Abstract

Mercury pollution has become one of the most concerned environmental issues in the world because of its high toxicity, non-degradability, and bioaccumulation. Attapulgite adsorbents modified by magnetic manganese-copper (Mn₈Cu₅-MATP) were fabricated by co-precipitation and ultrasonic impregnation method, aiming at removing Hg⁰ from coal-fired flue gas. BET, SEM, XRD, VSM, and XPS were used to systematically explore the physical and chemical properties of the adsorbents, the effects of manganese and copper additions, reaction temperature, and various components in the flue gas on the efficiency of Hg⁰ removal were investigated. Mn₈Cu₅-MATP exhibited the optimal properties, and excessive copper loadings led to the aggregation of the active components. The efficiency of mercury removal can be effectively improved by NO and HCl regardless of the absence and presence of O₂, because the NO⁺, NO₃, NO₂, and Cl⁻ produced during the reaction can promote the adsorption and oxidation of Hg⁰. SO₂ and H₂O inhibited the oxidation of Hg⁰ because of the competitive adsorption at the active sites, while a large amount of sulfite and sulfate were formed to block the pores. However, the introduction of copper caused the sample to obtain SO₂ resistance, which resulted in a mercury removal efficiency of 84.3% even under 1500 ppm SO₂. In addition, after 5 cycles of adsorption and regeneration, Mn₈Cu₅-MATP can still maintain excellent Hg⁰ removal ability. The fabricated adsorbent can save the actual production cost and effectively improve the mercury removal efficiency in sulfur-containing flue gas.

Introduction

Mercury has attracted widespread public attention due to its high toxicity, persistence, high volatility, and bioaccumulation (Li et al. 2017a, Wang et al. 2019a, Yang et al. 2020b). In recent years, mercury in coal-fired flue gas has been considered the main source of mercury pollution (Zhao et al. 2019). Therefore, it is necessary to control mercury emissions in coal-fired flue gas. Generally, mercury in coal-fired flue gas is divided into three categories, including elemental mercury (Hg⁰), divalent mercury (Hg²⁺), and particulate mercury (Hg⁰) (Wilcox et al. 2012, Xu et al. 2014). Among them, Hg²⁺ and Hg⁰ can be effectively removed by the wet desulphurization and particulate matter control devices (Yang et al. 2019b). However, Hg⁰ cannot be easily removed due to its chemical stability (Yang et al. 2019a). Therefore, it is urgent to develop a technology for removal Hg⁰.

At present, a variety of mercury removal methods have been proposed by researchers, such as chemical adsorption, photocatalytic oxidation, and thermal catalytic oxidation (Jia et al. 2020, Wu et al. 2017, Zhang et al. 2019). Among them, the flue injection technology of mercury removal adsorbent is validated to be a practical and feasible mercury removal technology (Chen et al. 2019). Activated carbon adsorbent has become a research hotspot in the field of mercury removal from flue gas owing to its excellent adsorption performance (Huang et al. 2019). However, the activated carbon injection technology is not only expensive, but also cannot be recycled, which impedes its practical application (Yang et al. 2019d). In addition, the pollution of fly ash has a negative impact on the resource utilization due to the incorporation of activated
carbon containing mercury (Zhao et al. 2017). More importantly, such technology cannot achieve the ultimate centralized control for mercury pollution in coal-fired flue gas. Instead, the mercury and its compounds in the flue gas were transferred to by-products such as fly ash, desulfurization slurry, and desulfurization gypsum through activated carbon, which increases the risk of environmental pollution caused by the secondary release of mercury (Wang et al. 2020). In order to avoid the risk, researchers consider incorporating magnetic materials into the adsorbent to achieve the purpose of separating the adsorbent from fly ash (Dong et al. 2009, Yang et al. 2018a, Zhou et al. 2019). Borderieux et al. (2004) prepared nano-Fe$_2$O$_3$ with high specific surface area for Hg$^0$ removal by ultrasonic impregnation, and evaluated Hg$^0$ removal efficiency under different conditions. The physicochemical properties of the adsorbent were systematically analyzed by XRD, SEM, BET, VSM, and XPS. The effects of manganese and copper additions, reaction temperature, and various components in the flue gas on the efficiency of Hg$^0$ removal were investigated. In addition, the regeneration performance of the adsorbent was also tested. The prepared adsorbent possessed high mercury removal efficiency, and exhibits excellent SO$_2$ resistance. The results of this work can provide valuable guidance for the development of mercury removal adsorbents with SO$_2$ resistance.

