Modeling the local potential at Pt nanoparticles in polymer electrolyte membranes

Mohammad Javad Eslamibidgoli, Pierre-Éric Alix Melchy and Michael H. Eikerling*

We present a physical-analytical model for the potential distribution at Pt nanodeposits in a polymer electrolyte membrane (PEM). Experimental studies have shown that solid deposits of Pt in PEM play a dual role in radical-initiated membrane degradation. Surface reactions at Pt particles could facilitate the formation as well as the scavenging of ionomer-attacking radical species. The net radical balance depends on local equilibrium conditions at Pt nanodeposits in the PEM, specifically, their equivalent local electrode potential. Our approach utilizes a continuum description of crossover fluxes of reactant gases, coupled with the kinetics of electrochemical surface reactions at Pt nanodeposits to calculate the potential distribution. The local potential is a function of the PEM structure and composition, which is determined by PEM thickness, concentrations of H2 and O2, as well as the size and density distribution of Pt particles. Model results compare well with experimental data for the potential distribution in PEMs.

1 Introduction

Prospects of unrivaled energy conversion efficiency and correspondingly reduced greenhouse gas emissions drive the global push towards polymer electrolyte fuel cell (PEFC) technology in automotive applications. Cost-effective utilization of materials as well as their stability and cycle life in the operating cell remain major challenges that must be successfully addressed. The durability and longevity of PEFCs are strongly affected by structural degradation of component materials, among which the polymer electrolyte membrane (PEM) is of central importance. The PEM degradation problem is critical for PEFC stacks in fuel cell buses that must operate for > 20,000 hours. PEsMs are exposed to thermal and mechanical stressors, coupled with the chemical attack of weak bonds of ionomer molecules by radical species, primarily H*, OH* and OOH. Experimental studies linked chemical degradation of the membrane to the concentrations of these radical species. Deposits of Pt-in-the-membrane (PITM) are a consequence of Pt dissolution in the cathode catalyst layer. Mobile Pt ion complexes diffuse and migrate into the membrane. They form solid deposits by precipitation in the presence of H2 and O2, crossed over from anode and cathode, respectively. Solid Pt nanodeposits provide catalyst surface sites for processes involved in formation or scavenging of radicals. In addition, surface reactions at PITM could facilitate the decomposition or formation of H2O2. In the latter case, H2O2 thus formed could react at impurities such as Fe2+ to produce radicals.

The effect of PITM on the durability of the PEM is still under debate. Rodgers et al. have observed a strong impact of the Pt density on the degradation of Pt-impregnated membranes. Ohguri et al. have investigated the formation of OH at Pt particles in the membrane. In their work, OH is detected at both the anode and the cathode side but the amount is much larger for the anode side. Ghassemzadeh et al. have observed that the chemical degradation rate was higher in the presence of Pt catalyst for a H2-rich mixture of H2 and O2 (90% H2, 2% O2, 8% Ar) as compared to an O2-rich mixture (20% O2, 2% H2, 78% Ar). A similar trend was reported by Aoki et al. and Ohma et al. Other researchers have observed severe membrane degradation in the presence of Pt particles. It has also been found that PITM can enhance durability by deactivating radicals and H2O2. Conditions such as low relative humidity, high temperature, and high cell voltage accelerate chemical degradation due to an increased formation of H2O2 in the cell. The balance of competing processes depends on local conditions such as temperature and relative humidity as well as the structure and local chemical composition of the PEM. The local chemical composition of the PEM is determined by pH and by mole fractions of H2 and O2 provided at opposite membrane sides. Local values of H2 and O2 concentrations can be calculated for given transport properties, composition and thickness of the PEM. The same conditions also determine the size, shape and density distribution of Pt deposits in the PEM. On the other hand, the formation of PITM has a feedback effect on concentrations of H2 and O2 as well as membrane humidification. Moreover, the rates of catalytic surface processes depend on size and shape of Pt nanoparticle deposits. Understanding the
impact of PITM on the chemical degradation of the PEM thus involves a complex phenomenology of local conditions and structure of the PEM, as well as structure-dependent transport and reaction processes.

The local open circuit potential (OCP) of a Pt nanoparticle, considered as a nanoelectrode in the PEM, is determined by the conditions listed above. Liu and Zuckerbrod have measured the OCP distribution at a Pt nanoprobe in the membrane, with H₂ and air provided at opposite membrane sides. 30 They have observed a step-like potential profile. The local electrode potential in the region close to the anode was found near 0 V vs. RHE. In the region near the cathode, the OCP was found to attain values between 0.8 V and 1.0 V. Takaichi et al. have measured the OCP distribution determined by H₂ and O₂ permeation in the membrane. 31 They have observed a change in the step position at different O₂ partial pressure and relative humidity. Later, using the microprobe technique, Ohishi et al. have studied the distribution of the OCP. 32 They have investigated the influence of operating conditions on O₂ transport properties and the effect on the potential at the probe insertion position.

