Abstract

Systems where resource availability approaches a critical threshold are common to many engineering and scientific applications and often necessitate the estimation of first passage time statistics of a Brownian motion (Bm) driven by time-dependent drift and diffusion coefficients. Modeling such systems requires solving the associated Fokker-Planck equation subject to an absorbing barrier. Transitional probabilities are derived via the method of images, whose applicability to time dependent problems is shown to be limited to state-independent drift and diffusion coefficients that only depend on time and are proportional to each other. First passage time statistics, such as the survival probabilities and first passage time densities are obtained analytically. The analysis includes the study of different functional forms of the time dependent drift and diffusion, including power-law time dependence and different periodic drivers. As a case study of these theoretical results, a stochastic model of water resources availability in snowmelt dominated regions is presented, where both temperature effects and snow-precipitation input are incorporated.

1. Introduction

A wide range of geophysical and environmental processes occur under the influence of an external time-dependent and random forcing. Climate-driven phenomena, such as plant productivity (Ehleringer et al., 1997), stenothermal populations dynamics (McClanahan & Maina, 2003), crop production (Rosenzweig & Parry, 1994), the alternation between snow-storage and melting in mountain regions (Hamlet & Lettenmaier, 1999; Marks et al., 1998), the life cycle of tidal communities (Barranguet et al., 1998; Bertness & Leonard, 1997; Charles & Dukes, 2009), and water-borne diseases outbreaks (Pascual et al., 2002; Patz et al., 2005) offer a few such examples. In particular, several environmental systems can be described by state variables representing the availability of a resource whose dynamics is forced by diverse environmental factors and climatic oscillations. Elevated regions water availability – mainly originating from the melting of snow masses accumulated during the winter period (under the forcing of increasing temperatures), and precipitation (moving from the solid precipitation to the rainfall regime) – offers a relevant case study (presented in Section 4). All of these processes are now receiving increased attention in several branches of ecology, climate sciences and hydrology, due to their inherent sensitivity to climatic variability.

Analogous dynamical patterns can be found in slowly-driven, non-equilibrium systems with self organized criticality (SOC), where the density of
potentially relaxable sites in the system can be described via a random
walk with time-dependent drift and diffusion terms (Adami 1995; Bak &
Paczuski 1995; Jensen 1998). In these systems, the time dependence in the
diffusion term derives from a gradual decrease of susceptible sites, so that
sites availability acts on the directionality and pathways (drift term) of the
“avalanches” till diffusion “kills” all the activity in the system (Redner 2001,
pp. 120–131). Similar dynamics occur in systems displaying stochastic reso-
nance, where noise becomes modulated by an external periodic forcing (see
Bulsara et al. 1994 1995 Gammaitoni et al. 1998 McDonnell et al. 2008
and references therein).

In many instances, the above mentioned processes are restricted to the
positive semi-plane or to the time at which a certain critical threshold is
reached, and are represented by a Fokker-Planck (FP) equation with an ab-
sorbing barrier. The main focus here is on the first passage time statistics
of the process, such as the survival probabilities and the first passage time
densities. In the following, a brief review of the general properties of the
time-dependent drift and diffusion processes with an absorbing barrier is pre-
scribed. For constant drift and diffusion, the conditional probabilities are usu-
ally obtained via the method of images due to Lord Kelvin (see Feller 1971,
p. 340). The applicability of this method to the solution of time-dependent
problems and its limitations are discussed and a necessary and sufficient cri-
terion is formulated in Section 2.2. The analysis is then extended to different
functional forms of the time-dependent drift and diffusion terms. Section 3.1
shows the analytical results for the first passage time statistics for a power-law
time dependent drift and diffusion, while time-periodic drivers are analyzed
in Section 3.2 (see Jung, 1993; Kim et al., 2010; Talkner et al., 2005, and references therein, for a more comprehensive review of periodically-driven stochastic processes). Finally, in Section 4, we present a stochastic model of the total mountain water equivalent during the apex phase of the melting season, incorporating both temperature effects and snow-precipitation input in the form of a power-law time-dependent Bm with an absorbing boundary.

2. Modeling Framework

When a time-dependent random forcing is the dominant driver of the dynamics, a general representation for the state variable $x(t)$ can be formulated in the form of a stochastic differential equation given by

$$dx(t) = \mu(t) \, dt + \sigma(t) \, dW(t)$$

where $\mu(t)$ and $\sigma(t)$ are purely time-dependent drift and diffusion terms, and $W(t)$ is a Wiener process with independent and identically Gaussian distributed (iid) increments $W(t) - W(s) \sim \mathcal{N}(0, t-s)$ for all $t \geq s \geq 0$. By assuming $t_0 = 0$, the solution of (1) takes the form

$$x(t) = x_0 + \int_0^t \mu(s) \, ds + \int_0^t [\sigma(s) \, dW(s)]$$

where $t$ is time and $x_0 = x(0)$ can be either a random or a non-random initial condition independent of $W(t) - W(0)$. The associated FP equation describing the evolution of the probability density function (pdf) of $x(t)$ can be expressed as

$$\frac{\partial p(x,t|x_0)}{\partial t} = -\mu(t) \frac{\partial p(x,t|x_0)}{\partial x} + \frac{1}{2} \sigma^2(t) \frac{\partial^2 p(x,t|x_0)}{\partial x^2},$$

where \( p(x,t|x_0) \) is the transition pdf with initial condition \( \delta(x - x_0) \) at \( t_0 \).