**Experimental**

### Adsorbent preparation

**MATP**

The raw attapulgite (ATP) was purchased from Yixiang New Materials Co., Ltd. The ATP was first washed with deionized water to remove soluble impurities on the surface. Then, the pre-treated ATP was added into the aqueous solution containing FeCl$_3$ and FeCl$_2$. The mass ratio of the ATP:FeCl$_3$:FeCl$_2$ was 3.66:2.57:1. Subsequently, concentrated ammonia was added to the ATP suspension during the stirring process until the pH value reached approximately 11. Further, the suspension was stirred at 70 °C for 90 min, after which the obtained sediment was washed to neutrality and dried at 105 °C for 12 h. Finally, the sample was calcined at 250 °C for 3 h under N$_2$ atmosphere to obtain the MATP.

**Mn$_x$-MATP and Mn$_x$Cu$_y$-MATP**

The MATP was immersed in a calculated amount of 50wt% Mn(NO$_3$)$_2$ solution (and Cu(NO$_3$)$_2$ solution), and then the mixture was exposed to an ultrasonic bath at 60 °C for 2 h. Subsequently, the obtained powder was dried at 105 °C for 12 h, and calcined at 450 °C for 4 h under N$_2$ atmosphere with a temperature rise rate of 7.5 °C/min. The obtained samples were represented by Mn$_x$-MATP or Mn$_x$Cu$_y$-MATP, where $x$ and $y$ represented the mass percent of element Mn and Cu on the samples, respectively.

### Adsorbent characterization

The specific surface areas and the pore size distributions of the adsorbent were analyzed on an ASAP 2020 analyzer (Micromeritics Inc., USA) using N$_2$ gas as an adsorbate at liquid-nitrogen temperature (77 K). The phase structure of the adsorbent was characterized by X-ray diffraction (XRD). The XRD pattern was recorded on a D/MX-IIIA diffractometer (Rigaku, Japan) with Ni-filtered Cu Ka radiation. The scanning range was set from 5 to 90° (2θ) with a step size of 0.02° and a step time of 2 min. The magnetism of the adsorbent was characterized by using a physical property measurement system using a VSM (LakeShore7404). The surface composition and the chemical state of the elements existing in the adsorbent were analyzed on a Thermo ESCALAB 250Xi apparatus using Al Ka radiation as the excitation source and the binding energies were referenced to the C1s at 284.8 eV.

### Measurement of Hg$^0$ adsorption performance

The mercury adsorption performance of the adsorbent was tested on a laboratory-scale fixed bed adsorption system, as
shown in Fig. 1. The gas compositions were N\textsubscript{2}, O\textsubscript{2}, NO, SO\textsubscript{2}, HCl, Hg\textsuperscript{0} vapor, and H\textsubscript{2}O vapor. The Hg\textsuperscript{0} concentration was maintained at approximately 55 μg/m\textsuperscript{3} by adjusting N\textsubscript{2} to flow through the mercury permeation tube (HE-SR, VICI Metronics, USA) and oil bath temperature. Hg\textsuperscript{0} capture experiments were performed in a quartz tube reactor (internal diameter was 7 mm) in the fixed bed reactor. During the experiment, the sample was fixed in the middle of the quartz tube reactor by quartz wool, while the quartz tube reactor was wrapped in a temperature-programmed tube furnace. A total of 50 mg of the prepared samples were used for each experiment. A total gas flow rate was controlled at 1 L/min, which resulted in a GHSV of approximately 400,000 h\textsuperscript{-1}. All the gas pipes after the oil bath were heated by electric heating tapes to ensure a stable temperature of 90°C for the purpose of preventing the deposition of Hg. A mercury analyzer (AFS-930, Beijing Titan Instruments Co., Ltd.) was utilized to detect the Hg\textsuperscript{0} concentration at the inlet and outlet of the quartz tube reactor. The Hg\textsuperscript{0} removal efficiency (\(\eta\)) of the reaction was calculated by the formulas as follows:

\[
\eta (\%) = \left(1 - \frac{[\text{Hg}^0]_{\text{out}}}{[\text{Hg}^0]_{\text{in}}}\right) \times 100\%
\]

where \([\text{Hg}^0]_{\text{in}}\) and \([\text{Hg}^0]_{\text{out}}\) represented the Hg\textsuperscript{0} concentration at the inlet and outlet of reaction. Sampling tests and analyses were performed in triplicates to minimize the error and uncertainty.

Results and discussion

Sample characterization

The crystal phases of MATP and Mn\textsubscript{8}Cu\textsubscript{y}-MATP samples were determined by XRD analysis, as shown in Fig. 2. After magnetic modification, distinct diffraction peaks were observed at 30.233°, 35.576°, 37.214°, 43.207°, 53.606°, 57.132°, and 62.722°, corresponding to magnetic Fe\textsubscript{3}O\textsubscript{4}(PDF 75-0033) particles (Xu et al. 2019). This phenomenon indicated that the magnetic component had been successfully loaded onto the ATP surface. After introducing the elements Mn and Cu, peaks were observed at 2\(\theta\) values of 30.118°, 35.485°, 37.169°, 43.176°, 53.639°, 57.137°, and 62.786°, corresponding to Mn\textsubscript{3}O\textsubscript{4}(PDF 13-0162)(Liu et al. 2018). The peak intensity was slightly increased due to the high overlap of the diffraction peaks of Mn\textsubscript{3}O\textsubscript{4} with Fe\textsubscript{3}O\textsubscript{4}. Besides, this phenomenon may also be ascribed to the increase of Fe\textsubscript{3}O\textsubscript{4} crystallinity caused by introducing manganese and copper oxides. In addition, the diffraction peaks associated with MnO\textsubscript{2} were not observed, which can be attributed to the existence of amorphous phase (Shan et al. 2019). The diffraction peaks at 36.512°, 42.401°, and 61.471° belonged to Cu\textsubscript{2}O (PDF 65-3288) were observed, while the distinct reflection at 35.477° and 38.560° could be ascribed to CuO (PDF 48-1548)(Hosseini et al. 2014). This phenomenon elucidated that the Cu\textsubscript{2}O and CuO coexisted on the sample. As the content of Cu increased, the diffraction peak of Mn\textsubscript{2}O\textsubscript{4} decreased imperceptibly, which can be ascribed to a
synergistic effect between copper and manganese oxides, thereby preventing manganese oxides from reaching the crystal structure. Such the synergistic effect can improve the oxygen vacancies and presumably the high catalytic activity (Cao et al. 2012). However, the crystallinity increased slightly when the Cu content was greater than 5, which reflected that the excessive CuOx was not conducive to the dispersion of Mn species.