Understanding the problem of electrostatic potential at isolated metallic nanoparticles in an electrolyte is fundamentally interesting and of broader practical impact. Specifically, the problem of Pt nanodeposits in polymer electrolyte membranes has received significant attention in recent years. However, to the best of our knowledge only one modeling work has been devoted to this topic. 33 Atrazhev et al. have developed a model to predict the potential distribution at a single Pt particle in the PEM. 33 Their model employs an ‘ad hoc’ formulation of the problem, in which the surface concentrations of reactant gases, H₂ and O₂, at a spherical Pt particle are obtained as functions of particle position. The relations are substituted in the Butler–Volmer equations and the charge balance condition is applied to numerically calculate the local mixed potential at the particle. Their model, however, suffers from physically inconsistent relations obtained for the current densities of hydrogen oxidation reaction (HOR) and oxygen reduction reaction (ORR), i.e. eqn (36) and (37) in their paper. 33 As discussed in their paper, at the position of the potential step, both HOR and ORR are controlled by diffusion of reactant gases to the particle surface; thus, at this position, each of the current densities must be independent of the particle potential. However, in their relevant equations the dependency still exists. In addition, the implementation and parameterization of HOR and ORR processes at the spherical Pt nanoelectrode. The diffusion limited current density of the HOR is

\[
\frac{j_{\text{HOR}}}{D_{\text{H}_2}} = 4 F c_{\text{H}_2} c_{\text{H}_2} (x) \frac{D_{\text{H}_2}^{\text{nano}}}{r_0},
\]

and that of the ORR is

\[
\frac{j_{\text{ORR}}}{D_{\text{O}_2}} = 4 F c_{\text{O}_2} c_{\text{O}_2} (x) \frac{D_{\text{O}_2}^{\text{nano}}}{r_0}.
\]

As shown in Fig. 2, four regimes can be distinguished to describe the mixed reaction kinetics at the surface of Pt nanodeposits in the PEM. The distinction is based on the comparison of diffusion and kinetically-limited current densities of HOR and ORR at the spherical Pt nanoelectrode. 34–36

In this paper, we present a rigorous and self-consistent formulation of the problem, which results in a physical–analytical model of the mixed-potential distribution at Pt nanodeposits in the PEM. The model employs continuum diffusion for the crossover of reactant gases, H₂ and O₂, coupled with local electrochemical reactions at the surface of Pt nanoparticles. The analytical solution gives the shapes of reactant concentrations and potential profile in terms of experimental parameters, including the relative concentration of H₂ and O₂ at the PEM boundaries, mass transfer coefficients, kinetic parameters of surface reactions at Pt, and size and density of Pt particles in the PEM. Model outcomes are compared to experimental measurements of the OCP at Pt nanodeposits in the membrane. 30,31

2 The model

The model incorporates a two-scale description of transport and reaction processes in the membrane, as illustrated in Fig. 1. At the macroscale, one-dimensional (1D) diffusion governs the distribution of redox species, i.e., H₂ and O₂, along the thickness variable x. Even though we do not consider the membrane embedded in the fuel cell configuration, we refer to the side at which hydrogen is supplied as the anode and the side at which oxygen is provided as the cathode. Concentrations of hydrogen and oxygen in the PEM are \(c_{\text{H}}(x)\) and \(c_{\text{O}}(x)\). The concentrations at the PEM boundaries are \(c_{\text{H}}(x=0)\) at x = 0 (anode side) and \(c_{\text{O}}(x=1)\) at x = 1 (cathode side). At the nanoscale, the hydrogen oxidation reaction (HOR), \(\text{H}_2 \rightleftharpoons 2\text{H}^+ + 2\text{e}^-\), and the oxygen reduction reaction (ORR), \(\text{O}_2 + 4\text{H}^+ + 4\text{e}^- \rightarrow 2\text{H}_2\text{O}\) proceed at the surface of Pt nanoparticles, which we assume spherical. As Pt nanoparticles are not connected to an electron source/sink, the resulting OCP must fulfill a condition that the rates of HOR and ORR processes are balanced at the particle level.

As shown in Fig. 2, four regimes can be distinguished to describe the mixed reaction kinetics at the surface of Pt nanodeposits in the PEM. The distinction is based on the comparison of diffusion and kinetically-limited current densities of HOR and ORR at the spherical Pt nanoelectrode. The diffusion limited current density of the HOR is

\[
\frac{j_{\text{HOR}}}{D_{\text{H}_2}} = 4 F c_{\text{H}_2} c_{\text{H}_2} (x) \frac{D_{\text{H}_2}^{\text{nano}}}{r_0},
\]

and that of the ORR is

\[
\frac{j_{\text{ORR}}}{D_{\text{O}_2}} = 4 F c_{\text{O}_2} c_{\text{O}_2} (x) \frac{D_{\text{O}_2}^{\text{nano}}}{r_0}.
\]

In this paper, we present a rigorous and self-consistent formulation of the problem, which results in a physical–analytical model of the mixed-potential distribution at Pt nanodeposits in the PEM. The model employs continuum diffusion for the crossover of reactant gases, H₂ and O₂, coupled with local electrochemical reactions at the surface of Pt nanoparticles. The analytical solution gives the shapes of reactant concentrations and potential profile in terms of experimental parameters, including the relative concentration of H₂ and O₂ at the PEM boundaries, mass transfer coefficients, kinetic parameters of surface reactions at Pt, and size and density of Pt particles in the PEM. Model outcomes are compared to experimental measurements of the OCP at Pt nanodeposits in the membrane. 30,31

![Model representation of a Pt nanoparticle in the membrane. The model assumes macroscale diffusion of H₂ and O₂ from the opposite membrane boundaries, coupled with local diffusion around Pt nanodeposits and reactions (HOR and ORR) at the Pt surface.](image-url)
where \( F \) is the Faraday constant, \( r_0 \) is the Pt particle radius, \( d_{\text{H}_2}^{\text{nano}} \) and \( d_{\text{O}_2}^{\text{nano}} \) are the diffusion coefficients of \( \text{H}_2 \) and \( \text{O}_2 \) at the nanoscale, respectively.