Eq. (3) can also be expressed as a continuity equation for probability

\[
\frac{\partial}{\partial t} p(x,t|x_0) = - \frac{\partial}{\partial x} j(x,t|x_0),
\]

where

\[
j(x,t|x_0) = \mu(t) p(x,t|x_0) - \frac{1}{2} \sigma^2(t) \frac{\partial p(x,t|x_0)}{\partial x},
\]

is the probability current (or flux) and \( p(x,t|x_0) \) is the conditional probability.

The solution of the FP equation in (3), is usually approached numerically (see for e.g., Schindler et al. (2005)). Whether this equation is analytically solvable for different functional forms of \( \mu(t) \) and \( \sigma(t) \) with an absorbing boundary, and whether these solutions can be applied in the study of the first passage statistics at such boundary is the main focus of this work. Case studies that employ these solutions are also presented.

2.1. Solution with Natural Boundaries

Consider first the solution of the FP equation (3) in the unbounded case. Given that the drift and diffusion coefficients depend only on time, the parabolic equation (3) can still be reduced to a constant-coefficient equation of the form

\[
\frac{\partial p(z,\tau)}{\partial \tau} = \frac{\partial^2 p(z,\tau)}{\partial z^2}
\]

by transforming the original variables \( x \) and \( t \) into

\[
\tau = \frac{1}{2} \int \sigma^2(t) dt + A
\]

and

\[
z = x - \int \mu(t) dt + B
\]
where $A$ and $B$ are generic constants. The solution with natural boundaries is then (Polyanin, 2002) 
\[ p(z, \tau) = \frac{1}{2\sqrt{\pi \tau}} \exp\left(-\frac{z^2}{4\tau}\right). \] Hence, given the initial condition 
\[ p(x, 0|x_0) = \delta(x - x_0), \tag{9} \]
the following normalized solution for an unrestricted process, starting from $x_0$, can be obtained as
\[ p_u(x, t|x_0) = \frac{1}{2\sqrt{\pi S(t)}} \exp\left[-\frac{(x - x_0 - M(t))^2}{4S(t)}\right], \tag{10} \]
where, assuming the integrability of $\mu(t)$ and $\sigma(t)$,
\[ M(t) = \int_0^t \mu(s)ds \tag{11} \]
and
\[ S(t) = \frac{1}{2} \int_0^t \sigma^2(s)ds. \tag{12} \]
It should be noted that the transformation in equations (8) and (7) also applies to any boundary condition imposed at a finite position. Therefore, as will be seen, it is not directly helpful in solving first passage time problems, as in that case it would lead to a problem with moving absorbing boundary conditions.

2.2. First Passage Time Distributions

For a Bm process commencing at a generic position $x_0$ at $t = 0$, the time at which this process reaches an arbitrary threshold $a$ for the first time (first passage time) is itself a random variable whose statistics are fundamental in many branches of science such as chemistry, neural-sciences and econometrics. In the following, it is assumed that the process is starting at a certain
state $x_0 > 0$ and that it is bounded to the positive semi-axis via an absorbing barrier $x = 0$. This hypothesis does not imply any loss of generality, considering that the solution of Eq. (3) with an absorbing boundary condition only depends on the distance of the initial point $x_0$ from the threshold, but not separately on $x_0$ and the threshold position. Eq. (3) is then solved with the boundary condition

$$p(0, t) = 0,$$ (13)

and the additional condition of $x = +\infty$ being a natural boundary to ensure that $j(+\infty, t | x_0) = 0$. For such a system, the survival probability $F(t | x_0)$ is defined as the probability of the process trajectories not absorbed before time $t$, i.e.

$$F(t | x_0) = \int_{0}^{+\infty} p(x, t | x_0) \, dx$$ (14)

and the first passage probability density $g(t | x_0)$ is either the "rate of decrease" in time of $F$

$$g(t | x_0) = -\frac{\partial}{\partial t} F(t | x_0)$$ (15)

or, alternatively, the negative probability current at the boundary

$$g(t | x_0) = \frac{\sigma^2(t)}{2} \frac{\partial}{\partial x} p(x, t | x_0) |_{x=0},$$ (16)

since $p(0, t | x_0) = 0$ from (13).