The surface morphology of the original ATP, MATP, and Mn8Cuy-MATP were investigated by FE-SEM. As shown in Fig. 3a, it can be clearly seen that the original ATP contained a smooth rod-like morphology, which facilitates the formation of metal oxide particles on the surface (Zhang et al. 2014). After the magnetic modification, some small particles appeared on the surface of ATP, denoting the successful loading of the magnetic substance (Fig. 3b). As exhibited in Fig. 3c–g, more particles were formed on the surface after introducing copper and manganese oxides. In addition, the particles on the surface gradually increased and dispersed more uniformly with the increasing of Cu content, which was attributed to the interaction between copper and manganese oxides. Nevertheless, the agglomeration phenomenon was extremely obvious on the surface when the Cu content was greater than 5 (Fig. 3h), which inhibited the activity of the sample to a certain extent. These results were consistent with the aforementioned XRD results.

The overall microstructure characteristics of the prepared samples were characterized by BET, as elaborated in Table 1. After modified by manganese, the specific surface area of the samples was higher than the MATP modified by manganese except for Mn8Cu5-MATP, which revealed that the synergistic effect between copper and manganese oxides was beneficial to the increase of BET surface area (Yi et al. 2017). However, the surface area was decayed with increasing the content of Cu except for Mn8Cu4-MATP, which may be related to the blockage of a few pores caused by the increase in the total load. Moreover, such decay trend of the surface area became more pronounced as the load increased. When the Cu content reached 6, the specific surface area was significantly decreased by the substantial agglomeration of the active components, which was in line with the SEM results. In addition, the MATP modified by manganese and copper possessed smaller average pore diameter and higher pore volume than the original MATP. Such phenomenon can be attributed to the removal of volatiles during the ultrasonic impregnation and calcination process as well as the chaotic accumulation of loaded active components, resulting in the formation of some new pores (Wang et al. 2016). Combined with SEM and BET, Mn8Cu5-MATP can provide a larger active surface area, leading to strong interactions, which was beneficial to the adsorption and catalytic oxidation of mercury.

Magnetism is an important factor in determining whether the adsorbent can be separated and recycled. Therefore, the magnetization of the samples was investigated by using the VSM (LakeShore7404), and the results were presented in Fig. 4. After modified by manganese, a slight decline of saturation magnetization was observed, from 17.78 to 16.46 emu/g, reflecting that the loading of manganese had a slight effect on the saturation magnetization. This phenomenon may be related to the increase in the crystallinity of Fe3O4 by the addition of manganese, which was consistent with the aforementioned XRD and SEM results. Notably, the influence of introducing copper towards the saturation magnetization was negligible, which changed from 16.46 to 16.02 emu/g. In addition, magnetization hysteresis and coercivity of the three samples were not observed, which suggested that they are superparamagnetic adsorbents. After tests, the three adsorbents can be separated from fly ash through an external magnets.

XPS analysis was usually utilized to elucidate the composition of different species and the element valence states on the samples. Thus, the chemical states of the fresh adsorbent was investigated, and the XPS spectra of Mn 2p, Fe 2p, Cu 2p, and O 1s regions were obtained, as elaborated in Fig. 5. As seen from the XPS spectra of Fe 2p (Fig. 5a), three peaks in a range from 705 to 730 eV corresponded to Fe 2p3/2, shake-up satellite and Fe 2p1/2, respectively. Moreover, the Fe 2p3/2 spectrum can be divided by deconvolution into three peaks at 709.6 eV, 710.9 eV, and 713.0 eV (Zhang et al. 2018). Among them, the peaks at 710.9 eV and 713.0 eV were assigned to the Fe3+ in
octahedral and tetrahedral coordination, respectively, while the peak at 709.6 eV corresponded to Fe$^{2+}$ (Chen et al. 2014). As shown in Table 2, Fe$^{3+}$ on the sample after mercury removal was 4.27% lower than that before the reaction, which indicated that some Fe$^{3+}$ on the surface was reduced to Fe$^{2+}$ during the oxidization of Hg$^0$. As for the Mn 2p spectra in Fig. 5b, two main peaks at 641.6 eV and 653.0 eV were observed, corresponding to Mn 2p$_{3/2}$ and Mn 2p$_{1/2}$, respectively. In addition, the shake-up satellite was observed at 647.5 eV. The Mn 2p$_{3/2}$ spectra can be separated into three peaks, which were corresponded to Mn$^{4+}$ (643.5 eV), Mn$^{3+}$ (641.9 eV) and Mn$^{2+}$ (640.7 eV).

