Gamow-Teller $\beta$ decay is forbidden if the number of nodes in the radial wave functions of the initial and final states is different. This $\Delta n = 0$ requirement plays a major role in the $\beta$ decay of heavy neutron-rich nuclei, affecting the nucleosynthesis through the increased half-lives of nuclei on the astrophysical $r$-process pathway below both $Z = 50$ (for $N > 82$) and $Z = 82$ (for $N > 126$). The level of forbiddenness of the $\Delta n = 1 \nu 1f_{5/2} \rightarrow \pi 0g_{7/2}$ transition has been investigated from the $\beta^-$ decay of the ground state of $^{207}$Hg into the single-proton-hole nucleus $^{207}$Tl in an experiment at the ISOLDE Decay Station. From statistical observational limits on possible $\gamma$-ray transitions depopulating the $\pi 0g_{7/2}$ state in $^{207}$Tl, an
upper limit of $3.9 \times 10^{-3}$% was obtained for the probability of this decay, corresponding to $\log f_t > 8.8$ within a 95% confidence limit. This is the most stringent test of the $\Delta n = 0$ selection rule to date. © 2019 The Authors. Published by Elsevier B.V. The theory of $\beta$ decay was developed by Fermi in 1934 [1]. In its modern form it is derived from the standard model of the electroweak interaction [2,3]. Based on the orbital angular momentum $L$ carried by the $\beta$ particle and neutrino, the $\beta$ decay is classified as allowed ($L = 0$), first-forbidden ($L = 1$) and so on. The so-called forbidden transitions are hindered, but not completely suppressed. The selection rules for allowed $\beta$ decay are total angular momentum change $\Delta I = 0, \pm 1$ and no parity change between the initial (decaying) and final (populated) states. In contrast, first-forbidden transitions have $\Delta I = 0, \pm 1, \pm 2$ and a change in parity. These are the selection rules which can be found in textbooks. However, in the case of allowed $\beta$ transitions, there is one additional rule: the number of nodes, $n$, in the radial wave functions of the decaying and populated states must be equal.

The $\Delta n = 0$ selection rule plays a major role in heavy neutron-rich nuclei. The single-particle shell-model orbitals for the $N \geq 126, Z < 82$ region ("south-east" of $^{208}$Pb) are shown in Fig. 1. The several pairs of $\Delta n = 1, \Delta I = 0$ orbitals are indicated. If the $\Delta n = 0$ selection rule is strictly obeyed, $\beta$ decay between them is forbidden, resulting in longer lifetimes. The greatest impact is on nuclei where the Fermi level lies high above $N = 126$ and/or much below $Z = 82$, e.g. nuclei on the astrophysical $r$-process pathway, influencing the nucleosynthesis of heavy elements. On the other hand, this selection rule has little effect on isotopes which are proton-rich or close to the stability line, making the experimental investigation of its validity difficult. We explored the $\nu 1g_{9/2} \rightarrow \pi 0g_{7/2}$ transition in the $\beta$ decay of $^{207}$Hg in a high-statistics experiment performed at CERN-ISOLDE. In this letter we provide the most stringent test of the $\Delta n = 0$ selection rule to date.

The $\beta$-decay probabilities are characterised by $log f t$ values, where $f$ is the Fermi function and $t$ is the partial half-life. For allowed ($L = 0$) decay $f t$ can be written as [5]:

$$f t = (B_F + B_{GT}) = \frac{\pi^2 \hbar^7 n \ln(2)}{2m_e^2 c^4} L$$

(1)

where $B_F$ and $B_{GT}$ are the Fermi (total spin of the electron and antineutrino is $S = 0$) and Gamow-Teller ($S = 1$) reduced transition probabilities, and are proportional to the $|M_F|^2$ and $|M_{GT}|^2$ matrix elements respectively. These in turn are summed over the single-particle matrix elements. These single-particle matrix elements are equal to zero if the number of radial nodes in the wave function, $n$, changes between the initial and final states. The $\Delta n = 0$ selection rule applies for both Fermi and Gamow-Teller transitions. For details see ref. [6].