2.3. Method of Images in Time-Dependent Systems

When the drift and diffusion terms are independent of $t$ and $x$, Eq. (3) with absorbing boundaries can be readily solved by the method of images, often adopted in problems of heat conduction and diffusion (Cox & Miller 1965; Daniels 1982; Lo et al. 2002; Redner 2001). This method can also
be used for solving boundary-value problems for a Bm with particular forms of time-dependent drift and diffusion. The basic premise of this method is that given a linear PDE with a point source (or sink) subject to homogeneous boundary conditions in a finite domain, its general solution can be obtained as a superposition of many ‘free space’ solutions (i.e. disregarding the boundary conditions) for a number of virtual sources (i.e. outside the domain) selected so as to obtain the correct boundary condition. The image source (or sink) is placed as mirror image of the original source (or sink) from the boundary with a strength or intensity selected to match the boundary condition.

Consider equation (3) with the conditions (9) and (13). To solve this problem with the method of images, the barrier at 0 is replaced by a mirror source located at a generic point \( x = y \), with \( y < 0 \) such that the solutions of the Fokker-Planck equation emanating from the original and mirror sources exactly compensate each other at the position of the barrier at each instant of time (Redner, 2001). This implies the initial conditions in (9) must now be modified to

\begin{equation}
p(x, 0) = \delta(x - x_0) - \exp(-\eta) \delta(x - y),
\end{equation}

where \( \eta \) determines the strength of the mirror image source. Due to the linearity of the FP equation, the solution in the presence of the initial condition (17) is the superposition of elementary solutions

\begin{equation}
p(x, t|x_0) = p_u(x, t|x_0) - \exp(-\eta) p_u(x, t|y).
\end{equation}

Since the condition (13) requires that \( p(0, t|x_0) = 0 \), one obtains that

\begin{equation}
\frac{(M(t) + x_0)^2}{4S(t)} = \eta + \frac{(M(t) + y)^2}{4S(t)}
\end{equation}
for all \( t > 0 \). By assuming \( t = 0 \), we have \( x_0^2 = y^2 \) and recalling that \( y < 0 \), the resulting image position is \(-x_0\). This, inserted again in Eq. (19), yields

\[
\frac{M(t)}{S(t)} = \frac{\eta}{x_0} = q,
\]

where the constant \( q \) is analogous to the Péclet number of the process – i.e. the ratio between the advection and diffusion rates (Redner, 2001).

After differentiating (20) with respect to \( t \), it is seen that the method of images requires that the drift and the diffusion terms be proportional to each other. Namely, the intensity \( \eta \) of the image source must be constant in time. In fact, only in this case it is still possible to transform the original time scale into a new one, for which the transformed process is governed by time-independent drift and diffusion terms. Hence, writing the drift and diffusion terms as

\[
\mu(t) = kh(t) \quad \text{and} \quad \sigma^2 = lh(t),
\]

the associated FP equation is

\[
\frac{\partial p}{\partial t} = h(t) \left( -k \frac{\partial}{\partial x} + l \frac{\partial^2}{\partial x^2} \right) p.
\]

Transforming the original time \( t \) variable in

\[
\tilde{\tau} = \int_0^t h(s) ds
\]

Equation (22) finally becomes

\[
\frac{\partial p}{\partial \tilde{\tau}} = \left( -k \frac{\partial}{\partial x} + l \frac{\partial^2}{\partial x^2} \right) p.
\]

This condition is valid for any time-dependent diffusion when the drift is identically vanishing. Assuming the proportionality in (20) between \( \mu(t) \)
and $\sigma(t)$, the general solution for (3) under conditions (9) and (13) can be written as

$$p(x, t|x_0) = \frac{1}{2\sqrt{\pi}S(t)} \left\{ \exp \left[ -\frac{(x-x_0-M(t))^2}{4S(t)} \right] - \exp(-x_0q) \exp \left[ -\frac{(x+x_0-M(t))^2}{4S(t)} \right] \right\},$$

(25)

provided $M(t) = qS(t)$. Substituting for constant drift and diffusion in (25) one recovers the well-known solution for a biased BM (Cox & Miller, 1965)

$$p(x, t|x_0) = \frac{1}{\sqrt{2\pi\sigma^2 t}} \left\{ \exp \left[ -\frac{(x_0-x+\mu t)^2}{2\sigma^2 t} \right] - \exp \left[ -\frac{2x_0\mu}{\sigma^2} \right] \exp \left[ -\frac{(x+x_0-\mu t)^2}{2\sigma^2 t} \right] \right\},$$

(26)

with survival function $F(t|x_0)$ given by

$$F(t|x_0) = \Phi \left\{ \frac{\mu t + x_0}{\sigma \sqrt{t}} \right\} - \exp \left( -\frac{2x_0\mu}{\sigma^2} \right) \Phi \left\{ \frac{\mu t - x_0}{\sigma \sqrt{t}} \right\},$$

(27)

where $\Phi$ is the standard normal integral, and first passage time distribution

$$g(t|x_0) = \frac{x_0}{\sigma \sqrt{2\pi t^{3/2}}} \exp \left[ -\frac{(x_0 + \mu t)^2}{2\sigma^2 t} \right].$$

(28)

Equation (28) is the Wald (or inverse Gaussian) density function, that for a zero drift becomes of order $t^{-3/2}$ as $t \to +\infty$ (the first passage time has no finite moments for pure diffusion).