Table 1

| Samples          | BET surface area (m$^2$g$^{-1}$) | Pore volume (cm$^3$g$^{-1}$) | Average pore diameter (nm) |
|------------------|----------------------------------|-------------------------------|----------------------------|
| MATP             | 127.51                           | 0.1776                        | 9.633                      |
| Mn$_8$-MATP      | 96.93                            | 0.2340                        | 10.894                     |
| Mn$_8$Cu$_1$-MATP| 107.36                           | 0.2332                        | 8.688                      |
| Mn$_8$Cu$_2$-MATP| 106.23                           | 0.2539                        | 9.060                      |
| Mn$_8$Cu$_3$-MATP| 105.19                           | 0.2382                        | 9.256                      |
| Mn$_8$Cu$_4$-MATP| 100.84                           | 0.2411                        | 9.460                      |
| Mn$_8$Cu$_5$-MATP| 101.98                           | 0.2395                        | 9.542                      |
| Mn$_8$Cu$_6$-MATP| 77.44                            | 0.1696                        | 8.761                      |
eV) (Feng et al. 2017, Yang et al. 2018a). Combined with the result that the crystal phase diffraction peaks related to MnO₂ were not observed in the XRD pattern, it is further confirmed that MnO₂ was present in the adsorbent with amorphous phase. After mercury removal, the contents of Mn⁴⁺ and Mn³⁺ decreased in varying degrees, from 29.18% and 34.09% to 25.49% and 32.17%, respectively, while Mn²⁺ increased significantly. This phenomenon was attributed to the fact that Mn⁴⁺ can directly oxidize Hg⁰ to Hg²⁺. In addition, Mn³⁺ can also participate in the oxidation of Hg⁰ under oxygen-containing conditions. The XPS spectra of Cu 2p were depicted in Fig. 5c; it can be seen obviously that two main peaks at 933.4 eV and 953.0 eV corresponded to Cu 2p₃/2 and Cu 2p₁/2, respectively, and two satellite peaks (962.1 eV and 942.1 eV). The two main peaks can be fitted into two peaks, of which Cu 2p with asymmetric characteristics at 932.6 eV and 952.5 eV was Cu⁺, while Cu²⁺ appeared at 934.3 eV and 953.7eV, accompanying with two shake-up satellites (Wang et al. 2019b). According to previous reports, Cu₂O was a p-type semiconductor catalyst with hole conduction capacity and preferentially adsorbing O₂, which led to a higher catalytic oxidation activity (Bao et al. 2014, Zhang et al. 2020). Moreover, more oxygen vacancies can be formed through the interaction between Mn⁴⁺/Mn³⁺/Mn²⁺ and Cu⁵⁺/Cu⁺ (Mn⁴⁺/Mn³⁺ +Cu⁺ → Mn²⁺ + Cu²⁺), thereby further improving the mercury removal efficiency (Yang et al. 2019c, Yang et al. 2018b). As exhibited in Fig. 5d, the O 1s peak was divided into three peaks at 529.6 eV, 531.7 eV, and 532.6 eV, corresponding to the lattice oxygen in metal oxides (Oₐ), chemisorbed oxygen (Oₙ), and oxygen in hydroxyl-like groups (Oₜ), respectively (Zhang et al. 2017). It can be seen that the content of Oₙ was significantly reduced after the reaction, confirming that Oₙ had been consumed.