Far from the $N = Z$ line, Fermi decays are isospin-forbidden ($\Delta T \neq 0$), so considering Gamow-Teller transitions only one obtains [5-7]:

$$f t = \frac{6147}{1.62 \Pi_{T+1}} |\Psi_f |^2 |\tau_{\pm} |^2$$

(2)

where $\tau_{\pm}$ is the isospin step operator converting either a proton to a neutron or a neutron to a proton respectively, $\sigma$ is the Pauli spin operator, and $\Psi_i$ are the initial and final total nuclear wave functions. From the form of the operators the selection rules of $\Delta I = 0, \pm 1$ with no parity change follow. The matrix element is related to the overlap $\mathcal{L}$ of the initial and final state wave functions:

$$\mathcal{L} = \int \Psi_i(t)|\Psi_f(r)|^2 dr.$$  

(3)

For $\Delta n \neq 0$, if the Hamiltonians are identical (i.e. spin-orbit and Coulomb effects are ignored) then the radial wave functions are orthogonal, and $\mathcal{L} = 0$. The assessment of the $\Delta n = 0$ selection rule requires a good understanding of both initial and final states. This is achieved in the vicinity of the doubly magic nuclei, when the wave functions can be given in terms of a few single-particle components.

According to our knowledge, the $\Delta n = 0$ selection rule was verified for a single case: that of the $\beta$ decay of $^{207}$Tl into $^{207}$Pb [8]. The present case of the $^{207}$Hg $\rightarrow$ $^{207}$Tl decay provides a more stringent test, due to larger spin-coupling coefficients and the stronger contributions of the relevant single-particle orbitals to the overall wave functions.

The $^{207}$Hg ground state has an expected spin-parity of $9/2^+$, corresponding to a neutron in the $\nu 1g_{9/2}$ orbital above the $N = 126$ magic number. The daughter nucleus $^{207}$Tl is one proton hole away from doubly magic $^{208}$Pb. It exhibits clear single-particle behaviour with the $7/2^+$ $0g_{7/2}$ hole state at an energy of 3474(6) keV [9]. This state has been populated in a number of particle transfer experiments [10-14]. In the present letter we examine the $\nu 1g_{9/2} \rightarrow \pi 0g_{7/2}$ $\beta$ decay, allowed in terms of spin-parities but forbidden by the $\Delta n = 0$ selection rule.

The $\beta$ decay of $^{207}$Hg into $^{207}$Tl has been studied at the ISOLDE Decay Station (IDS). A molten lead target was bombarded with 1.4 GeV protons. $^{207}$Hg ions were extracted at 30 kV from the VD5 FEBIAD source [15], separated by the General Purpose Separator (GPS) and collected on the tape at IDS. The average implantation yield was $4.8(2) \times 10^7$ pps. The dominant beam contaminant was $^{208}$Hg, with a presence of around 0.6 times that of $^{207}$Hg. However, with a $Q_{\beta} = 1.31(2)$ MeV and few $\gamma$ transitions [16] it does not impact the current results. $\beta$ decay and $\gamma$ rays were detected by three plastic scintillators in a close configuration and an array of high-purity germanium (HPGe) detectors, respectively. The HPGe array consisted of four Canberra Clover detectors, arranged at equal angular separation at a backward angle, and a Miniball [17] cluster detector along the beam axis. The full detector set-up had a gamma-ray add-back efficiency of 22% at 100 keV and 4% at 2.6 MeV, and a $\beta$-particle efficiency of $\sim30\%$. Extension of the efficiency calibration up to 2.6 MeV was performed by using the
relative intensities of the 583 keV and 2614 keV peaks from the β decay of 208-Tl [18], measured on a separate GPS mass setting during the same experiment.

