa (279 kg·ha⁻¹·mm⁻¹) but, at –10 kPa, the increase in yield per unit of water applied was significantly lower (210 kg·ha⁻¹·mm⁻¹). For the second year, the values for water use efficiency were about 80% of those obtained in the 1989 experiment, mainly as a result of a lower yield in the second year. The lowest values in water use efficiency were observed in both years, with the highest irrigation regime (–10 kPa), indicating that irrigation over –20 kPa must be the object of further studies.

A significant effect of soil depth on root length intensity was observed, and also for the interaction between irrigation treatments and depths the results were significantly different (Table 5). The pattern of root distribution along the soil profile shows, in both years, an exponential decrease in root length intensity with depth (Table 4). Root penetration was restricted at about 40 cm deep, where an horizon appeared with high soil bulk density values, about 1.75 g·cm⁻³. At such soil bulk density values root growth is severely impeded (Oliveira and Portas, 1993). Higher values for root intensity observed in both years for the 30 to 40 cm layer, indicate that roots tend to proliferate at the depth immediately above a restrictive layer.

A larger proportion of tomato roots, 88% for 1989 and 96% for 1990, were found in the top 40 cm of soil which agrees with data from Taylor et al. (1970), Bar-Yosef et al. (1980), Maynard et al. (1980), Tan and Fulton (1985), and Sanders et al. (1991). However, our root distribution results do not agree with those from Tindall et al. (1991) who reported that tomato root density under microirrigation did not rapidly decrease with depth. These authors worked with a clay subsoil with presence of large cracks and
consequently less impedance for root elongation.

The larger proportion of roots found in the area of the emitter, close to the plant, and decreasing with distance from the emitter (Figs. 2 and 3), was also observed by West et al. (1979) and Randall and Locascio (1988). Between 12% and 21% of total root length was found more than 0.5 m from the stem, which can be attributed to interpenetration of roots from plants of adjoining rows. Portas and Dordio (1980) reported that in open fields, at fruit setting stage, tomato root systems of adjoining 1.5-m-apart rows interpenetrate as result of lateral root spreading.