Similarly, the solution to the FP in equation (3) with a reflecting boundary at $x = 0$ can be obtained by the method of images provided that drift and diffusion are proportional to each other. The solution then becomes

$$p(x, t|x_0) = \frac{1}{2\sqrt{\pi}S(t)} \left\{ \exp \left[ -\frac{(x-x_0-M(t))^2}{4S(t)} \right] + \exp (-x_0q) \exp \left[ -\frac{(x+x_0-M(t))^2}{4S(t)} \right] - \frac{1}{2} \frac{M(t)}{S(t)} \exp \left( \frac{x_0}{x_0} \right) \left[ 1 - \text{erf} \left( \frac{x+x_0+M(t)}{2\sqrt{S(t)}} \right) \right] \right\},$$

(29)
with \( \frac{1}{2} \left[ 1 - \text{erf} \left( \frac{x+x_0+M(t)}{2\sqrt{S(t)}} \right) \right] \) being the Q-function representing the tail probability of a Gaussian distribution. Equation (29) generalizes the solution in Cox & Miller (1965) for a Bm with constant drift and diffusion and a reflecting boundary at 0.

3. Time Dependent Drift and Diffusion

3.1. Power-Law Time Dependence

As a first example of Bm with purely time-dependent drivers, the case of an unbiased diffusion \( (q = 0) \) and power-law time dependent diffusion term \( \sigma^2(t) = 2At^\alpha \) and \( \alpha > -1 \) are considered. For this process, the conditional probability \( p(x, t|x_0) \) with absorbing barriers at 0, takes on the form

\[
p(x, t|x_0) = \frac{\sqrt{1+\alpha}}{2\sqrt{\pi A}t} \exp \left[ -\frac{t^{-(\alpha+1)}(x-x_0)^2}{4A} \right] \left\{ 1 - \exp \left[ -\frac{t^{-(\alpha+1)}(x+x_0)^2}{4A} \right] \right\},
\]

while the survival function becomes

\[
F(t|x_0) = \text{erf} \left( \frac{x_0(1+\alpha)^{\frac{1}{2}}}{2\sqrt{\pi A}} t^{-(\alpha+1)} \right).
\]

Figure 1(a) shows the conditional probability (30) at a fixed time instance \( t = 15 \) time steps for \( A = 15 \), \( x_0 = 50 \), and \( \alpha = -0.1 \) (bold line) 0.5 (thin line), and 1 (dotted line). Given the asymptotic properties of the error function (Abramowitz & Stegun 1964), the long-time behavior of \( F(t|x_0) \) is then \( \sim \frac{x_0(1+\alpha)^{\frac{1}{2}}}{2\sqrt{\pi A}} t^{-(\alpha+1)} \), recovering for \( \alpha = 0 \) the \(-1/2\) tail decay of an unbiased constant diffusion (see Figure 1(b)). Also, by differentiating Eq. (31), one obtains

\[
g(t|x_0) = \frac{x_0}{2\sqrt{\frac{A\pi}{(\alpha+1)^3}}} t^{(3+\alpha)/2} \exp \left[ -\frac{x_0(\alpha+1)t^{-(\alpha+1)}}{4A} \right].
\]
whose tail behaves as $\sim t^{-\left(\frac{3+\alpha}{2}\right)}$. Hence, Eq. (32) is an inverse Gaussian distribution – that for $\alpha = 0$ becomes an inverse Gamma distribution with shape parameter $1/2$ (Johnson et al., 1994, pp. 284–285). These solutions characterize inter-arrival times between intermittent events when a system displays sporadic randomness (Gaspard & Wang, 1988; Molini et al., 2009; Rigby & Porporato, 2010).

The solutions in the case of proportional power-law diffusion and drift can be derived in an analogous manner. For $\mu(t) = qAt^\alpha$ and $\sigma(t) = \sqrt{2}A^{1/2}t^{\alpha/2}$, the conditional probability $p(x,t|x_0)$ takes the form

$$p(x,t|x_0) = \sqrt{\frac{\alpha+1}{\pi}}t^{-\left(\frac{\alpha+1}{2}\right)} \exp \left[ -\frac{(1+\alpha)t^{-\left(\frac{\alpha+1}{2}\right)}\left(-x^2 + \frac{Aq^{1+\alpha}}{t^{\alpha/2}} + x_0^2\right)}{4A} \right]$$

and the survival function, now incorporating the drift contribution, can be written as

$$F(t|x_0) = \Phi \left\{ t^{-\left(\frac{\alpha+1}{2}\right)} \left( \frac{Aq^{\alpha+1} + x_0^2 + x_0^2}{2\sqrt{A(\alpha+1)}} \right) \right\}$$