The analysis of this experiment revealed the level scheme of 207-Tl up to an energy of 3.94 MeV [19]. It is in good agreement with the previously established scheme [20], and contains a number of newly-observed states and transitions. The level scheme is now complete and balanced. A partial level scheme, showing levels and transitions used in this analysis, is shown in Fig. 2.

The four lowest-energy states correspond to shell model single-proton-hole states: the $\pi 2S_{1/2}$ ground state; the $\pi 1d_{3/2}$ state at 351 keV; the isomeric $\pi 0h_{11/2}$ state at 1348 keV (not shown on Fig. 2); and the $\pi 1d_{5/2}$ state at 1683 keV. At 2676 and 2709 keV lie the pair of states corresponding to the coupling of the $3^{-}$ octupole vibrational phonon to the ground state [20]. Above these, up to an energy of 3.8 MeV, lie a number of $(7/2, 9/2, 11/2)^{-}$ states, some of which result from octupole coupling with the $\pi 1d_{3/2}$ state and others involving other negative-parity particle-hole excitations.

No transitions into or out of the $\pi 0g_{9/2}$ proton-hole state at 3474(6) keV were observed. As the decay of this state was never observed [9], we used theoretical considerations to evaluate which states it would populate (see Fig. 2). The M3 and M2 transitions to the $1/2^{+}$ ground state and $11/2^{-}$ isomeric state, respectively, would be extremely weak and so are ignored. The high-energy 3123(6) keV E2 transition to the $3/2^{+}$ first excited state is expected to be dominant. This is a $g_{7/2} \rightarrow d_{5/2}$ transition connecting $\Delta j = 5\Delta l = 2$ states. The 1791(6) keV M1+E2 transition to the $5/2^{+}$ state may be of comparable strength, although the M1 decay in this $g_{7/2} \rightarrow d_{5/2}$ transition is $I$-forbidden. The next two excited states at 2676 keV and 2709 keV have spin-parity $(7/2^{-})$ and $(5/2^{-})$, respectively [20]. Many E1 transitions, some connecting equivalent single-particle and octupole states, have been observed in nearby nuclei [16,21-24]. Measured $B(E1)$ transition strengths are in the range of $10^{-3}-10^{-5}$ W.u. Therefore we adopt an upper limit of $B(E1) = 10^{-3}$ W.u. for the possible 798(6) keV and the 765(6) keV transitions. The typical E1 strength is an order of magnitude smaller than this upper limit.

Most of the observed states between 2709 and 3474 keV have spin-parity $(5/2^{+}, 7/2^{+}, 9/2^{+})$ [9]. Due to the lower energies of the possible E1 transitions into these states, the branching ratios from the $\pi g_{7/2}^{-}$ state should be smaller. In order to have comparable intensity to the 3123 keV E2 transition they need to have an unrealistically high strength of $B(E1) > 0.05$ W.u. Therefore these transitions are not considered. The properties of the four most probable depopulating transitions, including the estimated branching ratios, are given in Table 1. The latter are based on shell-model values of $B(M1)$ and $B(E2)$ transition strengths. These calculations assume pure $(g_{7/2}, 1d_{2}, 2s)$ proton hole states and standard effective E2 proton charge of 1.5e [25-27]. In order to obtain the strength of the $I$-forbidden $g_{7/2} \rightarrow d_{5/2}$ M1 transition, a $g_{p}[S \times Y_{2}]$ tensor term into the effective operator [28,29] was introduced. Adopting the $0g_{9/2}-1d_{5/2}$ vs. $1d_{3/2}-2s_{1/2}$ scaling calculated for a $^{132}$Sn core in the same model space [29], and considering the radial overlaps of the involved orbitals, the $B(M1)$ value of 0.0041 W.u. was obtained.

