Abstract
We report enhanced three-dimensional degenerated Raman sideband cooling (3D DRSC) of caesium (Cs) atoms in a standard single-cell vapour-loaded magneto-optical trap. Our improved scheme involves using a separate repumping laser and optimized lattice detuning. We load $1.5 \times 10^7$ atoms into the Raman lattice with a detuning of $-15.5$ GHz (to the ground $F = 3$ state). Enhanced 3D DRSC is used to cool them from $60$ µK to $1.7$ µK within $12$ ms and the number of obtained atoms is about $1.2 \times 10^7$. A theoretical model is proposed to simulate the measured number of trapped atoms. The result shows good agreement with the experimental data. The technique paves the way for loading a large number of ultracold Cs atoms into a crossed dipole trap and efficient evaporative cooling in a single-cell system.

Keywords: degenerated Raman sideband cooling, lattice, detuning

In this letter, we demonstrate an enhanced 3D DRSC scheme for trapped caesium atoms in a standard single-cell vapour-loaded MOT with a relaxed starting temperature requirement of approximately 60 μK. Instead of using the lattice light as a repumper, we introduce a separate repumping laser which enables freedom of choice in terms of lattice detuning. We then optimize the frequency detuning of the Raman lattice light, while considering simultaneously both the loading potential of the 3D Raman lattice and the heating losses owed to the interaction between the lattice light and trapped atoms. We propose a theoretical model to characterize the experimental results. The dependence of the number of atoms loaded in the lattice on the frequency detuning presents good agreement with the model.

2. Experimental setup

The experimental setup is shown in figure 1. The cold atoms are confined in a standard single-cell vapour-loaded MOT with a background pressure of \( \sim 2.5 \times 10^{-8} \) Pa [22]. The sample temperature is measured at \( \sim 200 \) μK using time-of-flight (TOF) methods and the atom number is measured at \( 9 \times 10^7 \) using absorption imaging. The MOT is compressed by increasing the magnetic field gradient to 30 G cm\(^{-1}\) over 25 ms and holding for 40 ms. Simultaneously the MOT beams are red detuned 45 MHz from the \( F = 4 \) to \( F' = 5 \) transition. Optical molasses cooling is performed for 2 ms during which time the magnetic field gradient is switched off and the MOT beams are further detuned to \( \sim 70 \) MHz. After optical molasses, the atom number is \( \sim 3 \times 10^7 \) with a temperature of 60 μK, which is relatively high compared with the \( \sim 10 \) μK reported by other groups [15–19]. The atoms are subsequently loaded into a 3D Raman lattice formed by four far-off-resonance laser beams; two counter-propagating beams along the \( y \) axis (beams 2 and 3 in figure 1), and two beams along each of the \( x \) and \( z \) axes (1 and 4 in figure 1). Using only four linearly polarized laser beams ensures stabilization of the Raman lattice [23]. The linear polarizations of the \( x \) and \( z \) beams lie in the \( x-z \) plane, whereas the \( y \) beams are polarized with \( \pm 10 \) degrees to the line bisecting the \( x \) and \( z \) beams.

The Raman lattice light is switched on 0.5 ms before the end of the optical molasses stage. As the optical molasses stage ends, the optical pumping and repumping lasers are switched on to begin the cooling cycle which is held for 12 ms. We use a laser power of 25 mW for each Raman lattice laser beam with a radius of 1.15 mm (1/e\(^2\)) and an optimized red detuning of \( \sim -15.5 \) GHz from the \( 6S_{1/2}, F = 3 \rightarrow 6P_{3/2}, F = 4 \) transition. A pair of Helmholtz coils provide a magnetic field of \( \sim 200 \) mG which brings two vibrational energy levels from different Zeeman hyperfine states into degeneracy. The mainly \( \sigma^+ \) polarized optical pumping laser is 8 MHz blue-detuned from the \( F = 3 \rightarrow F' = 2 \) transition. It is derived from the same laser that provides the repumping laser for the MOT and has an intensity of 1 mW cm\(^{-2}\). The optical pumping laser is tilted by just five degrees to generate a small amount of light along the magnetic field \( B \) in the \( x-y \) plane.