For positive $q$’s, $F(t|x_0)$ tends in the long term to $1 - \exp(-qx_0)$, while for negative $q$’s, $F(x,t|x_0) \sim \frac{2\sqrt{\alpha+1}}{2q^2}t^{-\left(\frac{\alpha+1}{2}\right)} \exp \left( -\frac{q\sqrt{At^{\alpha+1}}}{2\sqrt{\alpha+1}} \right)$. This fact implies that the probability for a trajectory to be eventually absorbed is 1 for the biased process directed towards the barrier, and $\exp(-qx_0)$ when the bias is away from the barrier (infinite aging). When the state variable represents the availability of a resource in time, the sign of $q$ determines if this resource
is subject to continuous accumulation (positive $q$), or it undergoes a total
depletion (negative $q$) with probability 1. Such a result is analogous to the
one of a simple biased Bm with constant drift and diffusion (Redner, 2001),
with the difference that in this case, $F(t|x_0)$ decays to 0 or $1 - \exp(-qx_0)$
with a rate that is governed by $\alpha$.

As an example, Figures 1 (c) and (d) respectively show a negatively biased
power-law time-dependent Bm and a positively biased one for the same set
of parameters in (b) and $q = -0.1$ and $q = 0.1$, for $A = 1$, $x_0 = 1$ and $\alpha = 0$
(constant diffusion, bold line), $-0.5$ (thin dotted line), $0.5$ (dashed line), and
1 (thin line). As evident in panel (c), $F(x,t|x_0)$ presents a faster decay to
zero with increasing $\alpha$, while for the positively biased Bm in panel (d) the
decay to the asymptotic value $1 - \exp(-qx_0)$ is slower with decreasing $\alpha$.

Finally, $g(t|x_0)$ can be obtained from (34) as

$$g(t|x_0) = \frac{x_0(1 + \alpha)^{3/2}}{2\sqrt{\pi At}^{3/2}} \exp \left[ -\frac{t^{-(\alpha+1)} \left( Aqt^{\alpha+1} + x_0 + \alpha x_0 \right)^2}{4A(1 + \alpha)} \right]$$  \hspace{1cm} (35)$$

where for $\alpha = 0$ the decay of $g(t|x_0)$ recovers the constant diffusion $t^{-3/2}$-law
for $t \to \infty$ and $q = 0$.

3.2. Periodic Drift and Diffusion

In this section, the case of a periodic diffusion in the form $\sigma^2(t) = [2A \cos(\omega t)]^2$ and $q = 0$ is considered. For periodically driven diffusion, the
conditional probability can be derived in the form

$$p(x, t | x_0) = \left( \frac{\omega}{\pi \vartheta(t)} \right)^{\frac{3}{2}} \exp \left[ -\frac{2\omega(x^2 + x_0)}{\vartheta(t)} \right] \left\{ \exp \left[ \frac{\omega(1 + x_0)^2}{\vartheta(t)} \right] - \exp \left[ \frac{\omega(x-x_0)^2}{\vartheta(t)} \right] \right\}$$  \hspace{1cm} (36)$$

\text{13}
where \( \vartheta(t) = A^2[2\omega t + \sin(2\omega t)] > 0 \). Thus, the solution becomes modulated in time with frequency \( \omega \). The survival probability is in turn

\[
F(t|x_0) = \text{erf} \left( x_0 \sqrt{\frac{\omega}{\vartheta(t)}} \right),
\]

that is represented in Figure 2 for different values of the frequency \( \omega \). Finally, the first passage time density is an \( \omega \)-modulated inverse Gaussian distribution

\[
g(t|x_0) = \frac{4x_0A^2 \omega^{3/2} \cos(\omega t)^2}{\sqrt{\pi}} \exp \left( -\frac{\omega x_0^2}{\vartheta(t)} \right). \tag{38}
\]

In the case \( q \neq 0 \), the conditional probability \( p(x, t | x_0) \) becomes

\[
p(x, t | x_0) = \frac{\sqrt{\omega}}{\sqrt{\pi}q\vartheta(t)} \left\{ \exp \left[ -\frac{\omega \left( x_0 - x + \frac{q\vartheta(t)}{4\omega} \right)^2}{\vartheta(t)} \right] \right.
\]
\[
- \exp \left[ -qx_0 - \frac{\omega \left( x_0 + x - \frac{q\vartheta(t)}{4\omega} \right)^2}{\vartheta(t)} \right] \right\}, \tag{39}
\]