The most stringent non-observation limits were obtained from $\beta\gamma\gamma$ coincidence data. Where a transition is not observed, an upper limit on the intensity can be deduced from the uncertainty in the relevant background area, $I_{\gamma} < N\sqrt{2A}$. $N$ is the number of standard deviations used, and $A$ is the background area below the expected peak. The $\gamma\gamma$ coincidences used are indicated in Fig. 2, and the resulting coincidence spectra for the four different gating transitions are shown in Fig. 3. The extracted intensity limits, for $N = 2$ (95% confidence limit), are given in Table 1. The limits cover all energies within $2\sigma$ (12 keV) of the central energy. As shown in Table 1, the highest-energy transition is expected to dominate. Assuming a lower limit of 90% for the branching ratio of the 3123 keV transition, we would obtain a maximum possible population of the 3474 keV $7/2^{+}$ state of $1.2 \times 10^{-3}$ leading to the final result $\log ft > 9.3$. However, we can reduce our reliance on the shell model calculations by considering any branching ratios between all four transitions. In this case, the maximum possible population of the 3474 keV $7/2^{+}$ state is $3.9 \times 10^{-3}$ leading to the final result $\log ft > 8.8$.

The shell model calculations performed for further interpretation are based on the Kuo-Herling interaction [30,31] in the $pp$ and $hh$ channels, and proton-neutron two-body matrix elements (TBMEs) from a HFB G-matrix [32,33] in the $ph$, $hp$ and $sh$ channels relative to $^{200}$Pb. The combined interaction KKH7B (or PBKH7) in a $(0g_{9/2}, 1d_{2}, 2s, 0h_{11/2})^{-1}(0h_{9/2}, 1f, 2p, 0i_{13/2})$ and $\nu(0h_{9/2}, 1f, 2p, 0i_{13/2})^{-1}(0h_{11/2}, 1g, 2d, 3s, 0j_{15/2})$ model space is provided by the OXBASH package [34] as PBALL.
Table 1

| EP (MeV) | IF Decays (%) | σ (mb/GeV) | B(E1, 0g) (W.u.) | B(E2, 0h) (%) |
|----------|---------------|------------|------------------|--------------|
| 274      | <1.07 × 10^{-3} | E2         | 2.67             | 92.3         |
| 1791     | <3.83 × 10^{-3} | M1+E2     | 0.0641 (M1)      | 1.9          |
| 798      | <3.21 × 10^{-3} | E1         | <10^{-3}         | <3.1         |
| 765      | <2.14 × 10^{-3} | E1         | <10^{-3}         | <2.7         |

The initial and final wave functions are:

$$\Psi_i(207{\mathrm{Hg}}; \frac{7}{2}^+) = \phi_C \cdot \sum_j \alpha_j (\pi j^{-2}h_0) (v1g_9/2)$$

(4)

$$\Psi_f(207{\mathrm{Pb}}; \frac{7}{2}^+) = \phi_T \cdot \pi (g_{9/2})$$

(5)

where $\phi_C$ is the $208{\mathrm{Pb}}$ core and $\sum_j \alpha_j (\pi j^{-2}h_0)$ is the wave function of two proton holes outside the core. The resulting reduced Gamow-Teller matrix element is given by the equation

$$\langle\Psi_f|\tau_1\sigma_k|\Psi_i\rangle = \sqrt{\tilde{J}_f \tilde{J}_i} \tilde{C} \alpha_{7/2} W(1, 1/2, f, j, 1/2, j)$$

(6)

where the notation $\tilde{J} = \sqrt{J_1 + J_2 + 1}$ is used. The Racah coefficient $W$ is equal to 0.19245 for this decay. $a_{7/2}^2$ is the probability that there are two holes in the $\pi G_{9/2}$ orbital in the ground state of $207{\mathrm{Hg}}$. The shell model calculation in the $\pi h_{11/2} - \nu p$ space yields $a_{7/2} = 0.095$. $\tilde{C} = (v1g_9/2)\pi (g_{9/2})$ is the overlap integral between the specified single particle states.