For the faradaic current densities of \( \text{HOR} \) and \( \text{ORR} \) at the particle surface, we use expressions in the form of the Butler–Volmer equation, i.e.,

\[
\dot{j}_\text{HOR} = \dot{j}_\text{HOR}^0 \left( \left( \frac{c_{\text{H}_2}}{c_{\text{ref}}} \right)^{\frac{\alpha}{b}} \exp \left[ \frac{\alpha}{b} \left( E(x) - E_{\text{eq}}^{\text{HOR}} \right) \right] - \exp \left[ - \frac{\alpha}{b} \left( E(x) - E_{\text{eq}}^{\text{HOR}} \right) \right] \right)
\]

and

\[
\dot{j}_\text{ORR} = \dot{j}_\text{ORR}^0 \left( \left( \frac{c_{\text{O}_2}}{c_{\text{ref}}} \right)^{\frac{\beta}{b}} \exp \left[ \frac{\beta}{b} \left( E(x) - E_{\text{eq}}^{\text{ORR}} \right) \right] - \exp \left[ - \frac{\beta}{b} \left( E(x) - E_{\text{eq}}^{\text{ORR}} \right) \right] \right)
\]

where \( b = \frac{RT}{F} \), \( c_{\text{H}_2} \) and \( c_{\text{O}_2} \) are surface concentrations of \( \text{H}_2 \) and \( \text{O}_2 \), respectively, and \( c_{\text{ref}} = 40.88 \times 10^{-6} \text{ mol cm}^{-3} \) is a reference concentration.\(^{38}\) It corresponds to the \( \text{O}_2 \) concentration at standard conditions. \( \alpha \) and \( \beta \) are the anodic and cathodic electron transfer coefficients, \( \dot{j}_\text{HOR}^0 \) and \( \dot{j}_\text{ORR}^0 \) are the exchange current densities of \( \text{HOR} \) and \( \text{ORR} \), and \( E_{\text{eq}}^i \) is the equilibrium potential of \( \text{ORR} \) (vs. RHE). \( R \) and \( T \) are the gas constant and temperature, respectively.

For a Pt nanodeposit at position \( x \), one of four possible scenarios will determine the local value of the OCP, \( E(x) \): (1) If \( \dot{j}_\text{HOR}^0 > \dot{j}_\text{ORR}^0 \), then the \( \text{HOR} \) is controlled by reaction kinetics and the \( \text{ORR} \) is diffusion-limited, as shown in Fig. 2(a); in this case, \( E(x) \) remains close to the equilibrium potential of the \( \text{HOR} \). (2) If \( \dot{j}_\text{HOR}^0 < \dot{j}_\text{ORR}^0 \), then the \( \text{HOR} \) is diffusion-limited and the \( \text{ORR} \) is kinetically controlled; in this case, \( E(x) \) shifts towards the equilibrium potential of the \( \text{ORR} \), as illustrated in Fig. 2(b). (3) The transition between the two cases occurs at the position where \( \dot{j}_\text{HOR} = \dot{j}_\text{ORR}^0 \), as shown in Fig. 2(c); in this regime, the current density at the particle is independent of \( E(x) \); it corresponds to a step-like change in \( E(x) \) at a position \( x_0 \). From the condition of equal diffusion-limited current densities in this regime, we will determine the value of \( x_0 \). (4) The last possible scenario is that both reactions are controlled kinetically, as depicted in Fig. 2(d); in this case, \( E(x) \) is found from the condition \( \dot{j}_\text{HOR} = \dot{j}_\text{ORR}^0 \), using eqn (3) and (4).

Following the distinction of different kinetic regimes for the local current density at the nanoparticle surface, the PEM can be divided into two spatial regions, viz. an anodic region at \( x < x_0 \), in which \( \dot{j}_\text{HOR}^0 > \dot{j}_\text{ORR}^0 \) and a cathodic region at \( x > x_0 \), in which \( \dot{j}_\text{HOR} < \dot{j}_\text{ORR}^0 \). In the anodic region, the \( \text{HOR} \) current is kinetically controlled, whereas the \( \text{ORR} \) is usually in the diffusion-limited regime. In the cathodic region, the \( \text{ORR} \) is kinetically controlled, whereas the \( \text{HOR} \) is usually in the diffusion-limited regime.

If a reaction at the Pt surface is kinetically controlled, the surface concentration of redox species will be equal to the bulk concentrations, i.e. \( c_{\text{H}_2} = c_{\text{H}_2}^{\text{bulk}} \) in the anodic region and \( c_{\text{O}_2} = c_{\text{O}_2}^{\text{bulk}} \) in the cathodic membrane region. For diffusion-limited reactions, we will assume zero surface concentration of the transport-limited reactant, i.e. \( c_{\text{H}_2} \approx 0 \) in the anodic region and \( c_{\text{O}_2} \approx 0 \) in the cathodic region. As we are interested in obtaining analytical solutions for the potential profile \( E(x) \), we will employ modified forms of the Butler–Volmer expressions in eqn (3) and (4), given by

\[
\dot{j}_\text{HOR} = 2\dot{j}_\text{HOR}^0 \left( \frac{c_{\text{H}_2}(x)}{c_{\text{ref}}} \right)^{\frac{1}{2}} \sinh \left[ \frac{1}{2b} \left( E(x) - E_{\text{eq}}^{\text{HOR}} \right) \right],
\]

and

\[
\dot{j}_\text{ORR} = \dot{j}_\text{ORR}^0 \left( \frac{c_{\text{O}_2}(x)}{c_{\text{ref}}} \right)^{\frac{1}{2}} \sinh \left[ \frac{1}{2b} \left( E(x) - E_{\text{eq}}^{\text{ORR}} \right) \right].
\]

