Abstract

We derive a new 3D model for magnetic particle imaging (MPI) that is able to incorporate realistic magnetic fields in the reconstruction process. In real MPI scanners, the generated magnetic fields have distortions that lead to deformed magnetic low-field volumes with the shapes of ellipsoids or bananas instead of ideal field-free points (FFP) or lines (FFL), respectively. Most of the common model-based reconstruction schemes in MPI use however the idealized assumption of an ideal FFP or FFL topology and, thus, generate artifacts in the reconstruction. Our model-based approach is able to deal with these distortions and can generally be applied to dynamic magnetic fields that are approximately parallel to their velocity field. We show how this new 3D model can be discretized and inverted algebraically in order to recover the magnetic particle concentration. To model and describe the magnetic fields, we use decompositions of the fields in spherical harmonics. We complement the description of the new model with several simulations and experiments, exploring the effects of magnetic fields distortion and reconstruction parameters on the reconstruction.

Keywords: magnetic particle imaging (MPI), model-based algebraic reconstruction, ideal and realistic magnetic field topologies, 3D model for MPI, field-free line (FFL), field-free point (FFP), expansions in spherical harmonics, reconstruction and modeling artifacts

1. Introduction

The smart design of magnetic coils for the generation of oscillating magnetic fields is a key challenge in magnetic particle imaging (MPI) [3, 17]. The generated magnetic fields combined with the non-linear magnetization response of the tracer material consisting of superparamagnetic iron oxide nanoparticles (SPIONs) determine the signal acquisition process in MPI and, ultimately, how the distribution of SPIONs can be reconstructed. For this reason an accurate description and analysis of realistic magnetic fields is essential to study modeling and reconstruction in MPI.

Since the first publication in 2005 [7], MPI has undergone major development steps based on a few major designs for the generation of magnetic fields. For two of these topologies, generally referred to as field-free point (FFP) and field-free line (FFL) topology, fully 3D commercial preclinical MPI scanners are available at the present moment that are able to track SPIONs with a high sensitivity and a high temporal resolution. This makes the biomedical imaging modality MPI to a promising tracer-based diagnostic tool, in particular for blood flow imaging or for quantitative stem cell imaging [20, 24, 26].

In the original scanner design for MPI developed at Philips research (introduced in [7], extended to a full in vivo 3D design in [32]), a static gradient field and a space-homogeneous time-varying drive field are combined in order to magnetize the SPIONs. The two fields are generated in such a way that a moving spot is created, at the center of which the resulting magnetic field is low. The center of this low-field spot in which the magnetic field ideally vanishes is called the FFP. As soon as the FFP moves over a distribution of SPIONs, the magnetization of the SPIONs starts to flip, inducing a measurable voltage signal in one or several receive coils. From this time-dependent voltage signal the position of the SPIONs can be reconstructed. In the original design [7,32], the FFP of the created field moves along a 3D Lissajous trajectory inside a rectangular volume. Later on, other FFP-trajectories have been introduced in MPI, see [16].

In [31], a second major design principle for magnetic fields was introduced in which the applied magnetic fields ideally vanish along a FFL. Compared to the FFP setting, the voltage signal is now created in a much larger area along an FFL, providing a higher sensitivity [31] during the scan. A second main advantage of the FFL topology is the availability of an efficient model-based reconstruction formula based on the inverse Radon transform [19].

For both field topologies, FFP and FFL, models for the reconstruction of the particle density have been derived. However, only in very idealized settings, as for a 1D-FFP along line segments [5, 8, 25] or a non-rotating FFL [3, 6, 19], simple and reliable reconstruction formulas are available. While these simple formulas can be incorporated successfully also in 2D and 3D reconstructions [9, 22, 27], they lead to artifacts once the directions of the magnetic fields are altering quickly, as for instance if the FFP is moving on a 3D Lissajous curve. This discrepancy is due to limited possibilities to describe the magnetization behavior of nonuniform anisotropic SPIONs correctly if the external magnetic fields are changing rapidly their orientation. In this case, complex numerical simulations of the Fokker-Planck equations for coupled Brown/Néel rotations are necessary to describe the imaging properly, see [13, 15, 30].

In practice, the signal is not only created on or along an FFP or FFL, but around it, in a low-field volume (LFV). Moreover, real magnetic fields involved in the generation of an FFP or an FFL contain distortions. In particular in the FFL setting, the LFV of the field has more the appearance of a slightly bended banana than that of a straight line [3, 6]. While using the inverse Radon transform for signals created by an ideal FFL yields a reasonable recovery of
the particle concentration, this is no longer the case for realistic magnetic fields. In this case, the given distortions lead to artifacts in the reconstruction, in particular at the boundary of the field of view (FOV) (as illustrated in the figures 5 and 6 below). A further problem arises from the particular dynamic generation of the FFL. In order to accelerate the signal acquisition process, the FFL is continuously rotated with a frequency \( f_{\text{rot}} \) [18]. As the classical filtered back-projection (FBP) is computed on a rectangular grid in Radon space, the regridding from the rotated Radon information causes additional artifacts in the reconstruction.

The goal of this article is to introduce and study a new 3D model for MPI that is able to incorporate realistic magnetic fields, and to provide a simple reconstruction algorithm at the same time. More precisely, for realistic uni-directional time-oscillating magnetic fields we aim at obtaining a model-based reconstruction formula that generalizes the known FFL and 1D-FFP formulas in MPI. This new model-based reconstruction reduces artifacts generated by distortions and the rotation dynamics of the magnetic fields and allows us to calculate the particle concentration in an efficient way based on an algebraic reconstruction method.

To this end, we introduce a family of magnetic fields in which the field is parallel to its own velocity field. For this family of fields, the direction of the field does not change over time, allowing to substitute the general MPI imaging equation with a simpler 3D integral equation that can be discretized in an efficient way. In the mathematical formulation we use spherical harmonic expansions of magnetic fields (as introduced in [3, 4, 29]) and, as important examples, we show that this modeling framework includes classical (ideal) models, like the 1D-FFP along a straight line [5, 25] and the ideal FFL [19]. In particular, we show that this formulation offers enough flexibility to model realistic magnetic fields, e.g. in an FFL-type setting, by including higher order harmonics into the expansion. The coefficients of the higher order harmonics can be measured in a calibration procedure providing a realistic MPI model for a particular scanner. In this context, our MPI modeling framework can be interpreted as a hybrid between model-based and measurement-based approach in which the parameters of the magnetic fields are determined in a preliminary step.

1.1. Contributions

(a) We introduce a new modeling framework in MPI based on the expansion of magnetic fields in spherical harmonics and homogeneous harmonic polynomials, and we show how ideal and realistic magnetic field topologies in MPI can be modelled within this framework.

(b) We state a new 3D MPI model for magnetic fields in which the velocity and the acceleration field are parallel. Applied to ideal cases, this general model explains the standard 1D-FFP and FFL reconstruction formulas.

(c) We use this new model to obtain a model-based reconstruction that is able to handle realistic magnetic fields in FFL-type imaging. This new model-based approach is able to reduce artifacts in the reconstruction caused by idealized assumptions on the magnetic fields.

(d) We give a numerical implementation of this reconstruction scheme and provide several simulations and experiments complementing our results.