3. Raman lattice

A 3D Raman lattice is usually used after the optical molasses stage to reach an effective 3D DRSC of atoms. The lattice consists of four beams with linear polarization in the \( y-z \) plane. The four beams are of equal amplitude and the same frequency, which is red detuned to the \( F = 3 \rightarrow F' = 4 \) transition. The field of the lattice is written as

\[
\mathbf{E}(r, t) = E_0 \mathbf{e}(r) e^{-i \omega t} + c.c.,
\]

\[
\mathbf{e}(r) = n_0 e^{i \alpha} + n_2 e^{i \beta} + n_3 e^{-i \gamma} + n_4 e^{i \delta},
\]

where \( E_0 \) is the amplitude of light field and \( n_i \) is the unit polarization vector of the \( i \)th lattice beam light [24] expressed as

\[
n_1 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad n_2 = \begin{pmatrix} \cos \alpha \\ 0 \\ \sin \alpha \end{pmatrix}, \quad n_3 = \begin{pmatrix} \cos \beta \\ 0 \\ \sin \beta \end{pmatrix}, \quad n_4 = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix},
\]

where \( \alpha \) and \( \beta \) are the intersection angles of the polarization direction for lattice beams 2 and 3 with the \( z \) axis, respectively. The optical potential for atoms in the ground \( F = 3 \) state is given as

\[
\mathbf{U}(r) = -\frac{2}{3} U_0 |\mathbf{e}(r)|^2 \mathbf{\hat{1}} \mathbf{e} + \frac{1}{3} U_0 (\mathbf{e}(r) \times \mathbf{e}(r)) \cdot \mathbf{\hat{F}},
\]

where \( \mathbf{\hat{1}} \) and \( \mathbf{\hat{F}} \) are the identity and angular momentum operators. The first term in equation (4) is the energy shift that is proportional to the energy density of optical field and identical for all Zeeman sub-levels. The second term indicates an effective magnetic field, the direction of which is determined by vector \( [\mathbf{e}(r) \times \mathbf{e}(r)] \) [24, 25]. The magnitude of the light shift induced by a single lattice beam is expressed as \( U_0 = \frac{\hbar T^2 I}{\Delta 8I} \), where \( \Gamma = 2\pi \times 5.28 \) MHz is the natural line width, \( \Delta \) is the lattice beam frequency detuning from the ground state \( 6S_{1/2}, F = 3 \) state, \( I \) is the intensity of beam light, and \( I_s = 1.1 \) mW cm\(^{-2}\) is the saturation intensity for caesium atoms.
The vibrational frequency of the 3D Raman lattice is crucial for determining the magnetic field used in 3D DRSC, so that the Zeeman splitting between two adjacent sub-levels with $\Delta mF = 1$ well matches the spacing of the vibrational levels in the lattice. The lattice potential according to equation (4) is shown in figure 2, where the detailed parameters can be found in the experimental part and the scheme describing directions and polarizations of the laser beam have been shown in figure 1. The corresponding vibrational frequencies are $v_x = 86.1$ kHz, $v_y = 48.2$ kHz and $v_z = 48.2$ kHz. After CMOT and optical molasses, the atoms are prepared in the ground state $F = 3$ state and the corresponding Landé factor $g$ is $-0.2514$. Taking into account the splitting of the Zeeman sub-levels in the $F = 3$ manifold, a theoretical value of 180 mG is in good agreement with the optimal magnetic field used in our experiment.

4. Optimization for frequency detuning of Raman lattice

In order to suppress losses owed to atoms being off-resonantly pumped by the lattice light and decaying to the ground $F = 4$ state, a weak repumping laser ($\sim 30 \mu$W) acting on the 6S$_{1/2}$, $F = 4 \rightarrow 6P_{3/2}, F' = 3$ transition is used. This light is derived from the same laser diode that provides trapping lasers in the MOT and so we can independently optimize the frequency detuning of the Raman lattice light. As a result, we can effectively trap and hold more atoms in the ground $F = 3$ state starting at a relatively high temperature of optical molasses.

The dependence of the atom number in the lattice on detuning is shown in figure 3(a). The number of atoms in the lattice initially increases with detuning because larger detuning reduces heating losses from the interaction between the lattice light and the atomic sample. As the red detuning increases further, however, the potential depth drops and so the atomic loading rate also drops. In order to understand the physical mechanism and find the optimal value of the detuning precisely, a theoretical analysis is briefly introduced here. In this model the atom number is determined by the loading potential of the Raman lattice and the interaction with the trapped atoms. Thus the detuning frequency has a great impact on the number of trapped atoms. We define the number of atoms trapped in the lattice by introducing two parameters, $\gamma$ and $\eta$, as

$$N = \gamma \times 1.965 \times U_0 + \eta \times \sigma(\omega),$$

where 1.965 $\times U_0$ is the loading potential of the Raman lattice and $\sigma(\omega)$ is the cross-section that characterizes the atomic loss during the interaction with the lattice beam. For a two-level atom, the cross-section of the atoms in the 6S$_{1/2}$, $F = 3$ state is given as

$$\sigma(\omega) = \frac{\sigma_0 \Gamma^2/4}{(\omega - \omega_0)^2 + \Gamma^2/4},$$