In eqn (5) and (6), we assume \( \dot{j}_\text{HOR}^0 = \dot{j}_\text{ORR}^0 = \frac{1}{2} \) (ref. 34) and \( \dot{j}_\text{ORR}^0 = 1.35.36 \) In eqn (5) the sinh-expression for the faradaic current density of the \( \text{HOR} \) represents a common interpolation.\(^{39}\) It allows for a continuous description of the \( \text{HOR} \) rate in the limit of small overpotential, \( E(x) \leq b/3 \), where \( c_{\text{H}_2}(x) \approx c_{\text{ref}} \) and high overpotential, \( E(x) \geq 3b \), where \( 2\sinh[2\beta(x)/2b] \approx \exp[E(x)/2b] \). The single term BV-equation for the \( \text{ORR} \) in eqn (6) is the standard form, accounting for the irreversible kinetics of the \( \text{ORR} \).

We apply the charge balance condition for anodic and cathodic regions in the PEM and at the transition between these regions, to obtain analytical relations for the potential profile. In the anodic region, i.e. for \( x < x_0 \), we have

\[
\dot{j}_\text{HOR} = \dot{j}_\text{ORR}^0.
\]

Inserting eqn (2) and (5) and solving for \( E(x) \) results in

\[
E(x) = 2b \sinh^{-1} \left[ \frac{1}{2} \frac{c_{\text{H}_2}(x)}{c_{\text{ref}}} \dot{j}_\text{ORR}^0 \right] / \dot{j}_\text{HOR}^0.
\]
Similarly, in the cathodic region of the PEM, \(i.e.\) for \(x > x_0\), we have

\[
\dot{J}_{\text{ORR}} = \dot{J}_{\text{HOR}}. \tag{10}
\]

In this case, using eqn (1) and (6) and solving for \(E(x)\), gives

\[
E(x) = E_{\text{eq}} - b \ln \left[ \frac{c_{\text{H}_2}(x)}{c_0} \right] \tag{11}
\]

with

\[
\dot{J}_{\text{HOR}} = 2FC_{\text{H}_2} \frac{D_{\text{nano}}^{\text{nano}}}{r_0}. \tag{12}
\]

At \(x = x_0\), both the current densities of HOR and ORR are controlled by diffusion and, therefore,

\[
\dot{J}_{\text{HOR}} = \dot{J}_{\text{ORR}}, \tag{13}
\]

which leads to a unique relation between the ratio of the bulk concentrations of the reactant gases at \(x_0\), and the diffusion coefficients,

\[
2c_{\text{O}_2}(x_0)D_{\text{O}_2}^{\text{nano}} = c_{\text{H}_2}(x_0)D_{\text{H}_2}^{\text{nano}}. \tag{14}
\]

Eqn (14) can be solved to find \(x_0\) whence the distributions \(c_{\text{H}_2}(x)\) and \(c_{\text{O}_2}(x)\) are known.

The last possible case is when both current densities of HOR and ORR are controlled by reaction kinetics,

\[
\dot{J}_{\text{HOR}} = \dot{J}_{\text{ORR}}. \tag{15}
\]

In this scenario, the potential profile is obtained using eqn (5) and (6), giving,

\[
E(x) = 2b \ln \left[ \frac{12^{1/3} + \left( \kappa(x) + \sqrt{\kappa(x)^2 - 12} \right)^{2/3}}{18^{1/3} + \left( \kappa(x) + \sqrt{\kappa(x)^2 - 12} \right)^{2/3}} \right], \tag{16}
\]

where

\[
\kappa(x) = 9 \left( \frac{c_{\text{O}_2}(x)\rho_{\text{ORR}}}{c_{\text{H}_2}(x)\rho_{\text{HOR}}} \right) \exp \left[ \frac{E_{\text{eq}}}{b} \right]. \tag{17}
\]

Eqn (8), (11) and (16) allow expressing the potential profile in the PEM through the distribution of concentrations, \(c_{\text{H}_2}(x)\) and \(c_{\text{O}_2}(x)\). In order to obtain the concentrations, we must solve 1D diffusion equations for hydrogen and oxygen in the distinct PEM regions.