1.2. Outline of the paper

We continue this introductory part by giving a brief overview about the general imaging concepts in MPI (section 2). We further give a mathematical description of important ideal and
realistic magnetic field topologies encountered in MPI (section 3). The new model used for the algebraic reconstruction of the particle concentration with realistic field topologies is derived in section 4. It is formulated in terms of magnetic fields that are parallel to their velocity field. This family of fields contains all relevant ideal and realistic topologies in the considered FFL-type imaging scenario. The numerical details to obtain a discrete system matrix from the given continuous model, including approximation and discretization techniques, are provided in section 5. Finally, the experiments in section 6 show that the new algebraic reconstruction approach based on a model with realistic magnetic fields is very promising and outperforms a direct reconstruction using a filtered back projection (FBP). We conclude this article in section 7. Since our presentation is focused on the FFL-type imaging situation, we show in the appendix how the FFP-type imaging model can be derived within our modeling framework.

2. Principles of MPI signal generation

2.1. General imaging model in MPI

The basic concept of MPI is to recover a density \( c(r) \) of SPIONs from their non-linear magnetization in an applied time-varying magnetic field \( B(r, t) \). In an MPI scanner, this change in the magnetization of the superparamagnetic particles is measured in terms of voltage signals induced in one or several receive coils. Neglecting particle-particle interactions, the corresponding general imaging equation is determined by Faraday’s law of induction and is given as ([17, equation (2.36)])

\[
\frac{du_{\nu}}{dt} = -\mu_0 \frac{d}{dr} \int_{\Omega} \langle \varrho_{\nu}(r), \overline{M}(B(r, t)) \rangle c(r) \, dr. \tag{1}
\]

In this formula, the signal \( u_{\nu} : \mathbb{R} \rightarrow \mathbb{R} \) denotes the induced voltage \( u_{\nu}(t) \) for a given receive coil \( \nu \in \{1, \ldots, V\} \) at a time \( t \), and the constant \( \mu_0 \) the permeability in free space. The function \( \varrho_{\nu} : \Omega \rightarrow \mathbb{R}^3 \) on the domain \( \Omega \subset \mathbb{R}^3 \) describes the sensitivity vector of the receive coil \( \nu \) pointing in direction of the central axis of the coil. The function \( c : \Omega \rightarrow \mathbb{R}^+ \) describes the density \( c(r) \) of the magnetic particles at a point \( r \in \Omega \). Finally, \( \overline{M} : \mathbb{R}^3 \rightarrow \mathbb{R}^3 \) gives the magnetization response of a single mean SPION depending on the applied magnetic field \( B(r, t) \) at position \( r \) and time \( t \).

This equation describes a general imaging situation in MPI. For a particular measurement setup the sensitivities \( \varrho_{\nu} \), the magnetization response function \( \overline{M} \) and the employed magnetic fields \( B(r, t) \) have to be modelled or specified.

2.2. Magnetic fields and magnetization

The magnetization \( \overline{M} \) of a single SPION is aligned along the direction of the applied magnetic field \( B(r, t) \) and can be written as

\[
\overline{M}(B(r, t)) = \overline{m}(|B(r, t)|) \frac{B(r, t)}{|B(r, t)|}. \tag{2}
\]

A classical way to describe the modulus \( \overline{m} \) of the magnetization is the Langevin theory of paramagnetism. In this theory the mean modulus \( \overline{m} \) is modelled as

\[
\overline{m}(|B|) = m_0 L(|B|), \tag{3}
\]
with the Langevin function \( L : \mathbb{R} \to \mathbb{R} \) and the constant \( \lambda \) given by
\[
L(x) = \coth x - \frac{1}{x} \quad \text{and} \quad \lambda = \frac{\mu_0 m_0}{k_B T}.
\]
Here, \( m_0 \) denotes the magnetic moment of a single SPION, \( \mu_0 \) again the permeability in free space, \( k_B \) the Boltzmann constant, and \( T \) the temperature. The Langevin function \( L(x) \) is an odd function satisfying \( \lim_{x \to \pm \infty} L(x) = \pm 1 \). Its derivative is given by
\[
L'(x) = \begin{cases} 
\frac{1}{3}, & x = 0, \\
\frac{1}{x^2} - \frac{1}{\sinh^2(x)}, & x \neq 0.
\end{cases}
\]  

For the modulus \( |B| \), we therefore get \( m'(|B|) = m_0 \lambda L'(\lambda |B|) \) and asymptotically \( \lim_{|B| \to \infty} m(|B|) = m_0 \). For a large vector field strength \( |B| \) the saturation of the magnetization is therefore described by \( m_0 \). The derivative \( m'(0) = m_0 \lambda / 3 \) is a measure for the magnetic susceptibility of a particle.

2.3. Extension of curl- and divergence-free magnetic fields

In a volume with no magnetic field source and constant permeability \( \mu_0 \), as for instance in the interior of a cylindrical coil, a magnetic field \( B \) can be regarded both as a divergence-free and a curl-free vector field (see [3, section 2.1.2] or [11, section 5.4]), i.e. it satisfies the two equations
\[
\nabla \cdot B = 0 \quad \text{and} \quad \nabla \times B = 0.
\]

The second identity implies that \( B \) is locally a conservative vector field and can be written as the gradient \( B = \nabla \varphi_B \) of a potential function \( \varphi_B \). The fact that \( B \) is divergence-free then implies that \( \varphi_B \) satisfies the Laplace equation \( \Delta \varphi_B = 0 \). In particular, assuming that the vector field \( B \) is sufficiently smooth, the identity \( \Delta \varphi_B = 0 \) implies that also every component \( B_j \) of the vector field \( B = (B_1, B_2, B_3) \) is a solution of the Laplace equation \( \Delta B_j = 0, \ j \in \{1, 2, 3\} \).

As proposed in [4], this fact enables us to extend the components \( B_j \) of the vector field \( B \) in terms of spherical harmonics in order to get a compact description of the magnetic fields in MPI.

2.3.1. Homogeneous harmonic polynomials. A homogeneous polynomial in \( \mathbb{R}^3 \) of degree \( l \in \mathbb{N}_0 \) is a linear combination of the monomials
\[
x^{i_1} y^{i_2} z^{i_3}, \quad i_1 + i_2 + i_3 = l.
\]

The space \( P_l \) of all homogeneous polynomials of degree \( l \) has the dimension
\[
\dim P_l = \frac{(l + 1)(l + 2)}{2}.
\]

Herein, the subspace \( \mathcal{H}_l \) of homogeneous harmonic polynomials of degree \( l \) is given by the polynomials \( p \in P_l \) satisfying the Laplace equation
\[
\Delta p(x, y, z) = 0.
\]

In this way, the spaces \( \mathcal{H}_l \) are natural candidates to approximate and expand the components \( B_j \) of the magnetic field \( B \). The dimension of the harmonic spaces \( \mathcal{H}_l \) is given by
\[
\dim \mathcal{H}_l = \dim P_l \cdot \dim P_{l-2} = 2l + 1.
\]
2.3.3. Expansion of the components $B_j$ in spherical harmonics. If the components $B_j$ of the magnetic field $B = (B_1, B_2, B_3)$ satisfy the Laplace equation, we can expand them in terms of homogeneous harmonic polynomials and obtain the decomposition

$$B_j(x, y, z) = \sum_{i=0}^{\infty} \sum_{m=-l}^{l} c_{lj}^m P_{lm}(x, y, z), \quad j \in \{1, 2, 3\},$$

where $c_{lj}^m$ are the expansion coefficients.
Table 2. Spherical harmonic coefficients of a 2D rotating FFL using ideal magnetic fields.

| Coil name    | $B_1$ | $B_2$ | $B_3$ | Time dependent part |
|--------------|-------|-------|-------|---------------------|
| Select Maxwell | $c_{1}^{1} = -g$ | $c_{1}^{2} = -g$ | $c_{10}^{3} = 2g$ | $1$ |
| Select quad 0 | $c_{1}^{1} = g$ | $c_{1}^{2} = -g$ | $c_{10}^{3} = 2g$ | $1$ |
| Select quad 45 | $c_{1}^{1} = g$ | $c_{1}^{2} = -g$ | $c_{10}^{3} = 2g$ | $1$ |
| x-drive | $c_{10}^{2} = d$ | $c_{10}^{3} = d$ | $-2\pi f_{rot}$ | $\sin 2\pi f_{rot} \sin \pi f_{rot}$ |
| y-drive | $c_{10}^{2} = d$ | $c_{10}^{3} = d$ | $-2\pi f_{rot}$ | $\cos 2\pi f_{rot}$ |

or, in spherical coordinates,

$$B_j(r, \theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} c_{lm}^{j} r^l Y_{l,m}(\theta, \phi), \quad j \in \{1, 2, 3\}.$$  

We assume that the magnetic fields are properly smooth, so that there are no issues with convergence at this place.