**Effect of manganese and copper loading**

The mercury removal performance of the MATP with different manganese loadings was investigated at 100–300 °C to determine the best manganese content. As seen from Fig. 6a, it was clearly observed that the mercury removal efficiency of the five samples increased at first and then decreased with the reaction temperature increasing. Among them, four kinds of adsorbents containing manganese reached the highest mercury removal efficiency at 150 °C. In general, the increase of reaction temperature was beneficial to increase the molecular kinetic energy of reactants, thus promoting the catalytic oxidation of Hg⁰. Nevertheless, the excessive high reaction temperature can inhibit the adsorption process of Hg⁰ on the adsorbent surface, resulting in the reduction of Hg⁰ removal efficiency. Additionally, the mercury removal efficiency enhanced with the increase of manganese loading. The mercury removal efficiency reached the highest when the Mn loading increased to 8%. However, the mercury removal efficiency remained relatively constant although the manganese loading further increased to 10%. Such phenomenon can be attributed to the growth of crystalline size and surface blocking caused by excessive manganese loading (Kim et al. 2014). Hence, the Mn₈-MATP was selected as the best manganese loading sample for consideration of actual cost and mercury removal efficiency.

Figure 6b showed the effect of different copper loadings on the mercury removal performance of the adsorbent. It can be clearly observed that the mercury removal efficiency of all adsorbents first increased and then decreased with increasing temperature. The mercury removal efficiency reached the maximum at 150 °C. Moreover, the mercury removal efficiency of all adsorbents after the introduction of copper was higher than that before, which indicated that the synergy between copper and manganese oxides was beneficial to improve the mercury removal efficiency. In addition, the mercury removal efficiency improved with the increase of copper loading until the copper loading reached 5%. However, the mercury removal efficiency was significantly reduced when the copper loading further increased to 6%. This phenomenon can be attributed to the blockage of a large number of pores caused by excessive metal oxides, which was consistent with the BET result. Therefore, combined with a series of characterization results mentioned above, Mn₈Cu₅-MATP possessed the unique microstructure, larger specific surface area, more active sites, and stronger oxygen migration ability, which was beneficial to mercury removal.

Effect of individual flue gas components

Effect of O₂

O₂ is one of the key factors affecting the efficiency of mercury removal. As shown in Fig. 7, the effect of different O₂ concentrations in the simulated flue gas on the efficiency of mercury removal at 150 °C was investigated. It can be obviously seen that the mercury removal efficiency was 81.1% despite absence of O₂, which was due to the consumption of a large amount of Oₐ and Oₐ₁. When the O₂ concentration improved from 0 to 6%, the mercury removal efficiency significantly increased to 91.1%, which can be ascribed to the regeneration of Oₐ and Oₐ₁ consumed during the removal process and the replenishment of gas-phase oxygen (Chen et al. 2018). Nevertheless, the improvement of mercury removal efficiency was negligible when the O₂ concentration further increased to 9%, which denoted that 6% O₂ was sufficient to complete the oxidation of Hg₀.

Effect of NO

As an inherent component of coal-fired flue gas, NO is usually approximately 4 orders of magnitude higher than the concentration of mercury, which has an important effect on the oxidation of Hg₀. As described in Fig. 8, the effect of NO on the efficiency of mercury removal under different conditions was investigated. The efficiency of mercury removal under 500 ppm NO without O₂ was greatly improved compared with the pure N₂ atmosphere. Moreover, the mercury removal efficiency was further improved from 94.5 to 98.4% after the addition of 6% O₂. This result demonstrated that the mercury removal can be greatly promoted by NO with or without O₂, which was similar to previous reports (Li et al. 2012). However, the change in the removal efficiency of mercury was negligible when the concentration of NO was further increased to 1000 ppm, because 500 ppm NO was sufficient to oxidize mercury. The strong promoting effect of NO on mercury removal was attributed to the reaction of NO with reactive oxygen species on the surface of the adsorbent to
form NO⁺, NO₃⁻, and NO₂, which promoted the oxidation of mercury. The involved mechanisms can be explained by the following reactions (Shan et al. 2019):