From this information we obtain a limit $|\tilde{C}| < 0.191$. This is a stricter limit than that obtained from the $\beta$ decay of $207{\mathrm{Pb}}$ for the overlap of the $\nu 3s_{1/2}$ and $\pi 2s_{1/2}$ orbitals [8]. The reasons are the lower experimental log $ft > 8.35$ limit in the case of $207{\mathrm{Pb}}$, and the lower $3p_{3/2}$ contribution to the $207{\mathrm{Pb}}$ ground state ($a_{1/2} = 0.05$ using the same shell model calculation).

The overlap integral $\tilde{C}$ is very sensitive to the difference between the neutron and proton well radii. By calculating the value of the integral using a Woods-Saxon potential, using known proton and neutron separation energies and fixing the surface thickness and neutron radius parameter to $a = 0.65$ fm and $r_v = 1.25 \times A^{1/3}$ fm respectively, the result suggests that $G_{9/2}$ proton well radius parameter is between 0% and 1.5% larger than the $g_{9/2}$ neutron orbital parameter. Knowledge of these parameters is important in models of transfer reactions and neutron skin calculations.

So far we have not considered mixing in the $347(6)$ keV state. Indeed, spectroscopic factor measurements suggest that the $G_{9/2}$ orbital is dominant but with large mixing [12]. The other components might be populated by allowed $\beta$ decay. Another $7/2^-$ state with $h_{11/2} \times 3^+$ configuration is expected $\approx 500$ keV above the $7/2^-$ state, but in this case the phonon coupling is not stretched. Due to vector coupling coefficients the mixing is expected to be small [35,36] and is not considered. More important are certain two-particle-three-hole ($2p - 3h$) excitations. Such states are obtained if in $207{\mathrm{Hg}}$ a neutron in a $N < 126$ orbital decays into a $Z > 82$ orbital. In these $2p - 3h$ final states both the proton and neutron cores are broken. Shell-model calculations were performed, allowing hole states $\pi (g_{9/2}, d, 5/2, 11/2)$ and $\nu (h_{9/2}, f, p, i_{13/2})$ to be excited to selected particle states $\pi (h_{9/2}, f_{7/2}, i_{13/2})$ and $\nu (g_{9/2}, i_{13/2})$. Respectively the high-spin states of $207{\mathrm{Pb}}$ were well-reproduced. The yrast $7/2^+$ state is predicted to be $78 \%$ of $\tilde{g}_{9/2}$. In this approach all relevant Gamow-Teller transitions $\nu (h_{9/2}, f, l) \rightarrow \pi (h_{9/2}, f_{7/2}, i_{13/2})$, are accounted for. The Gamow-Teller strength into the $7/2^+$ state was calculated. Considering a quenching factor of 0.56 [38], a population of this state at a level of $8 \times 10^{-3}$% is predicted, corresponding to $\log ft = 8.53$.

In conclusion, the theoretically predicted population of the yrast $7/2^+$ state is around twice the experimentally determined upper limit for the excited state at $347(6)$ keV. An uncertainty of 50% in the population predicted by the shell model would reconcile the observed and predicted values.

While no peak was observed in the $351$ keV $\gamma\gamma$ coincidence spectrum at the expected energy of $3123$ keV, a small peak at $3142$ keV (shown in Fig. 3) implies the existence of a state with an energy of $3494$ keV. This lies three standard deviations away from $347(6)$ keV, and with no other supporting transitions a spin-parity assignment is not possible. Nevertheless, in the case that the state at $3494$ keV is the $7/2^+$ state previously placed at $347(6)$ keV, this would imply an observed $\beta$-feeding intensity of $8(1) \times 10^{-3}$% and $\log ft = 8.53(9)$. This is exactly the value predicted by the shell model for the population of the yrast $\pi G_{9/2}$-dominated $7/2^+$ state. It would still imply that the $\Delta n = 0$ selection rule is observed, as the observed population of this state from the $\beta$ decay of $207{\mathrm{Hg}}$ would be fully accounted for by the $2p - 3h$ mixing.