3. Ideal and realistic magnetic fields in MPI

All major magnetic field topologies in MPI can be written compactly in terms of spherical harmonic expansions for a few involved generating fields. In the following, we review the (ideal) magnetic field topology generating a FFL and provide the mathematical representation with respect to the spherical harmonics expansion. We also explain how such expansions can be obtained for realistic magnetic field topologies. Further interesting descriptions of classical field topologies generating a FFP along a Lissajous curve and a line segment are given in appendices A.1 and A.2.

3.1. Ideal rotating field-free line (FFL) in the $xy$-plane

A magnetic field topology to generate a dynamically rotating FFL in the $xy$-plane was developed in [6]. The building elements of this rotating FFL are listed in table 2, see also [3] for a derivation.

The complete magnetic field $\mathbf{B}(r, t)$ to generate the rotating FFL is given by

$$\mathbf{B}(r, t) = \mathbf{B}_{\text{Maxwell}}(r) + \mathbf{B}_{\text{Quad0}}(r) \cos(2\pi f_{rot}t) + \mathbf{B}_{\text{Quad45}}(r) \sin(2\pi f_{rot}t) + \mathbf{B}_{x-\text{drive}}(r) \sin(2\pi f_{rot}t) - \mathbf{B}_{y-\text{drive}}(r) \cos(2\pi f_{rot}t),$$

where $f_d$ and $f_{rot}$ denote the drive and rotation frequencies of the FFL. The potential function $\varphi_B$ of the conservative vector field $\mathbf{B}(r, t)$ has the form
\[ 
\varphi_h(r, t) = g \left( z^2 - (x \sin(\pi f_{rot} t) - y \cos(\pi f_{rot} t))^2 \right) + d (x \sin(\pi f_{rot} t) - y \cos(\pi f_{rot} t)) \sin(2\pi f_d t). 
\]

We denote by FFL\((t)\) the set of all \(r\) at which the field \(B(r, t)\) vanishes at \(t \in \mathbb{R}\).

**Lemma 3.1.** The field-free line FFL\((t)\) at a time \(t \in \mathbb{R}\) can be parametrized as

\[
\text{FFL}(t) = \left\{ \begin{array}{l}
\left( \frac{\cos(\pi f_{rot} t)}{\sin(\pi f_{rot} t)} \right) h + \frac{d}{2g} \left( \begin{array}{l}
\sin(\pi f_{rot} t) \sin(2\pi f_d t) \\
- \cos(\pi f_{rot} t) \sin(2\pi f_d t)
\end{array} \right) | h \in \mathbb{R} \\
\end{array} \right\}.
\]

The set FFL\((t)\) is a line in the xy-plane perpendicular to \((\sin(\pi f_{rot} t), -\cos(\pi f_{rot} t), 0)\) and with distance \(\frac{d}{2g} \sin(2\pi f_d t)\) to the origin.

**Proof.** Every point \(r = (x, y, z)\) in the set FFL\((t)\) satisfies by definition \(B(r, t) = 0\). Therefore, the formula (5) for \(B(r, t)\) gives \(z = 0\), and for \(x\) and \(y\) the system of equations

\[
g \left( \begin{array}{c}
\sin(2\pi f_{rot} t) \\
\cos(2\pi f_{rot} t)
\end{array} \right) - g \left( \begin{array}{c}
\cos(\pi f_{rot} t) \\
\sin(\pi f_{rot} t)
\end{array} \right) = \left( \begin{array}{c}
d \sin(2\pi f_d t) \sin(\pi f_{rot} t) \\
d \sin(2\pi f_d t) \cos(\pi f_{rot} t)
\end{array} \right).
\]

Factoring out the term \(\sin(\pi f_{rot} t)\) in the first line and \(\cos(\pi f_{rot} t)\) in the second, we can simplify this expression as

\[
\begin{vmatrix}
\sin(\pi f_{rot} t) & \cos(\pi f_{rot} t) \\
\sin(2\pi f_d t) & \cos(2\pi f_d t)
\end{vmatrix} = 0. \tag{6}
\]

Identity (6) implies that \(\sin(\pi f_{rot} t)x - \cos(\pi f_{rot} t)y - \frac{d}{2g} \sin(2\pi f_d t) = 0\) and, thus, the second stated characterization of the FFL. In particular, it implies that all admissible points \((x, y)\) lie on a line in the xy-plane perpendicular to \((\sin(\pi f_{rot} t), -\cos(\pi f_{rot} t), 0)\). From this normal form of the FFL the parametrized description of the FFL given in lemma 3.1 follows with a standard linear algebra argument. \(\square\)

### 3.2. Non-rotating FFL in the xy plane

We can slightly modify the magnetic fields from the last subsection to generate non-rotating FFL’s. For this, it is only necessary to substitute the time-depending rotating angle \(2\pi f_{rot}\) in (5) with a fixed angle \(\alpha \in [0, 2\pi]\). The corresponding magnetic field for a non-rotating FFL is given by

\[
B(r, t) = 2g \begin{pmatrix}
y \cos \frac{\alpha}{2} - x \sin \frac{\alpha}{2} \\
x \sin \frac{\alpha}{2} - y \cos \frac{\alpha}{2}
\end{pmatrix} + \begin{pmatrix}
d \sin(2\pi f_d t) \sin \frac{\alpha}{2} \\
d \sin(2\pi f_d t) \cos \frac{\alpha}{2}
\end{pmatrix}.
\]

From lemma 3.1 we can derive that FFL\((t)\) is in this case given as
FFL\((t) = \left\{ r \mid \langle e_\alpha, r \rangle = \frac{d}{2g} \sin(2\pi f_d t) \right\},
\]

where \(e_\alpha = (\sin(\frac{\alpha}{2}), -\cos(\frac{\alpha}{2}), 0)\) denotes the normal vector of the FFL in the \(xy\)-plane. In particular, the direction of the FFL is now independent of the time \(t\).

3.3. Realistic magnetic fields in magnetic particle imaging

While the ideal field topologies of the last sections are represented by only a few spherical harmonics, a realistic magnetic field is accurately described by a larger amount of spherical harmonic coefficients. By incorporating these higher order spherical harmonics in the description of the magnetic fields a realistic and scanner-adapted model of the magnetic field topologies is obtained. The magnetic field coefficients in the expansion can be determined by measuring the field at a discrete set of spherical nodes with a subsequent numerical evaluation of the spherical integrals providing the inner product between field and spherical harmonics, see [3, 29]. In a second step, the expansion coefficients can then be incorporated into the MPI model that will be introduced in the next section. This calibration procedure is much less time consuming than the one used in an entirely measurement-based approach for MPI, in which a complete system matrix has to be measured [10].