\[
\begin{align*}
\text{NO} (g) & \rightarrow \text{NO} (ad) \quad (2) \\
\text{NO} (ad) + O (ad) & \rightarrow \text{NO}_2 (ad) \quad (3) \\
\text{NO} (ad) + 1/2\text{O}_2 (g) & \rightarrow \text{NO}_2 (ad) \quad (4) \\
\text{Hg}^0 (ad) + \text{NO}_2 (ad) & \rightarrow \text{HgNO}_2 (ad) + \text{NO} (ad) \quad (5) \\
\text{Hg}^0 (ad) + 2\text{NO}_2 (ad) + \text{O}_2 (g) & \rightarrow \text{Hg(NO}_3)_2 (ad) \quad (6) \\
\text{HgO} (ad) + 2\text{NO}_2 (ad) + 1/2\text{O}_2 (g) & \rightarrow \text{Hg(NO}_3)_2 (ad) \quad (7)
\end{align*}
\]

Effect of HCl

Generally, there is a certain amount of chlorine in the coal; thus, the HCl produced during the combustion process possesses a significant effect on the Hg⁰ oxidation. It can be observed from Fig. 9 that the mercury removal efficiency can be promoted by HCl regardless of the absence and presence of O₂. The mercury removal efficiency was increased from 81.0 to 90.9% when 10 ppm HCl was introduced in the pure N₂ atmosphere, whereas the increment was negligible when the concentration of HCl was increased to 20 ppm. Nevertheless, the mercury removal efficiency was further improved to 96.5% and 98.2% after adding 6% O₂ under the conditions of 10 and 20 ppm HCl, respectively. These phenomena elucidated that the oxidation of Hg⁰ can be facilitated greatly by HCl, which can be explained by the Langmuir-Hinshelwood mechanism (Li et al. 2011). HCl is first adsorbed on the surface of the adsorbent and reacts with active oxygen to obtain active chlorine, and then further reacts with adsorbed Hg⁰ to form HgCl₂. The detailed reaction mechanisms are as follows (Hou et al. 2014):

\[
\begin{align*}
\text{HCl} (g) & \rightarrow \text{HCl} (ad) \quad (8) \\
2\text{HCl} (ad) + O^* (ad) & \rightarrow 2\text{Cl}^* (ad) + \text{H}_2\text{O} (ad) \quad (9) \\
\text{Cl}^* (ad) + \text{Hg}^0 (ad) & \rightarrow \text{HgCl} (ad) \quad (10) \\
\text{HgCl} (ad) + \text{Cl}^* (ad) & \rightarrow \text{HgCl}_2 (ad) \quad (11)
\end{align*}
\]

Effect of SO₂ and H₂O

As an inherent component of coal-fired flue gas, SO₂ usually inhibits the Hg⁰ removal efficiency. Therefore, the effect of SO₂ towards Hg⁰ removal efficiency under the condition of 6% O₂ was investigated, as presented in Fig. 10a. After introducing 500 ppm SO₂, the removal efficiency of Hg⁰ was almost unchanged, because SO₂ was oxidized to SO₃ by O₂ and further reacted with Hg⁰ to form HgSO₄ (Tao et al. 2012). This reaction mechanism enabled a certain concentration of SO₂ to promote the oxidation of mercury, thus counteracting the negative effects. However, with the increase of SO₂ concentration to 1000 ppm and 1500 ppm, the Hg⁰ removal efficiency decreased to 87.1% and 84.3%, respectively. Such inhibition phenomenon can be ascribed to a competitive adsorption at the active sites between SO₂ and Hg⁰, and the inhibition effect was far greater than the promotion effect (Xu et al. 2017). Moreover, the binding capacity of SO₂ to the active sites was stronger than that of Hg⁰. On the other hand, plenty of sulfites and sulfates were obtained through the reaction of SO₂ with metal oxides, which not only consumed the active sites but also blocked the pores for mercury removal (Chen et al. 2017). Interestingly, the inhibitory effect was weakened after the adding copper compared with the previously reports because copper oxides reacted with SO₂ preferentially and protect the active sites from poisoning, resulting in a certain SO₂ resistance (Dong et al. 2021). In addition, the effect of H₂O on the efficiency of mercury removal was also evaluated, as reflected in Fig. 10b. As the concentration of H₂O increased from 0 to 2%, 5% and 8%, the mercury removal efficiency decreased to 88.2%, 86.3, and 83.1%, respectively, which demonstrated that H₂O was unfavorable for the removal of Hg⁰. The mechanism of such inhibition effect was similar to that of SO₂. During the mercury removal, the competitive adsorption occurred between H₂O and Hg⁰. H₂O vapor was adsorbed on the active sites of the adsorbent, thereby hindering the interface reaction between Hg⁰ and the active sites (Li et al. 2017b).