We define \(\xi = x/T\) as the dimensionless coordinate along the membrane thickness and \(\xi_0 = x_0/T\) as the dimensionless position of the potential step. In the anodic region \((\xi < \xi_0)\), the reaction–diffusion equation for \(\text{O}_2\) is

\[
\frac{d^2c_{\text{O}_2}(\xi)}{d\xi^2} = A^{-2}c_{\text{O}_2}(\xi), \tag{18}
\]

and that for \(\text{H}_2\), using eqn (7), is

\[
\frac{d^2c_{\text{H}_2}(\xi)}{d\xi^2} = 2A^{-2}c_{\text{H}_2}(\xi), \tag{19}
\]

with

\[
\delta^2 = \frac{D_{\text{nano}}^{\text{H}_2}}{D_{\text{nano}}^{\text{O}_2}}. \tag{20}
\]

and

\[
A = \frac{1}{7} \left( 4\pi n_{\text{Pt}} \left( \frac{D_{\text{nano}}^{\text{H}_2}}{D_{\text{nano}}^{\text{O}_2}} \right) \right)^{-1/2}, \tag{21}
\]

where \(n_{\text{Pt}}\) is the number of Pt particles per unit PEM volume. The product \(AL\) represents the dimensional reaction penetration depth of \(\text{O}_2\). In the dilute limit of the Pt particle distribution, we have \(A \gg 1\), and in the dense limit \(A \ll 1\).

The diffusion coefficients at nanoscale and macroscale are distinguished as the structure and effective transport resistance of the medium is different at the two scales. The macroscale diffusion coefficient corresponds to diffusion in a random composite medium, with randomly mixed resistances due to polymer and water-filled domains. Nanoscale diffusion coefficients, on the other hand, approach the values for water. Therefore, the macroscopic diffusion coefficient will be smaller than the value in water by a factor that incorporates percolation effects. We consider this value as 10 because the diffusion coefficient of \(\text{H}_2\) and \(\text{O}_2\) in water is one order of magnitude larger than its value in Nafion. This ratio is included in \(A\) in eqn (21).

Due to the large overpotential for the ORR at the anode, we assume that \(\text{O}_2\) is completely used up at \(\xi = 0\). The boundary conditions of eqn (18) and (19) are given by

\[
c_{\text{O}_2}(\xi = 0) = 0, \quad c_{\text{O}_2}(\xi_0) = c_{\text{O}_2}^0, \tag{22}
\]

and

\[
c_{\text{H}_2}(\xi = 0) = c_{\text{H}_2}^0, \quad c_{\text{H}_2}(\xi_0) = c_{\text{H}_2}^0. \tag{23}
\]

The solutions of eqn (18) and (19), subject to the boundary conditions (22) and (23), are

\[
c_{\text{O}_2}(\xi) = c_{\text{O}_2}^0 \sinh \left( \frac{A^{-1}\xi}{\sinh(\xi_0)} \right), \tag{24}
\]

and

\[
c_{\text{H}_2}(\xi) = \frac{2}{\delta^2} c_{\text{O}_2}^0 \sinh \left( \frac{A^{-1}\xi}{\sinh(\xi_0)} \right) + \left( c_{\text{H}_2}^0 - c_{\text{H}_2}^0 - \frac{2}{\delta^2} c_{\text{O}_2}^0 \right) \frac{\xi}{\xi_0} + c_{\text{H}_2}^0. \tag{25}
\]

Similarly, in the cathodic region of the PEM \((\xi > \xi_0)\), the reaction–diffusion equation of \(\text{H}_2\) is

\[
\frac{d^2c_{\text{H}_2}(\xi)}{d\xi^2} = A^{-2}c_{\text{H}_2}(\xi), \tag{26}
\]

and that of \(\text{O}_2\), using eqn (10), is

\[
\frac{d^2c_{\text{O}_2}(\xi)}{d\xi^2} = A^{-2} \frac{\delta^2}{2} c_{\text{H}_2}(\xi). \tag{27}
\]
Here, for simplicity, we assume \( \frac{D_{\text{H}_2}}{D_{\text{O}_2}} = \frac{D_{\text{H}_2}^{\text{macro}}}{D_{\text{O}_2}^{\text{macro}}} \), so that \( A \) is the same as defined in eqn (21).

The boundary conditions are

\[
e_{\text{H}_2}(0) = e_{\text{H}_2}^0, \quad e_{\text{H}_2}(1) = 0, \tag{28}
\]

and

\[
e_{\text{O}_2}(0) = e_{\text{O}_2}^0, \quad e_{\text{O}_2}(1) = 0, \tag{29}
\]

The solutions of eqn (26) and (27) are

\[
e_{\text{H}_2}(\xi) = e_{\text{H}_2}^0 \sinh(A^{-1}(\xi - 1)) - \frac{1}{2} \sinh(A^{-1}(0 - 1)) \tag{30}
\]

and

\[
e_{\text{O}_2}(\xi) = e_{\text{O}_2}^0 + \frac{1}{2} \sinh(A^{-1}(0 - 1)) - \frac{1}{2} \sinh(A^{-1}(\xi - 1)) \tag{31}
\]

To obtain the equations for \( e_{\text{H}_2}^0 \) and \( e_{\text{O}_2}^0 \), we apply the continuity condition at \( \xi = \tilde{\xi}_0 \),

\[
\frac{de_{\text{H}_2}(\xi)}{d\xi} \Bigg|_{\xi=\tilde{\xi}_0} = \frac{de_{\text{H}_2}(\tilde{\xi}_0)}{d\tilde{\xi}_0} = \frac{de_{\text{O}_2}(\tilde{\xi}_0)}{d\tilde{\xi}_0} \quad \frac{de_{\text{O}_2}(\xi)}{d\xi} \Bigg|_{\xi=\tilde{\xi}_0} \tag{32}
\]