Indeed, comparing the numbers of positions at which a measurement has to be conducted, we can get a rough estimate of the involved time expenses. To acquire the magnetic field representation for the presented method using five different coils and 45 evaluations points per coil based on the Gauss–Legendre quadrature on the sphere [33] (which is exact for all spherical harmonics up to degree \(l \leq 4\), see [29] for concrete applications in MPI), we require in total 225 magnetic field measurements to set up our 3D model. Note that this number is independent from the future resolution of the reconstruction. On the other hand, a simple measurement-based approach for the system matrix with a resolution of 2 mm for a circular surface with a diameter of 173 mm would required around 5500 measurements.

Our approach can consequently be considered as a hybrid reconstruction method in which a part of the model (in our case the generating magnetic fields) is measured, but the tracer response is modelled. An example of expansion coefficients for a realistic coil taken from [3] is shown in figure 1. While we have seen in section 3.1 that an ideal \(y\)-drive field in the generation of a rotating FFL is represented by a single spherical harmonic coefficient, a corresponding realistic \(y\)-drive field contains a large number of higher degree spherical harmonic coefficients. These higher degree spherical harmonics have in return an impact on the LFV of the generated magnetic field. While the ideal magnetic field generates a straight LFV (see figure 3(b)) a corresponding realistic LFV has more the curved shape of a banana (figure 3(c)).

In this work, the spherical harmonic coefficients \(c_{lm}^{y}\) are obtained via a simulation using a 3D model of the wires used to build the coils of an actual scanner. This model includes most of the imperfection leading to those higher harmonics, like some geometrical variation introduced for the fabrication of the coils or the current path required to connect the different current carrying path of the coil. The details are given in [3].

4. A new 3D MPI model for realistic magnetic fields

In this main section, we derive a new model for MPI that incorporates realistic field topologies and allows for a simple reconstruction at the same time. This model is based on the assumption that the applied magnetic field is parallel to its velocity field. This assumption is general enough
Figure 1. Spherical harmonic coefficients of an MPI y-drive coil from a simulation of a realistic coil. The moduli of the spherical harmonic coefficients $c_{lm}$ are displayed up to degree $l = 4$ and $-4 \leq m \leq 4$ in a sphere with radius $R = 0.05$ m. Light and dark filling colors indicate positive or negative coefficients, respectively.

to guarantee that realistic FFL-type field topologies are included. Further, we will show that the reconstruction formula for an ideal FFL topology is a special cases of this model.

4.1. An imaging model for magnetic fields with parallel velocity field

A time-dependent magnetic field $B(r, t)$ is called **parallel to its velocity field** if

$$\frac{d}{dt} B(r, t) = \lambda(r, t) \cdot B(r, t)$$

holds for some real-valued $\lambda = \lambda(r, t)$ for all $r \in \Omega$, $t \in \mathbb{R}$, as soon as $B(r, t) \neq 0$. In other words, at any position $r \in \Omega$ and time $t$ the direction of the velocity $\frac{d}{dt} B(r, t)$ is pointing in the same or in the reversed direction of the magnetic field $B(r, t)$. If $B(r, t) \neq 0$ the parallelity (7) implies that the magnetic field $B(r, t)$ does not change its direction over time:

$$\frac{d}{dt} \frac{d}{dt} B(r, t) = \frac{1}{B(r, t)} \left( \frac{d}{dt} B(r, t) - B(r, t) \left( \frac{d}{dt} B(r, t), \frac{B(r, t)}{|B(r, t)|} \right) \right) = 0.$$

In particular, in case of parallelity the acceleration of the magnetic field is also only performed tangentially in direction of the field $B(r, t)$. Namely, we have

$$\frac{d^2}{dt^2} B(r, t) = \frac{B(r, t)}{|B(r, t)|} \frac{d^2}{dt^2} |B(r, t)|.$$

**Theorem 4.1.** We assume that the function $m: \mathbb{R} \to \mathbb{R}$ is odd and twice continuously differentiable and that the magnetic field $B(r, t)$ is differentiable and parallel to its velocity field.
Then the time derivative of the magnetization $\overline{\mathbf{M}}(\mathbf{B}(r, t))$ defined in (2) can be simplified to

$$
\frac{d}{dt} \overline{\mathbf{M}}(\mathbf{B}(r, t)) = \overline{\mathbf{m}}(|\mathbf{B}(r, t)|) \frac{d}{dt} \mathbf{B}(r, t).
$$

(8)

In particular, the general MPI imaging model stated in (1) can be rewritten as

$$
u(\nu) = -\mu_0 \int_{\mathbb{R}^3} \left< \mathbf{g}(\mathbf{r}), \frac{d}{dt} \mathbf{B}(\mathbf{r}, t) \right> \overline{\mathbf{m}}(|\mathbf{B}(\mathbf{r}, t)|) c(\mathbf{r}) \, d\mathbf{r}.
$$

(9)

**Proof.** In the case that $\mathbf{B}(\mathbf{r}, t) \neq 0$, we use the chain rule to calculate the derivative of the vector field $\overline{\mathbf{M}}(\mathbf{B}(r, t))$ given in (2):

$$
\frac{d}{dt} \overline{\mathbf{M}}(\mathbf{B}(r, t)) = \overline{\mathbf{m}}(|\mathbf{B}(r, t)|) \left( \frac{d}{dt} \mathbf{B}(r, t), \frac{\mathbf{B}(r, t)}{|\mathbf{B}(r, t)|} \right) + \overline{\mathbf{m}}(|\mathbf{B}(r, t)|) \frac{d}{dt} \frac{|\mathbf{B}(r, t)|}{|\mathbf{B}(r, t)|}.
$$

Since $\mathbf{B}(r, t)$ is parallel to its velocity field $\frac{d}{dt} \mathbf{B}(r, t)$, we have $\frac{d}{dt} \frac{\mathbf{B}(r, t)}{|\mathbf{B}(r, t)|} = 0$ and

$$
\frac{d}{dt} \overline{\mathbf{M}}(\mathbf{B}(r, t)) = \overline{\mathbf{m}}(|\mathbf{B}(r, t)|) \frac{d}{dt} \mathbf{B}(r, t).
$$

In the case that $\mathbf{B}(r, t) = 0$, we take a closer look to the univariate function $\overline{\mathbf{m}}(x)/x$. Since $\overline{\mathbf{m}}$ is odd and twice differentiable, we have

$$
\overline{\mathbf{m}}(x) \rightarrow \overline{\mathbf{m}}(0) \quad \text{and} \quad \frac{d}{dx} \overline{\mathbf{m}}(x) = \frac{\overline{\mathbf{m}}(x) - \overline{\mathbf{m}}(x)}{x^2} \rightarrow \overline{\mathbf{m}}'(0) = 0,
$$

and, thus, that the derivative of the function $\overline{\mathbf{m}}(x)/x$ vanishes at $x = 0$. Therefore, we get also in the case $\mathbf{B}(r, t) = 0$:

$$
\frac{d}{dt} \overline{\mathbf{M}}(\mathbf{B}(r, t)) = \frac{d}{dt} \left( \frac{\overline{\mathbf{m}}(|\mathbf{B}(r, t)|)}{|\mathbf{B}(r, t)|} \mathbf{B}(r, t) \right) = \overline{\mathbf{m}}'(0) \frac{d}{dt} \mathbf{B}(r, t).
$$

\[\square\]

4.2. The 2D-MPI imaging equation for an ideal FFL

As an important example, we show that the reconstruction formula for 2D-MPI imaging with an ideal FFL is a special case of theorem 4.1. In appendix A.3, we will see that theorem 4.1 implies also the well-known reconstruction formula for 1D-FFP imaging.