In the absence of the $\Delta n = 0$ selection rule, the lifetimes of the $207{\mathrm{Hg}}$ and $207{\mathrm{Pb}}$ nuclei would be shorter. Assuming $\log ft$ equal to the modal average of the empirical distribution for allowed transitions [39], the Gamow-Teller transitions would take approximately 5% and 20% of the decay intensity into $207{\mathrm{Pb}}$ and $209{\mathrm{Pb}}$ respectively, shortening the half-life of $207{\mathrm{Hg}}$ by around 7% and that of $207{\mathrm{Pb}}$ by around 20%. The effects are much larger for extremely neutron-rich heavy nuclei. Close to $208{\mathrm{Pb}}$ the contributions of the relevant wave functions in the mother/daughter nuclei are very low, with amplitudes $a_{1/2} = 0.05$ for $207{\mathrm{Pb}}$ and $a_{7/2} = 0.095$ for $207{\mathrm{Hg}}$. These increase dramatically for extremely neutron-rich nuclei, when either exploring deeper into the proton shell below $Z = 82$ or extending further into $N > 126$ (see the ordering of orbitals on Fig. 1). For example, the $r$-process path is predicted to cross the $Z = 82$ line at around neutron number $N = 160\sim 170$ [40]. In this region, just below $Z = 82$, the $\Delta n = 0$ selection rule will have an impact on the lifetimes by forbidding the $\nu 3s_{1/2} \rightarrow \pi 2s_{1/2}$ and $\nu 2d_{3/2} \rightarrow \pi 1d_{3/2}$ Gamow-Teller transitions. The effect of this selection rule for the decay of $N = 126$ $r$-process waiting-point nuclei is negligible because of the minimal contribution from $N > 126$ orbitals. The same selection rule also affects nuclei ‘south-east’ of $^{132}\text{Sn}$ [41] due to the existence of $\Delta n = 1$, $\Delta l = 0$ neutron-proton orbital pairs in the region of $N > 82$ and $Z < 50$. Experimental investigation of the forbiddenness in this mass region is an interesting possibility but remains challenging due to the large $Q_\beta$ values.

The $\beta$ decay of $207{\mathrm{Hg}}$ was studied and a search was made for $\gamma$-rays following the $n$-forbidden $\nu 1g_{9/2} \rightarrow \pi 0g_{9/2}$ Gamow-Teller $\beta$ decay. From the non-observation of this decay, a $\log ft > 8.9$ limit at 95% confidence level was deduced. This is the most stringent test of the $\Delta n = 0$ rule to date, and suggests that the selection rule is indeed obeyed. The rule has implications for the decays of the neutron-rich nuclei in both the $N > 82$, $Z < 50$ and $N > 126$, $Z < 82$ regions. In the latter region, the lifetimes of nuclei on the astrophysical $r$-process path are considerably increased, affecting the nucleosynthesis of heavy elements.

Acknowledgements

Support from the European Union seventh framework through ENSAR contract no. 262010, the Science and Technology Facilities Council through grants ST/P005314/1, ST/L005743/1 and ST/ J000051/1 (UK), the MINECO projects FPA2015-64969-P, FPA2015-65035-P and FPA2017-87568-P (Spain), FWO-Vlaanderen (Belgium), GOA/2015/010 (ROF KU Leuven), the Excellence of Science programme (EOS-FWO), and the Interuniversity Attraction Poles.
Programme initiated by the Belgian Science Policy Office (BriX network P7/12) is acknowledged. ZnP acknowledges support by the ExtreMe Matter Institute EMMI at the GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany. PHR and SMJ acknowledge support from the UK Department for Business, Energy and Industrial Strategy via the National Measurement Office.