where, again, the absorption at the barrier represents a recurrent (\( q < 0 \)) or a transient (\( q > 0 \)) state, as was observed for the power-law drift and diffusion process in Section 3.1. The recurrent case is illustrated in Figure 3 (b)-(d), where we report the time-position evolution of \( p(x, t | x_0) \) as a function of increasing \( \omega \). From (39), given \( \frac{\omega}{\vartheta} > 0 \), the expression for the survival function can be derived and takes the form

\[
F(t|x_0) = \frac{1}{2} \left[ 1 + \text{erf} \left( \frac{q\vartheta(t) + 4x_0\omega}{4\sqrt{\omega}\vartheta(t)} \right) \right.
\]
\[
+ \exp (-qx_0) \text{erfc} \left( \frac{q\vartheta(t) - 4x_0\omega}{4\sqrt{\omega}\vartheta(t)} \right) - 2\exp (-qx_0) \right], \tag{40}
\]

which, given the equality \( \text{erfc}(-x) = 2 - \text{erfc}(x) \), can be alternatively expressed as

\[
F(t|x_0) = \Phi \left\{ \frac{q\vartheta(t) + 4x_0\omega}{2\sqrt{2\omega}\vartheta(t)} \right\} - \exp (-qx_0) \Phi \left\{ \frac{q\vartheta(t) - 4x_0\omega}{2\sqrt{2\omega}\vartheta(t)} \right\}. \tag{41}
\]
The first passage time density \( g(t|x_0) \) is given by
\[
\begin{align*}
g(t|x_0) &= \frac{4A^2x_0\omega^{3/2}\cos(\omega t)^2}{\sqrt{\pi}\vartheta(t)^{3/2}} \exp\left[-\frac{(q\vartheta(t) + 4x_0\omega)^2}{16\omega\vartheta(t)}\right].
\end{align*}
\] (42)

The method of images can also be applied to the solution of different forms of periodic drivers, such as the case \( \mu(t) = q(B + A\cos(\omega t)) \) and \( \sigma(t) = \sqrt{2(B + A\cos(\omega t))} \), with \((B + A\cos(\omega t)) > 0\). In this last case, the drift term is the same as the one usually investigated in neuron dynamics by simple integrate-and-fire models displaying stochastic resonance (see for example the neuron dynamics case in Bulsara et al., 1994, 1995). In those models, the diffusion is usually constant so that the condition in equation (20) is not satisfied. Thus, it is often implied that \( \mu(t) \ll \sigma^2/2 \) to approximately resemble a time dependent diffusion with drift identically vanishing or that \( B >> A \) (approximating the simpler constant drift and diffusion case).

In these cases, the method of images only offers approximated solutions (Bulsara et al., 1994, 1995). Specifically, for a time dependent (and periodic) drift \( \mu(t) = B + A\cos(\omega t) \) and constant diffusion \( \frac{1}{2}\sigma^2 \), an approximation for \( p(x, t|x_0) \) in the presence of an absorbing barrier at 0 can still be obtained by using the method of images conditional to the fact that \( \mu(t) \ll \sigma^2/2 \). Only by adopting this assumption in fact, we can obtain an (approximated) solution for the survival function by means of Eq. 25 although drift and diffusion are not strictly proportional to each other. In this way we find
\[
F(t|x_0) = \frac{1}{2} \left\{ \text{erfc} \left( \frac{Bt + A\sin(\omega t)}{\sqrt{2\sigma\sqrt{t}}} - x_0 \right) \right. \\
- \left. \exp \left[ \frac{2x_0(B\omega t + A\sin(\omega t))}{\sigma\omega t} \right] \text{erfc} \left( \frac{Bt + A\sin(\omega t)}{\sqrt{2\sigma\sqrt{t}}} + x_0 \right) \right\}
\] (43)

and, analogous to Bulsara et al. (1994), from equation (15) the first passage
density can be expressed as

\[
g(t \mid x_0) = x_0 \exp \left\{ -\frac{[Bt + \frac{A \sin(\omega t) - x_0}{2\pi \sigma t}]}{2\sigma^2 t} \right\} \sqrt{\frac{2\pi \sigma t}{\sqrt{2\pi \sigma t}}} A \exp \left\{ \frac{[x_0 + Bt + \frac{A \sin(\omega t)}{2\pi \sigma t}]^2}{2\sigma^2 t} \right\} \text{erfc} \left( \frac{Bt + \frac{A \sin(\omega t) + x_0}{\sqrt{2\pi \sigma t}}} {2\sigma^2 t} \right) \left[ t \cos(\omega t) - \frac{1}{\omega} \sin(\omega t) \right] \]

(44)

The approximated nature of the solution is evidenced by the fact that, the image source intensity is no longer constant in time, so that by evaluating the probability current in 0 we obtain

\[
\tilde{g}(t \mid x_0) = \frac{x_0}{\sqrt{2\pi \sigma t^{3/2}}} \exp \left\{ -\frac{\left[ \frac{\omega(Bt - x_0) + A \sin(\omega t)}{2\sigma^2 t} \right]^2}{2\omega^2 \sigma^2 t} \right\}, \quad (45)
\]

which is different from (44). In any case, the first passage time pdf in equation (44) is in good agreement with the numerical simulations in Bulsara et al. (1994, 1995). Also, when \( A \to 0 \) both the (44) and the (45) tend to the first passage time pdf for a simple biased Bm.