In section 3.2, the magnetic field

$$
\mathbf{B}(r, t) = 2g \begin{pmatrix} -\left( e_x, r \right) - \frac{d}{2g} \sin(2\pi f_d t) \sin \frac{\alpha}{2} \\ \left( e_x, r \right) - \frac{d}{2g} \sin(2\pi f_d t) \cos \frac{\alpha}{2} \end{pmatrix}
$$

was used to generate the non-rotating FFL $(t) = \{ r | (e_x, r) = \frac{d}{2g} \sin(2\pi f_d t) \}$. Here, $e_x = (\sin(\frac{\pi}{2}), -\cos(\frac{\pi}{2}), 0)$ denotes the normal vector of the FFL in the $xy$-plane. The particular definition of $\mathbf{B}(r, t)$ implies that for all points $r$ in the $xy$-plane the magnetic field $\mathbf{B}(r, t)$ is parallel to its velocity field $\frac{d}{dt} \mathbf{B}(r, t)$. Thus, if we assume that the support $supp \ c = \Omega \subset \mathbb{R}^3$
is a compact 2D region in the \( xy \) plane, we can use the simplified imaging equation (9) for a model-based reconstruction. Inserting the magnetic field of the non-rotating FFL in the model equation (9) and using a simplified 2D integral over the domain \( \Omega \) in the \( xy \)-plane, we get the formula

\[
u_\omega(t) = -2 \pi d \mu_0 f_A \cos(2 \pi f_A t) \int_{\Omega} \langle \varrho(r), e_\nu \rangle \overline{m'} \left( 2g \left| e_\nu \right| - \frac{d}{2g} \sin(2 \pi f_A t) \right) c(r) \, dr.
\]

The vector \( e_\nu^* = (\cos \frac{\nu}{2}, \sin \frac{\nu}{2}, 0) \) is perpendicular to \( e_\nu \) in the \( xy \) plane. With the basis vectors \( e_\nu \) and \( e_\nu^* \), we can write every point in the \( xy \)-plane as \( r = se_\nu + we_\nu^* \). Using Fubini’s theorem, we rewrite the bivariate integral above as the iterated integral

\[
u_\omega(t) = -2 \pi d \mu_0 f_A \cos(2 \pi f_A t) \int_{\Omega} \langle \varrho(s, w), e_\nu \rangle \overline{m'} \left( 2g \left| s - \frac{d}{2g} \sin(2 \pi f_A t) \right| \right) c(s, w) \, ds \, dw.
\]

Assuming that the coil sensitivity is constant \( \varrho(r) = \varrho_0 \), this equation simplifies to

\[
u_\omega(t) = -2 \pi d \mu_0 f_A \cos(2 \pi f_A t) \langle \varrho_0, e_\nu \rangle \int_{\mathbb{R}} \overline{m'} \left( 2g \left| s - \frac{d}{2g} \sin(2 \pi f_A t) \right| \right) c(s, w) \, ds \, dw
\]

\[
= -2 \pi d \mu_0 f_A \cos(2 \pi f_A t) \langle \varrho_0, e_\nu \rangle \int_{\mathbb{R}} \overline{m'} \left( 2g \left| s - \frac{d}{2g} \sin(2 \pi f_A t) \right| \right) \mathcal{R}(e_\nu, s) \, ds,
\]

where \( \mathcal{R}(e_\nu, s) \) denotes the Radon transform of \( c \) for the line given by \( \langle r, e_\nu \rangle = s \). For an ideal non-rotating FFL we can therefore recover the following imaging model originally stated in [19, theorem 1].

**Corollary 4.2.** Let \( \overline{m'} : \mathbb{R} \to \mathbb{R} \) be odd and twice continuously differentiable, and let \( B(r, t) \) be the magnetic field generating an ideal non-rotating FFL as derived in section 3.2. Then, the imaging equation (8) in theorem 4.1 simplifies to

\[
u_\omega(t) = -2 \pi d \mu_0 f_A \cos(2 \pi f_A t) \langle \varrho_0, e_\nu \rangle \left( \overline{m'}(|2gs|) \ast \mathcal{R}(e_\nu, \cdot) \right) \left( \frac{d}{2g} \sin(2 \pi f_A t) \right),
\]

(10)

where \( \ast \) denotes the standard one-dimensional convolution between the kernel function \( \overline{m'}(|2gs|) \) and the Radon transform \( \mathcal{R}(e_\nu, s) \) with respect to the second variable \( s \).

**Remark 1.** Formula (10) provides a direct way to reconstruct the particle concentration \( c \) from the voltage signal \( u_\omega \) [1, 3, 6, 19]. Dividing the voltage signal \( u_\omega \) by the velocity and sensitivity factor \( -2 \pi d \mu_0 f_A \cos(2 \pi f_A t) \langle \varrho_0, e_\nu \rangle \) and regridding the so obtained time signal
onto the interval \([-\frac{d}{\Delta t}, \frac{d}{\Delta t}]\), we get an expression for \((\overline{\mathbf{m}}'(2g \cdot \cdot) \cdot \mathcal{Rc}(e_{a}, s))(x)\). Deconvolution then yields the Radon transform \(\mathcal{Rc}(e_{a}, s)\) of the concentration \(c\). By applying the FBP to the Radon data \(\mathcal{Rc}(e_{a}, s)\) we finally can reconstruct \(c\). Note that in some works, the deconvolution step is omitted in the reconstruction, see [21].

**Remark 2.** For a rotating FFL as given in section 3.1, the imaging equation (9) leads to the same formula (10), with the only difference that the fixed angle \(\alpha\) is replaced with the rotating angle \(\alpha(t) = 2\pi f_{rot}t\). Note that in this case the parallelity assumption of theorem 4.1 is not satisfied. However, if \(f_{b} \gg f_{rot}\), parallelity of the magnetic field \(\mathbf{B}(r, t)\) to its velocity field is almost given and the simplified imaging equation (9) provides a good approximation to the general imaging equation (1).

### 4.3. An approximative model for realistic magnetic fields

Apart from the ideal FFL and 1D-FFP imaging setups described in the previous section 4.2 and in the appendix (appendix A.3), no analytic inversion formulas for the reconstruction of the particle distribution \(c\) are known. Our imaging equation (9) allows to derive a discrete MPI model for a much wider class of imaging setups, provided that the magnetic fields are (approximately) parallel to its velocity field. In particular, this allows us to incorporate more complex magnetic fields and to reconstruct the particle density \(c\) algebraically from a modelled system matrix.

As a first step towards a discretization of the integral in (9), we approximate the derivative \(\overline{\mathbf{m}}'(x)\) for \(0 \leq x < b\) using a piecewise constant function and a threshold \(b > 0\). The energy of the function \(\overline{\mathbf{m}}'\) is in general concentrated in a small region around the origin. In this way, \(\overline{\mathbf{m}}'(|\mathbf{B}(r, t)|)\) gets essentially large only in the LFV of the magnetic field \(\mathbf{B}(r, t)\), i.e., in those regions in which the modulus \(|\mathbf{B}(r, t)|\) is small. The chosen threshold \(b > 0\) therefore gives a bound for the LFV of \(\mathbf{B}(r, t)\) in which \(\overline{\mathbf{m}}'\) is large enough to give an impact for the integral equation (9).