where $\omega$ is the frequency of the lattice light, $\omega_0$ is the transition frequency from the 6S$_{1/2}$, $F = 3$ state to the 6P$_{3/2}$, $F = 4$ state and $\sigma_0 = \sigma(\omega_0)$ is defined as the maximum cross-section [26]. The number of atoms trapped in the 3D Raman lattice can be expressed as a function of lattice detuning $\Delta$:

$$N = \gamma \times \frac{1.965\hbar \omega \Gamma^2}{8I \Delta} + \eta \times \frac{\sigma_0}{1 + 4\Delta^2/\Gamma^2}.$$
in our experiment. We obtain $1.5 \times 10^7$ atoms in the ground $F = 3$ state in the lattice. The spatial distribution and integrated optical density of the cold atomic cloud are illustrated in figures 3(b) and (c).

5. Experimental results

The 3D Raman lattice successfully isolates the atoms into individual lattice sites [19–21]. We optimize the magnetic field and find that 200 mG is beneficial to degenerate $|F = 3, mF = 3; v\rangle$, $|F = 3, mF - 1; v - 1\rangle$ and $|F = 3, mF - 2; v - 2\rangle$ states by Raman coupling from lattice beams. $v$ and $mF$ denote the vibrational quantum number and hyperfine sublevel respectively. The optical pumping takes place in the $6S_{1/2}, F = 3 \rightarrow 6P_{3/2}, F' = 2$ transition. $v$ is conserved in the Lamb–Dicke regime and thus leads to a rapid loss of the vibrational quantum number. The atoms then populate at the vibrational ground $|F = 3, mF = 2; v = 0\rangle$ state, which is not resonant with the $\sigma^+$ polarized beam and simultaneously depopulated by a weak $\pi$ polarized component from the beam. In the end, all atoms are transferred to the dark $|F = 3, mF = 3; 0\rangle$ state.

After 12 ms of cooling, the optical pumping and repumping lasers are switched off while the lattice light is turned down adiabatically according to $p(t) = P(0) [1 + t/t_0]^{-2}$ in 500 $\mu$s, where $t_0$ is typically defined at 100 $\mu$s [19, 20]. Then, $1.2 \times 10^7$ atoms spin-polarized in the $F = 3, mF = 3$ state at a density of $10^{10}$ cm$^{-3}$ remain after cooling. The spatial distribution of atoms is shown in figure 4(a) where the absorption image is taken horizontally after 10 ms TOF. The Gaussian fitting has been performed both in the vertical and in the horizontal direction as shown in figures 4(b) and (c), respectively.

The temperature of the ensemble is measured at 1.7 $\mu$K using the TOF method shown in figure 4(d).

During 3D DRSC atoms that fall to the $F = 4$ ground state need be pumped back to the ground $F = 3$ state, so often the lattice light is set at 9.2 GHz red detuned from the $F = 3 \rightarrow F' = 4$ transition so that the lattice light also acts as a repumper [15, 17, 20]. However, as shown in figure 3(a), this frequency detuning of the lattice beam is not optimal for the atoms at a high initial temperature of $\sim 60 \mu$K because of the large and rapid loss of the atoms in the Raman lattice. One can clearly see that a larger red detuning of $\sim 15.5$ GHz greatly facilitates loading a large number of atoms into the lattice. The optimization of the frequency detuning of the lattice beam allows us to obtain an enhanced DRSC in a 3D Raman lattice for caesium atoms.

6. Conclusion

In conclusion, we have performed 3D DRSC on trapped caesium atoms in a vapour cell starting from a high initial temperature of $\sim 60 \mu$K. We begin with $3 \times 10^7$ atoms and finish with $1.2 \times 10^7$ atoms spin-polarized in the $F = 3, mF = 3$ state. At the end of the cooling stage, we obtain a temperature of 1.7 $\mu$K. Taking into account the loading potential of the 3D Raman lattice and its heating loss for the trapped atoms, we propose a theoretical model to simulate the atom numbers loaded into the lattice. The numbers at different frequency detuning are given, resulting in a good agreement with the theoretical analysis. As a result, the detuning of the Raman lattice light is optimized to avoid large and rapid loss of the caesium atoms at a relatively high temperature. Our scheme’s greatest advantage is the relaxed starting temperature requirement, meaning that 3D DRSC can be directly accomplished in a standard single cell vapour-loaded MOT without reliance on any additional devices such as a Zeeman slower. Furthermore, only conventional red detuned optical molasses has been performed in the ground $F = 4$ state, which is relatively simple compared with the blue Sisyphus cooling in the ground $F = 3$ state [18]. This simple and robust scheme can be adapted to a number of other atomic species. The enhanced 3D DRSC paves the way for effective loading of the cold atomic sample into the optical dipole trap and following evaporation cooling to obtain the Cs BEC in a single-cell system.