Inserting eqn (25) and (30), we obtain

\[
\left( \frac{2A^{-1}\tilde{\xi}_0 \coth(A^{-1}\tilde{\xi}_0) - \frac{1}{2}}{A^{-1}\tilde{\xi}_0 \coth(A^{-1}\tilde{\xi}_0) - \frac{1}{2}} \right) e_{\text{H}_2}^0 = (A^{-1}\tilde{\xi}_0 \coth(A^{-1}\tilde{\xi}_0 - 1)) - 1) e_{\text{H}_2}^0 + e_{\text{H}_2}^0 \tag{33}
\]

Similarly, by inserting eqn (24) and (31) into eqn (32), we obtain

\[
\left( A^{-1}\frac{\delta^2}{\delta\xi^2} \coth(A^{-1}\tilde{\xi}_0 - 1) - \frac{\delta^2}{2} \right) e_{\text{O}_2}^0 = (A^{-1}(\tilde{\xi}_0 - 1) \coth(A^{-1}(\tilde{\xi}_0 - 1) - 1) e_{\text{O}_2}^0 + e_{\text{O}_2}^0 \tag{34}
\]

Eqn (33) and (34) are solved to obtain \( e_{\text{H}_2}^0 \) and \( e_{\text{O}_2}^0 \) (see Appendix for the solutions). In the dilute limit of Pt particles, as \( A \gg 1 \),

\[
e_{\text{H}_2}^0 = e_{\text{H}_2}^0 (1 - \tilde{\xi}_0) \quad \text{and} \quad e_{\text{O}_2}^0 = e_{\text{O}_2}^0 \tilde{\xi}_0. \tag{35}
\]

Substituting the relations for \( e_{\text{H}_2}^0 \) and \( e_{\text{O}_2}^0 \), obtained in the Appendix, into eqn (14) the position of the potential step is found as

\[
\tilde{\xi}_0 = \frac{1}{1 + \frac{2}{e_{\text{O}_2}^0}}. \tag{35}
\]

It indicates that as the uniform distribution of particles is assumed, \( \tilde{\xi}_0 \) is independent of the size and density of particles and only depends on the relevant concentrations of reactant gases at boundaries and the ratio of diffusion coefficients. This result is independent of the particle shape. The effect of particle shape appears in the form of the diffusion limited current densities and as well in \( \tilde{\xi}_0 \) is obtained by applying the charge balance condition for the limiting current densities of HOR and ORR as given in eqn (13). In this equation, as the parameters affecting the particle shape are assumed to be the same for HOR and ORR, they cancel out from both sides of the equation for any particle shape. In addition, for a uniform distribution the step position is independent of \( A \), hence of the particle shape.

2.1 Model parameters

Physical properties and constants are listed in Table 1. The adopted values for the macroscale diffusion coefficients correspond to \( \text{H}_2 \) and \( \text{O}_2 \) diffusion in Nafion. Exchange current densities of the ORR and HOR have been extracted from ref. 36 and 42, respectively.

As the molar concentrations of \( \text{H}_2 \) and \( \text{O}_2 \) in Nafion are reasonably small for the relevant partial pressures, we use Henry's law to relate \( \text{H}_2 \) and \( \text{O}_2 \) concentrations at the membrane boundaries to external partial pressures,

\[
e_{\text{H}_2}^0 = H_{\text{H}_2} p_{\text{H}_2}^0, \quad e_{\text{O}_2}^0 = H_{\text{O}_2} p_{\text{O}_2}^0. \tag{36}
\]

Table 2  Ranges for parameters

| Description                  | Value          |
|------------------------------|---------------|
| H₂ pressure at membrane|anode, P₀H₂, kPa | 21–125       |
| O₂ pressure at membrane|cathode, P₀O₂, kPa | 21–125       |
| Particle radius, r₀, nm     | 50–5000       |
| Membrane thickness, l, µm   | 25–200         |
| Particle density, nₚ, cm⁻³   | 10⁻⁷–10⁻⁶     |

Substituting eqn (36) into eqn (35), we obtain

\[ x₀ = \frac{l}{1 + 2\beta \frac{P₀H₂}{P₀H₂}}. \]  

(37)

where

\[ \beta = \frac{D_{\text{macro}} H₀O₂}{D_{H₂} H₀H₂}. \]  

(38)

The value of \( \beta \) used in this work is taken from ref. 25. It is reported as 0.38 ± 0.05, evaluated experimentally in permeability tests of crossover hydrogen and oxygen at 100% RH and 65 °C. ²⁵

The evaluated ranges of parameters are listed in Table 2. The ranges correspond to values of parameters reported in the literature. As a baseline for parametric studies, we consider a membrane with \( l = 50 \) µm in which particles with \( r₀ = 150 \) nm are uniformly distributed with \( nₚ = 5 \times 10^9 \text{ cm}⁻³ \). The range of \( nₚ \) is estimated based on the amount of Pt in the membrane. Results of electron microscopy-energy dispersive spectroscopy analysis have been used to quantify the amount of Pt transported from cathode to the membrane. ²⁵ This study estimates that ≈13% of Pt in the cathode is transported into the membrane following 3000 potential cycles. This amount corresponds to ≈0.38 mg Pt, if we consider a Pt loading of 0.1 mg cm⁻² for a 5 × 5 cm membrane. Equivalently, this amount results in a uniform distribution of Pt particles with \( r₀ = 150 \) nm and \( nₚ ≈ 10^{10} \text{ cm}⁻³ \) across a membrane with \( l = 50 \) µm.