Regeneration performance test

In the actual production, if the deactivated adsorbent can be regenerated and reused by a facile regeneration method, the operating cost of mercury removal from coal-fired flue gas
will be greatly reduced. In general, Hg\textsuperscript{0} is oxidized to HgO through O\textsubscript{A} and O\textsubscript{B} over the surface, which causes the active sites to be covered gradually with increasing HgO and eventually leads to deactivation of the adsorbent (Liao et al. 2016). The thermal treatment at high temperature has been proved to be a simple and effective method for mercury desorption and regeneration of active adsorption sites (Yang et al. 2015). The mercury and its oxides are desorbed and decomposed by high temperature heating, and the oxygen vacancies are supplemented by gas-phase oxygen to obtain regenerated adsorbents (Zhou & Diao 2020). Therefore, we achieved the regeneration of the deactivated adsorbent by desorption at 400°C for 1 h in the N\textsubscript{2} atmosphere and then heating at 200°C for 30 min in an air atmosphere. As displayed in Fig. 11a, the mercury removal efficiency after 5 cycles was reduced by approximately 2.3% compared with the original adsorbent. Moreover, the decrease in saturation magnetization before and after the cycles was negligible (Fig. 11b). These phenomena demonstrated that the as-prepared adsorbent possessed excellent regeneration performance, which can accomplish the regeneration and recycling of the deactivated adsorbent.

**Conclusion**

In summary, we successfully fabricated Mn\textsubscript{8}Cu\textsubscript{5}-MATP by co-precipitation and ultrasonic impregnation methods and utilized to remove Hg\textsuperscript{0} from coal-fired flue gas. BET, SEM, XRD, VSM, and XPS were employed to systematically analyze the physicochemical properties of the as-prepared adsorbents. The effects of manganese and copper additions, reaction temperature and various components in the flue gas on the efficiency of Hg\textsuperscript{0} removal were investigated by the fixed-bed system. The results demonstrated that 8% Mn loading had reached the optimal mercury removal performance. The introduction of 5% Cu facilitated the dispersion of manganese oxides and the oxidation of Hg\textsuperscript{0}; however, excessive Cu can cause the accumulation of active components. The efficiency

of mercury removal can be effectively promoted by NO and HCl with or without O2, because the NO+, NO3, NO2, and Cl- produced during the reaction can facilitate the adsorption and oxidation of Hg0. SO2 and H2S inhibited the oxidation of Hg0 owing to the competitive adsorption at the active sites. Moreover, the pores can be blocked by the sulfite and sulfate formed through SO2 and metal oxides. Interestingly, the introduction of Cu caused the sample to obtain SO2 resistance, which resulted in the mercury removal efficiency of 84.3% even under 1500 ppm SO2. In addition, the mercury removal efficiency after 5 cycles was reduced by only 2.3% compared with the original adsorbent, denoting excellent regeneration performance. This paper provides a reference for the development of mercury removal adsorbents with SO2 resistance. Further studies to investigate the mechanism of SO2 resistance are warranted.