As highlighted in Figure (4), when the magnitude of \( \mu(t) \) becomes significant, the two pdfs diverge due to the losses of probability density at the barrier (Eq. (45)). For this reason, the method of images cannot be considered a general approach to solving problems described by Eq. (3) with a time-dependent Péclet number.

4. A Case Study: Snowmelt Dynamics

Snowmelt represents one of the paramount sources of freshwater for many regions of the world, and is sensitive to both temperature and precipitation fluctuations (Barnett et al., 2004, 2005; Barnett & Pierce, 2009; Pepin & Lundquist, 2008; Perona et al., 2001; You et al., 2010). Snow dynamics is
characterized by an accumulation phase during which snow water equivalent (i.e. the amount of liquid water potentially available by totally and instantaneously melting the entire snowpack) increases until a seasonal maximum $h_0$ is reached, followed by a depletion phase in which the snow mantel gradually decays (and releases the stored water content) due to the increasing air temperature. Such a dynamics is complex and its general description requires numerous physical parameters that are rarely measured or available. In this section, we focus on a stochastic model describing the total water equivalent from both snow and rainfall during the melting season, as forced/fed by both precipitation (moving from the solid to the liquid precipitation regime) and increasing air temperature.

Due to the simplified nature of our stochastic model, we will consider the total potential water availability (in terms of water equivalent) as the key variable, thus neglecting any further effects connected with snow percolation and metamorphism (De Walle & Rango, 2008). Snowfalls are here assumed to become more sporadic progressing into the warm season and the predominant controls over fresh water availability during the melting period are increasing air temperature and liquid precipitation. Accordingly, the melting phase is described by a power-law time dependent drift directed towards the total depletion of the snow mantle and by a power-law diffusion whose positive and negative excursions represent respectively precipitation events and pure melting periods. The melting process is often described by a linear function of time by using the so called “degree-day” approach with time-varying melting-rate coefficients (De Walle & Rango, 2008). Considering that temperature varies seasonally and increases during the melting
season, a power-law form for drift and diffusion during the spring season, still represents a parametrically parsimonious and effective approximation of the basic driver of the process.

Under these assumptions, the dynamics of the total water equivalent depth for unit of area $h$ – i.e. the amount of fresh water potentially available from both snow accumulation and rainfall (Bras, 1990) – at a given point in space can be reasonably described by the Langevin equation

$$dh = -qkt^\alpha dt + \sqrt{2kt^\alpha}dW(t)$$  \hspace{1cm} (46)

where $k$ (with dimension $L^2/T^{\alpha+1}$) represents the accumulation/ablation rate. Note that here $h$ includes both the rainfall and snowmelt contributions. Also, we hypothesize that both the drift and the diffusion scale with the same exponent $\alpha$. This is a reasonable assumption given that variability of the process is expected to increase proceeding into the warm season. The initial condition is given by the snow water equivalent ($SWE$) $h_0$, accumulated during the cold season. The survival probability $F(t|h_0)$ for a given initial $SWE$ and the first passage time density $g(t|h_0)$ can be respectively calculated from (34) and (35). Figure 5 shows few sample trajectories of the process (panel (a)) obtained by the numerical simulation of Eq. (46) by means of a forward Euler algorithm with a time step of $10^{-2}$ days. The conditional probability $p(h,t|h_0)$ at different instants, the first passage time density $g(t|h_0)$, and the survival function $F(t|h_0)$, for the case $\alpha = 0.25$ and $k = 0.24 \text{ mm}^2/\text{days}^{\alpha}$ are also shown in panels (b) to (d). Here, we calibrated the parameters to obtain the mode of the first passage time at about 40 days after reaching the maximum $SWE$ of the season $h_0$. The first passage time statistics presented offer important clues about the timing between melting
and summer fresh-water availability under different climatic scenarios (consider for example the FPT pdf in Figure 5(c)).

5. Conclusions

The first passage time properties of Brownian motion with purely time-dependent drift and diffusion coefficients subjected to an absorbing barrier were investigated. These processes can be used to mimic a variety of environmental and geophysical phenomena, representing the availability of a resource and its dynamics in time (e.g. the ablation phase of a snow mass accumulated during the winter period and forced by temperature and precipitation). Survival functions and pdfs for the first passage times at the barrier were derived for power-law and periodic forcing time-dependent drift and diffusion terms for the associated Fokker Planck equation using the method of images. The general properties and limitations of this method were also reviewed, with reference to previous results obtained in the field of neural sciences and stochastic resonance. Particularly, we discussed how the applicability of the method of images to a Bm with time-dependent drift and diffusion is limited to the case of a process with constant Péclet number, i.e. with a time-independent ratio of drift and diffusion.