3 Results and discussion

Fig. 3 shows the concentration profiles of H₂ and O₂ across the PEM and the step position, \( z₀ \), in dilute and dense limit of Pt particles. As shown, the position of \( z₀ \), given by eqn (35) (or (37)), depends on the relative concentrations of reactant gases at the membrane boundaries. The step shifts towards the cathode as \( P₀H₂ \) increases relative to \( P₀O₂ \) and vice versa. In the uniform particle distribution regime, \( z₀ \) is independent of \( A \), as can be seen from eqn (37).

As shown in Fig. 3, in the dilute limit of Pt particles, as \( A \gg 1 \), the concentration profiles are linear, given by \( c_{H₂}(z) = c_{H₂}(1 - z) \) and \( c_{O₂}(z) = c_{O₂}(z) \) (see eqn (24), (25), (30) and (31)). As \( A \rightarrow 1 \) concentration profiles deviate from linear curves. According to eqn (18) and (19), nonlinearity occurs when the local rate of reactant consumption is of similar order of magnitude as the rate of reactant flux. In dense limit, as \( A \ll 1 \), both concentrations approach to zero at \( z₀ \) which is expected as a trivial solution to eqn (14).

For the case of a dense Pt band formed in the PEM, due to the small rate of transport and high rate of consumption at the position of the dense Pt layer, the concentration of reactants must approach to zero at the band position. In this case, the potential step is found to occur in the vicinity of the band, which is in agreement with experiment.²⁵ The particle deposition process in the membrane is due to repeated oxidation/dissolution and reduction/deposition of the migrated Pt ions by crossover O₂ and H₂, respectively.²⁸ At \( x₀ \) optimal conditions are provided for the deposition of particles to form the Pt band.

Fig. 4 shows the potential distribution at spherical Pt particles in the PEM for a uniform distribution with \( nₚ = 10^{10} \text{ cm}⁻³ \). In Fig. 4(a)–(c), the potential profile in the mixed kinetic regime (see Fig. 2(d) and eqn (16)) is compared to those of mixed “kinetic-diffusion” regimes in the two PEM regions (see Fig. 2(a) and (b), eqn (8) and (11)). The results indicate that for particles with radius smaller than \( r₀ \approx 125 \) nm, the

![Fig. 3 Analytical solution of concentration profiles of H₂ and O₂ in dilute limit (4 ≫ 1) and dense limit (4 ≪ 1) of uniformly distributed Pt deposits for various relative concentrations of H₂ and O₂ at the PEM boundaries. The position of potential step, \( z₀ \), is indicated as vertical dashed line which is independent of particle density.](image1)

![Fig. 4 Potential distribution at spherical Pt nanodeposits in the PEM. The graphs shown in (a) to (c) illustrate change in the local reaction regime with increasing size of the Pt nanoelectrode.](image2)
transition of ORR from diffusion-limited to kinetically controlled regime occurs at $\zeta < \zeta_0$. Similarly, for this particle size range, the transition of HOR from diffusion-limited to kinetically controlled regime occurs at $\zeta > \zeta_0$. In the region between the two dashed lines in Fig. 4(a), both HOR and ORR are controlled by the reaction kinetics. This case is more relevant to Pt in the membrane, as the average PITM size reported in the literature is smaller than 125 nm.43,44 It implies that in the vicinity of the potential step the concentration gradient of the reactants close to the particle surface is negligible as both reactions are kinetically controlled. On the other hand, for particles with radius greater than $r_0 \approx 125$ nm the transition occurs at $\zeta_0$, as shown in Fig. 4(b) and (c) (also see Fig. 2(c) and eqn (14)).

In Fig. 5(a), the potential profile is plotted as a function of the particle size at a particle density of $n_{Pt} = 5 \times 10^7$ cm$^{-3}$, for a membrane with thickness of $l = 50$ $\mu$m. As shown, the OCP depends on the particle size, especially close to the step. As the particle size increases the potential decreases in the anodic region and increases in the cathodic region. The OCP change as a function of microelectrode size has been experimentally reported.45 Particle size dependence of potential has also been obtained in the model by Atrazhev et al.33

Fig. 5(b), shows the potential profile for a constant particle size (150 nm) as a function of $n_{Pt}$. As $n_{Pt}$ increases, the potential decreases in anodic region and increases in the cathodic region. For a constant particle size and uniform particle distribution, as the PEM thickness increases the potential decreases in the anodic region and increases in the cathodic region, as shown in Fig. 5(c). At $\zeta_0$, the value of the potential drop only depends on the particle size. At this position, the ratio of the concentrations of reactant gases is independent of the particle density (see eqn (14)); thus, according to eqn (8) and (11) the potential drop is independent of $n_{Pt}$.

Fig. 6 shows the current density distribution at Pt nanoparticles in the PEM as a function of particle density, corresponding to the potential distribution shown in Fig. 5(b). At $\zeta < \zeta_0$, the current density increases from zero to a maximum value at $\zeta_0$ (see eqn (2)); and at $\zeta > \zeta_0$, the current density decreases to zero (see eqn (1)). As $n_{Pt}$ increases, the local flux becomes smaller due to the higher consumption of crossover gases.