In the following, we restrict our attention to the approximation of the function \(\overline{\mathbf{m}}'(x)\) in the positive interval \([0, b]\). We consider \(N\) nodes \(0 < x_{1} < \cdots < x_{N} < b\) and set \(x_{N+1} = b\), \(x_{0} = 0\). The approximation of \(\overline{\mathbf{m}}'(x)\) with piecewise constant functions is defined on the intervals \(I_{n} = [x_{n}, x_{n+1}), n = 0, \ldots, N\). We construct

\[
\overline{\mathbf{m}}_{N}'(x) = \sum_{n=0}^{N} s_{n} \chi_{I_{n}}(x)
\]

(11)
in such a way that \(\lim_{N \to \infty} \overline{\mathbf{m}}_{N}'(x) = \overline{\mathbf{m}}'(x)\) for all \(x \in [0, b]\). Here, the indicator function \(\chi_{I_{n}}\) is defined as \(\chi_{I_{n}}(x) = 1\) if \(x \in I_{n}\) and \(\chi_{I_{n}}(x) = 0\) if \(x \notin I_{n}\). Two schemes to obtain the nodes \(x_{n}\) and the values \(s_{n}, n = 0, \ldots, N\), are given in section 5 (we will use the Langevin function (3) to model \(\overline{\mathbf{m}}\)). This construction allows us to approximate the time-derivative of the magnetization derived in (8) with a piecewise constant function:

\[
\overline{\mathbf{m}}_{N}'(|\mathbf{B}(r, t)|) \frac{d}{dt}\mathbf{B}(r, t) = \begin{cases} 
  s_{n} \frac{d}{dt}\mathbf{B}(r, t) & \text{if } |\mathbf{B}(r, t)| \in I_{n}, \\
  0 & \text{if } |\mathbf{B}(r, t)| \geq b
\end{cases}
\]

\[= \sum_{n=0}^{N} s_{n} \chi_{I_{n}}(|\mathbf{B}(r, t)|) \frac{d}{dt}\mathbf{B}(r, t).
\]
Using the approximate derivative $m'_N$ instead of $m'$, the imaging equation given in equation (9) can be written as

$$ u_\nu(t) = -\mu_0 \sum_{n=0}^{N} s_n \int_{F_n(t)} \left\langle \varphi_\nu(r), \frac{d}{dt} B(r, t) \right\rangle c(r) dr, \tag{12} $$

where

$$ F_n(t) = \{ r \in \Omega \mid |B(r, t)| \in I_n \}. \tag{13} $$

Introducing the kernel functions

$$ K_\nu(r, t) = -\mu_0 \left\langle \varphi_\nu(r), \frac{d}{dt} B(r, t) \right\rangle, $$

we finally obtain the integral equation

$$ u_\nu(t) = \sum_{n=0}^{N} s_n \int_{F_n(t)} K_\nu(r, t) c(r) dr. \tag{14} $$

We have the following limiting relation between the approximate model (14) and the original equation (9).

**Theorem 4.3.** Let $\text{supp } c = \Omega \subset \mathbb{R}^3$ be a compact set. For $t \geq 0$, let the function $K_\nu(r, t) c(r)$ be integrable over $\Omega$ and $\overline{m'}$ be twice continuously differentiable. Set $b > 0$ such that

$$ \max_{r \in \Omega} |B(r, t)| < b. $$

Let $\overline{m'}_N$ be an approximation of $\overline{m'}$ given in (11) such that $\lim_{N \to \infty} \overline{m'}_N(x) = \overline{m'}(x)$ uniformly on $[0, b)$. Then, we have

$$ \lim_{N \to \infty} \sum_{n=0}^{N} s_n \int_{F_n(t)} K_\nu(r, t) c(r) dr = \int_{\Omega} \overline{m'}(|B(r, t)|) K_\nu(r, t) c(r) dr. $$

**Proof.** If $\overline{m'}$ is twice continuously differentiable, theorem 5.1 below together with one of the node selection strategies given in section 5.2 guarantees the existence of a piecewise uniform approximation $\overline{m'}_N$ of $\overline{m'}$ on the interval $[0, b)$. In fact, theorem 5.1 shows that both constructions given in section 5.1 are adequate. The domain $\Omega$ corresponds to the disjoint union $\bigcup_{n=0}^{N} F_n(t)$ and the uniform convergence of $\overline{m'}_N$ yields

$$ \lim_{N \to \infty} \sum_{n=0}^{N} s_n \int_{F_n(t)} K_\nu(r, t) c(r) dr = \lim_{N \to \infty} \sum_{n=0}^{N} s_n \chi_{I_n} \int_{\Omega} \overline{m'}(|B(r, t)|) K_\nu(r, t) c(r) dr $n_{\Omega} \int_{\Omega} \overline{m'}(|B(r, t)|) K_\nu(r, t) c(r) dr = \int_{\Omega} \overline{m'}(|B(r, t)|) K_\nu(r, t) c(r) dr. \quad \square $n_{\Omega} \int_{\Omega} \overline{m'}(|B(r, t)|) K_\nu(r, t) c(r) dr = \int_{\Omega} \overline{m'}(|B(r, t)|) K_\nu(r, t) c(r) dr. \quad \square $
We will use the approximate imaging equation given in (14) to obtain a model-based algebraic reconstruction formula. We can regard (14) however also as an approximative MPI imaging model in case that the magnetic field $B(r, t)$ is, as in theorem 4.1, parallel to its velocity field.

5. Numerical implementation of the new model

5.1. Piecewise linear approximation of the magnetization function $\mathbf{m}$

In this section, we shortly provide two ways on how to approximate the magnetization function $\mathbf{m}$ with a piecewise linear function $\mathbf{m}_N$, and, at the same time, on how to approximate the derivative $\mathbf{m}'$ with a piecewise constant function $\mathbf{m}'_N$. The approximation $\mathbf{m}_N$ on the positive half-axis consists of a polygon with $N + 2$ linear polynomials. For this, we consider $N$ nodes $0 < x_1 < \cdots < x_N < b$ and set $x_{N+1} = b$, $x_0 = 0$. The linear polynomials are defined on the intervals $I_n = [x_n, x_{n+1})$, $n = 0, \ldots, N$, and on $I_{N+1} = [x_{N+1}, \infty)$.

(a) (Secant approximation scheme) For $n \in \{0, \ldots, N\}$, set

$$s_n = \frac{\mathbf{m}(x_{n+1}) - \mathbf{m}(x_n)}{x_{n+1} - x_n}.$$

(b) (Tangent approximation scheme) For $n \in \{0, \ldots, N\}$, set

$$s_n = \begin{cases} \mathbf{m}'(0) & \text{if } n = 0, \\ \mathbf{m}'(\frac{x_{n+1} + x_n}{2}) & \text{if } n > 0. \end{cases}$$

For both choices, we get for $x \geq 0$ the following approximants for the magnetization $\mathbf{m}$ and its derivative $\mathbf{m}'$:

$$\mathbf{m}'_N(x) = \sum_{n=0}^N s_n \chi_{I_n}(x), \quad \mathbf{m}_N(x) = \int_0^x \sum_{n=0}^N s_n \chi_{I_n}(y) dy.$$

An illustration of the approximation $\mathbf{m}_N$ for the secant scheme is shown in figure 2. For negative $x$, we expand $\mathbf{m}_N$ and $\mathbf{m}'_N$ such that $\mathbf{m}_N$ is odd and $\mathbf{m}'$ is even on $\mathbb{R}$, i.e.,

$$\mathbf{m}'_N(x) = \mathbf{m}'_N(-x), \quad \mathbf{m}_N(x) = -\mathbf{m}_N(-x) \quad \text{for } x \in \mathbb{R}.$$