Where the time dependence is of the power-law type, the derived first passage time density and survival functions share many analogies with the statistics of inter arrival times between intermittent events when the considered system displays sporadic randomness. In the case of a periodic time-dependence, first passage time statistics appear to be modulated by the frequency of the forcing. The periodic forcing case has been also used to
show the approximate nature of solutions obtained by the method of images, when time-dependent drift and diffusion terms are not linearly related. We finally show how a Bm with power-law decaying drift and diffusion can be used to describe the warm season dynamics of the total water equivalent in mountainous regions.

6. Acknowledgments

This study was supported, in part, by the National Science Foundation (nsf-ear 0628342, nsf-ear 0635787 and NSF-ATM-0724088), and the Bi-national Agricultural Research and Development (BARD) Fund (IS-3861-96). We wish to thank Adi Bulsara for the helpful suggestions. We also thank Demetris Koutsoyiannis and the other three anonymous reviewers for their helpful suggestions.

Figure 1: Conditional probability $p(x,t|x_0)$ at different fixed times $t$ (a) and survival function $F(t|x_0)$ (b) for the pure power-law time dependent process described in Section 3.1, together with $F(t|x_0)$ for the negatively biased power-law process (c) and for the positively biased one (d). Panel (a) represents $p(x,t|x_0)$ at a fixed time $t = 15$ steps for $A = 15$, $x_0 = 50$, and $\alpha = -0.1$ (bold line), $= 0.5$ (thin line), and $= 1$ (dotted line). In (b) $F(t|x_0)$ is displayed as a function of $t$ for $A = 1$, $x_0 = 1$ and $\alpha = 0$ (constant diffusion, bold line), $\alpha = -0.5$ (thin dotted line), $\alpha = 0.5$ (dashed line), and $\alpha = 1$ (thin line). Panels (c) and (d) display respectively a negatively biased power-law time dependent $B^m$ and a positively biased one for the same set of parameters in (b) and $q = -0.1$ and $q = 0.1$. 
Figure 2: Survival function $F(t|x_0)$ for the periodic purely diffusive process described in Section 3.2, and for $A = 15$ and $x_0 = 50$. Upper, dashed and lower curves represent $F$ for $\omega = 0.0001$, $\omega = 0.015$, and $\omega = 0.045$, respectively.
Figure 3: Conditional probability $p(x, t|x_0)$ for the periodic negatively biased Bm described in Section 3.2. Panel (a) represents $p(x, t|x_0)$ at a fixed time $t = 3$ steps for $A = 15$, $x_0 = 50$, $q = -0.05$, and $\omega = 0.0001$ (bold line), $= 0.5$ (thin line), and $= 0.9$ (dotted line). Also, contour plots (b) to (d) show $p(x, t|x_0)$ for $A = 15$, $x_0 = 450$ and $q = -0.01$ as a function of $x$ and $t$, for $\omega = 0.0001$ (panel (b)), $\omega = 0.015$ (panel (c)), and $\omega = 0.045$ (panel (d)) respectively. Note how the negative drift forces the probability mass toward the barrier.
Figure 4: First passage densities $g(t|x_0)$ (bold black line, Eq. 44), and $\tilde{g}(t|x_0)$ (red dotted line, Eq. 45), respectively for (a) $\mu = 0.065$, $\sigma = 0.5$, $x_0 = 25$, $A = 0.032$ and $\omega = 0.016$; (b) $\mu = 0.065$, $\sigma = 0.35$, $x_0 = 15.5$, $A = 0.025$ and $\omega = 0.04$; (c) $\mu = 0.065$, $\sigma = 0.2$, $x_0 = 25$, $A = 0.03$ and $\omega = 0.07$, and (d) $\mu = 0.065$, $\sigma = 0.2$, $x_0 = 25$, $A = 0.03$ and $\omega = 0.15$. The discrepancy between $\tilde{g}(t|x_0)$ and $g(t|x_0)$ clearly signifies the failure of the method of images for problems with time-dependent Péclet numbers.
Figure 5: Sample trajectories of specific water equivalent from elevated regions during the melting season (a), and analytical results for the coupled stochastic melting-precipitation process of equation (46) (panels (b) to (d)). Numerical results were obtained by simulating Eq. (46) by means of an Euler algorithm with step $10^{-2}$ days. Panel (a) shows few sample trajectories of the process together with the curve of maximum values (upper curve) and minimum values (lower curve) over an ensemble of 10000 simulations, for $\alpha = 0.25$ and $k = 0.24 \text{ mm}^2/\text{days}^\alpha$. Analytical results for the conditional probability $p(h, t|h_0)$ at different instants, the first passage time density $g(t|h_0)$, and the survival function $F(t|h_0)$, are also shown in panels (b) to (d).