Fig. 7 compares the model and experimental data of the potential profile for various partial pressures of H$_2$ and O$_2$. In the experimental measurements of Takaichi et al.,31 seven Pt microelectrode probes, with 30 $\mu$m in diameter, were used to measure the OCP determined by H$_2$ and O$_2$ permeating in the PEM. The microelectrodes are sandwiched between eight thin membrane films, 25 $\mu$m Nafion$^\text{TM}$ (NRE211, Dupont, 3 $\times$ 7 cm), resulting in the total thickness of about 200 $\mu$m. H$_2$ at ambient pressure was fed to the anode side. At the cathode side, O$_2$ was held at a partial pressure of 21 kPa, 25 kPa, 101 kPa and 119 kPa. In the experimental study performed by Liu and Zuckerbrod,30 flattened Pt wires with an initial diameter of 25 or 50 $\mu$m were used. Two Pt microelectrodes were laminated within a membrane electrode assembly with a dimension of 5 $\times$ 5 cm. Three layers of membranes were used. Two 10 $\mu$m GORE-SELECT$^\text{TM}$ (GSM) membranes sandwiched a membrane with variable thickness, X. The two microelectrodes were laminated in between the outer 10 $\mu$m GORE-SELECT membrane and membrane X, both aligned with the gas inlet region, one close to the cathode and the other close to the anode.
The position of the microelectrode area the cathode side was varied by changing the thickness of the membrane X. Both anode and cathode were standard GORE-PRIMEA® Series 5510 electrodes with Pt loadings of 0.4 mg cm$^{-2}$. H$_2$ and air under 100 kPa pressure were fed to the anode and cathode sides, respectively. The potential at the microelectrodes was measured under OCP conditions at 60 °C.

To compare our model with the experimental data, we assumed a spherical Pt microelectrode with $r_0 = 5$ μm in a membrane with $l = 200$ μm and a dilute particle density of $n_{pt} = 10^7$ cm$^{-3}$. For the H$_2$ partial pressure we assumed 100 kPa and for the O$_2$ partial pressure we used the values reported in experiment. The variation in microelectrode shape does not demand a modification of the model; it is merely a parametric effect in the diffusion-limited current densities at the particle surface. We use eqn (37) to determine $\xi_0$ with $\beta = 0.38$ for all pressure settings.

The potential shapes calculated from the model are in a very good agreement with values of the potential found in experiment. As shown in Fig. 7, the step-like potential profile is very well reproduced in the model and the dependence of the position of the step to relative partial pressures at membrane boundaries is captured. Discrepancies might be due to a combination of the effect of microelectrode size and shape. Microelectrodes used in the experiments are large compared to the thickness of the membrane; hence, the spatial localization of potential values is relatively imprecise and represents effective values. In contrast, the model predicts the exact local value of the potential at a spherical microelectrode in the PEM. It is required to perform experimental studies with smaller microelectrodes in order to obtain better spatial resolution.

4 Conclusions

We presented an analytical model to determine the potential distribution at spherical Pt nanodeposits in the polymer electrolyte membrane. The approach incorporates a continuum description of crossover fluxes of reactant gases at the macroscale, coupled with the kinetics of electrochemical surface reactions at Pt nanodeposits. The potential distribution is obtained as a function of the local composition of the PEM, which is given by concentrations of H$_2$ and O$_2$ as well as the size and density distribution of Pt particles. In good agreement with experimental data, the model predicts a step-like potential profile. In the anodic region of the PEM, the potential is close to the equilibrium potential of the HOR. In the cathodic region, the potential is closer to the equilibrium potential of the ORR. For a uniform distribution of Pt particles, the position of the step is only determined by the relative partial pressures of H$_2$ and O$_2$ at the membrane interfaces as well as their permeation properties in the PEM. In the future we will use this model to rationalize the balance of species involved in chemical degradation of polymer electrolyte membranes.

Appendix

In this appendix, the solutions of eqn (33) and (34) for $c^{\xi_0}_{H_2}$ and $c^{\xi_0}_{O_2}$ are presented. Rewriting the eqn (33) and (34),

$$\mathcal{R}c^{\xi_0}_{H_2} = \mathcal{F}c^{\xi_0}_{O_2} + \mathcal{T}^{\xi_0}_{H_2} = \mathcal{F}c^{\xi_0}_{O_2} + \mathcal{W}.$$  

(39)

$c^{\xi_0}_{H_2}$ and $c^{\xi_0}_{O_2}$ are given by:

$$c^{\xi_0}_{H_2} = \frac{\mathcal{F}W - \mathcal{T}V}{\mathcal{W} - \mathcal{FV}}, \quad c^{\xi_0}_{O_2} = \frac{\mathcal{R}W - \mathcal{F}V}{\mathcal{W} - \mathcal{FV}}.$$  

(40)

where,

$$\mathcal{R} = A^{-1}\xi_0\coth[A^{-1}(\xi_0 - 1)] - 1,$$  

(41)

$$\mathcal{F} = \frac{2A^{-1}\xi_0}{\delta^2}\coth[A^{-1}\xi_0] - \frac{2}{\delta^2},$$  

(42)

$$\mathcal{T} = -c^0_{H_2}.$$  

(43)
\[
\psi = \left[ \frac{\delta^2 A^{-1}(\xi_0 - 1)}{2} \coth[A^{-1}(\xi_0 - 1)] - \frac{\delta^2}{2} \right].
\]
\[
\xi = (\xi_0 - 1)A^{-1}\coth[A^{-1}\xi_0] - 1,
\]
\[
\psi = \frac{\rho}{\epsilon_0}. 
\]