Example 5.1. For the tangent scheme, we obtain a simple approximation of the derivative $\mathbf{m}'$ already for $N = 0$. In this case, using the Langevin model (3) to describe $\mathbf{m}$ and formula (4) for the derivative, we get the approximation

$$\mathbf{m}'_N(x) = \begin{cases} \frac{m_0 \lambda}{3}, & 0 \leq x < b, \\ 0, & x \geq b. \end{cases}$$

Then, if $F_0(t) = \{ r \in \mathbb{R}^3 : |B(r, t)| < b \}$
denotes the LFV at time \( t \) in which the modulus of the magnetic field is smaller than \( b \), we obtain in (14) the simple integral equation

\[
u_\nu(t) = -\frac{\mu_0 m_0 \lambda}{3} \int_{F_0(t)} \left( \varrho_\nu(r) \frac{dB(r, t)}{dt} \right) c(r)dr,
\]

i.e., the voltage signal \( u_\nu \) is approximately generated by integrating the particle density together with the velocity term \( \left( \varrho_\nu(r), \frac{dB(r, t)}{dt} \right) \) over the LFV \( F_0(t) \).

**Theorem 5.1.** If \( \overline{m} \) is twice continuously differentiable then, for both, the tangent and the secant approximation scheme, we have the properties:

\[
\sup_{x \in [0, b)} |\overline{m}'(x) - \overline{m}'_N(x)| \leq \sup_{x \in [0, b)} |\overline{m}'(x)| \max_{n \in \{0, \ldots, N\}} (x_{n+1} - x_n),
\]

(16)

\[
\sup_{x \in [0, b)} |\overline{m}(x) - \overline{m}_N(x)| \leq \sup_{x \in [0, b)} |\overline{m}'.(x)| \sum_{n=0}^{N} (x_{n+1} - x_n)^2.
\]

(17)

**Proof.** For both, the tangent and the secant scheme, the mean value theorem provides for \( x \in I_n \) the estimate

\[
|\overline{m}(x) - \overline{m}_N(x)| \leq \sup_{\xi \in I_n} |\overline{m}'.(\xi)| (x_{n+1} - x_n).
\]

This immediately implies (16). We can use this estimate also to obtain (17):

\[
|\overline{m}(x) - \overline{m}_N(x)| = \left| \int_0^x (\overline{m}(x) - \overline{m}_N(x)) dx \right| \leq \sum_{n=0}^{N} \int_{I_n} |\overline{m}(x) - \overline{m}_N(x)| dx
\]

\[
\leq \sup_{\xi \in [0, b)} |\overline{m}'.(\xi)| \sum_{n=0}^{N} (x_{n+1} - x_n)^2.
\]

(18)

5.2. Selection of the nodes

The nodes \( x_1, \ldots, x_N \) in the interval \((0, b)\) can be chosen in several different ways. Based on our result in theorem 5.1, we provide two simple options:
(a) Equidistant points (the simplest choice):
\[ x_n = \frac{b n}{N + 1}, \quad n \in \{0, \ldots, N\}. \]

(b) \( L_1 \)-optimal points: choose \( x_1, \ldots, x_N \) in \( (0, b) \) such that the \( L_1 \)-norm
\[ \int_0^b |m'(x) - m_N'(x)| \, dx \]

is minimized.

Theorem 5.1 ensures that both choices lead to a uniform convergence of \( m_N' \) towards \( m' \) on the interval \( [0, b) \). The \( L_1 \)-optimized variant yields a better approximation quality for the derivative \( m' \) as well as for the magnetization function \( m \). This can be seen particularly in the estimate (18), in which an \( L_1 \)-optimal ensemble makes the second inequality redundant.

In case of the tangential scheme, we give an explicit formula for the \( L_1 \)-norm. We assume that the derivative \( m' \) is positive and strictly monotonically decreasing when \( x \geq 0 \), and \( m(0) = 0 \). This is indeed the case if the magnetization \( m \) is given as in (3) by the Langevin model. Then, we get the explicit formula
\[ \int_0^b |m'(x) - m_N'(x)| \, dx = \sum_{n=0}^N \int_{x_n}^{x_{n+1}} |\frac{m'(x) - m_N'(x)}{2}| \, dx \]

\[ = m'(0)x_1 - m(x_1) + \sum_{n=1}^N \left( \int_{x_n}^{x_{n+1}} m'(x) \, dx - \int_{x_n}^{x_{n+1}} m_N'(x) \, dx \right) \]

\[ = m'(0)x_1 + \sum_{n=1}^N 2 \left( m \left( \frac{x_n + x_{n+1}}{2} \right) - m(x_n) \right) - m(x_{N+1}) = F(x_1, \ldots, x_N). \]

Thus, in order to find the ensemble in which the \( L_1 \)-norm gets minimal, we only have to minimize the functional \( F \).

5.3. Full discretization and model-based imaging matrix

We assume to have \( T \) discrete time measurements \( u_\nu = (u_\nu(t_1), \ldots, u_\nu(t_T)) \) of the voltage signal \( u_\nu \). To discretize the particle density \( c(r) \), we use the representation
\[ c(r) = \sum_{k=1}^K c_k \delta_k(r) \]

of \( c \) in a given set of basis functions \( \delta_k, k = 1, \ldots, K \). The approximate model equation stated in (12) can now be discretized as
\[ u_\nu(t_j) = \sum_{n=0}^N s_n \sum_{k=1}^K c_k \int_{F(t_j)} K_\nu(r, t_j) \delta_k(r) \, dr. \]
We denote by $S_{\nu,n} \in \mathbb{R}^{T \times K}$ the rectangular matrix with the entries
\[
(S_{\nu,n})_{j,k} = \int_{F_n(t_j)} K_{\nu}(r,t_j) \delta_k(r) dr
\]
Then, a model-based discrete imaging equation to recover the particle concentration can be written as
\[
u
\]
\[
S_{\nu}\mathbf{c} = \mathbf{u}_{\nu}, \quad (19)
\]
where $\mathbf{c} = (c_1, \ldots, c_K)$ and $S_{\nu} \in \mathbb{R}^{T \times K}$ is the modelled system matrix for the receive coil $\nu$. In our implementation, we sample the concentration $c(r)$ with a Dirac comb such that $c_k = c(r_k)$ are the sought concentration values at the positions $r_k$ and the system matrix entries $(S_{\nu,n})_{j,k}$ are given by
\[
(S_{\nu,n})_{j,k} = \begin{cases} 
K_{\nu}(r_k, t_j) & \text{if } r_k \in F_n(t_j), \\
0 & \text{otherwise}.
\end{cases}
\]

5.4. Algebraic reconstruction of the particle concentration

In order to solve the system of equation (19) for the particle concentration $\mathbf{c}$, we combine the information of all $V$ receive coils. In this way, we get the system
\[
\begin{pmatrix}
\mathbf{u}_1 \\
\vdots \\
\mathbf{u}_V
\end{pmatrix} =
\begin{pmatrix}
S_1 \\
\vdots \\
S_V
\end{pmatrix}
\mathbf{c}.
\]
From this system we extract the particle concentration $\mathbf{c}$ by calculating the solution of the normal equation $S^T S \mathbf{c} = S^T \mathbf{u}$ iteratively using the LSQR algorithm [23] together with an early stopping rule.

Remark 3. Although the particle reconstruction in MPI is in general an ill-posed inverse problem [5, 14, 22], at that stage, we did not incorporate additional regularization for the solution of the linear system $\mathbf{u} = S \mathbf{c}$. The various discretization steps applied in our model and the early stopping of the LSQR procedure already provide a certain regularization of the problem.

In combination with our model, one could of course apply also more advanced regularization schemes as for instance described in [28].

6. Experiments

Based on the phantom presented in figure 3(a), two types of magnetic field topologies are used to study the influence on the reconstruction: an ideal rotating FFL magnetic field, represented by a few low-degree spherical harmonics, as described in section 3.1; and a realistic one, obtained either from a realistic numerical model of the magnetic coil or from measurements. A concrete example of such a realistic field is given in section 3.3.

The influence of the higher degree spherical harmonics on the LFV can be observed by comparing figure 3(b) which illustrates the LFV at 2 mT for ideal topologies at a given time.
Figure 3. Ideal and realistic rotating FFL’s: (a) A phantom composed of circles (in white) of 4, 6, 8 and 10 mm diameter inside a 100 mm diameter circle. This phantom is placed inside a 173 mm diameter imaging area. The reconstructions along the illustrated horizontal (Top: 1st line, bottom: 3rd line) and vertical (4th line) lines are shown in figures 9, 11 and 13. (b) and (c) Show the LFV (in red) with a field amplitude smaller than 2 mT for an ideal and a realistic field topology, respectively ($f_{\text{rot}} = 100$ Hz).

Figure 4. Two sinograms of the phantom from figure 3(a) for an ideal FFL topology with $f_{\text{rot}} = 100$ Hz used as input data for the FBP. (a) Sinogram of a phantom in which the maximal displacement of the Radon transform is adapted to the support of the phantom. It is used to generate the reconstruction shown in figure 5 (row 1, left). (b) Same sinogram padded with zero, to increase the reconstruction area of the FBP.

$t = 17.25$ μs in our sequence, with figure 3(c) which shows the corresponding LFV for the realistic field topology used afterwards in our simulations. The LFV compared to an ideal FFL is slightly bended and interrupted on the upper part. To highlight the effect of these differences on the reconstructed particle concentrations, we run now experiments comparing side by side the images obtained either by a FBP for ideal and realistic fields or by our algebraic reconstruction procedure (cf subsection 5.4).

6.1. General experimental parameters

The modelled FFL scanner uses the same coils to move the FFL and to receive the signals used for the reconstruction. Those two coils are the drive coils. For all the presented results, the drive field frequency is fixed at $f_d = 25$ kHz and the line rotation frequency $f_{\text{rot}}$ is varied from 100 Hz to 1000 Hz. Due to the RAM limitation of 1 TB in our system, a rotation frequency of 10 Hz has not be conducted. 250 and 25 projections were used for the 100 Hz and 1000 Hz reconstruction, respectively. It is common to set the drive frequency between $<1$ kHz and 150 kHz, and the rotation frequency from $<1$ Hz to 100 Hz. The sampling frequency is set to 8 Mhz (4 Mhz for FBP), thus obtaining 160 points per projection (80 for FBP) and emulating
the common properties of the acquisition hardware used. Note that in order to do a frequency filtering on the measured signal, the whole rotation was always simulated to obtain a perfectly resolved spectra. Indeed, the hardware of an actual MPI scanner always filters out a frequency range around $f_d$. To reproduce this effect, we always removed all the information below $1.4 f_d$ from the measured signal. Furthermore, a Gaussian noise was added to all simulations. For the signal simulation, a spatial discretization of $1 \times 1 \times 1 \text{mm}^3$ was used, whereas a discretization of $1.3 \times 1.3 \times 1 \text{mm}^3$ was used for the system matrix. The solution of the proposed discretized MPI model (19) was solved using Matlab’s LSQR implementation, which was always stopped after 20 iterations. This has been optimized by visual inspection in a simulation using a rotation frequency $f_{rot}$ of 100 Hz, a threshold of $b = 10 \text{ mT}$ and kept constant for all further tests.
Figure 7. Influence of the threshold $b$ on the information included in the system matrix $S_{\nu}$ for $f_{\text{rot}} = 100\,\text{Hz}$ at $t = 17.25\,\mu\text{s}$ using the secant approximation scheme with $N = 30$ equidistant nodes. The normalized entries of the system function $S_{\nu}$ are displayed: (a) for a threshold of $b = 2\,\text{mT}$ and (b) for a threshold of $b = 10\,\text{mT}$.

6.2. Comparison with the filtered back projection

We compare our method with the FBP, which is commonly used for FFL systems to perform the image reconstruction [1, 21]. The FBP implementation of Matlab (Version 7.11.0) was used to perform the first test. The Radon projections are obtained by the reconstruction steps described in remark 1, using half a period of a drive field sweep with frequency $f_{\text{d}}$ for fixed approximate angles $\alpha \approx 2\pi f_{\text{rot}} t$ and for discrete values of the displacement variable $s = \frac{d}{2} \sin(2\pi f_{\text{d}} t)$ in a subinterval of $[-\frac{d}{2}, \frac{d}{2}]$. The so obtained Radon data is assembled into a sinogram and then reconstructed using the FBP algorithm. The reconstruction results for the FBP applied to ideal and realistic FFL topologies are displayed in figures 5 and 6. Note that, as we use approximate fixed angles $\alpha$ for the Radon projections, the continuous rotation of the FFL in a drive field sweep causes rotation artifacts in the FBP reconstructions that have to be corrected. This is in particular visible for $f_{\text{rot}} = 1000\,\text{Hz}$.

The sinogram obtained using the ideal model of a rabbit sized FFL MPI scanner [3] is illustrated in figure 4(a). To fully assess the differences between the reconstruction methods over the whole scanner opening, we additionally pad this ideal sinogram with zeros, as shown in figure 4(b).

The results of the FBP reconstructions are compared with the images obtained by our method. The system matrix $S_{\nu}$ for the algebraic reconstruction in (19) is constructed using the threshold $b = 10\,\text{mT}$ and the secant approximation scheme with $N = 30$ equidistant nodes for the discretization of the Langevin function. The information about the magnetic field $B(r, t)$ and its time-derivative is obtained by measurements or simulations.

Figures 5 and 6 highlight the main advantages of our method. Indeed, the presented model-based reconstruction method compensates the main artifacts introduced by the idealized assumptions in the FBP reconstruction. The rotation artifacts which appear in all images produced by the FBP and which are (independently of the field complexity) only linked to the continuous rotation of the LFV during an acquisition are compensated in our method. The distortion artifacts visible in both figures 5 and 6, introduced by the more complex realistic field topology, are also corrected. In particular, this can be observed by the corrected geometric distances between two points of the phantom.

We would like to point out that the ring artifacts in figure 6 (left and middle) are produced by
the FBP algorithm as a consequence of erroneous Radon data at the upper and lower boundary of the sinogram. These boundary errors stem from numerical issues that arise during the recovery of the Radon data $Rc(e^\alpha, s)$ from the voltage signals $u_\alpha(t)$ as described in corollary 4.2 and remark 1. Namely, this recovery gets ill-conditioned when the velocity of the FFL tends to zero, which is the case at the boundary of the FOV. This is particularly evident in the zero padded sinogram displayed in figure 4(b). The two visible horizontal gray lines (which are also present in the figure 4(a) mark these singularities which in turn lead to the production of ring artifacts by the FBP algorithm, see e.g. [2]. A closer look at the left and center images in figure 6 shows that there are high oscillations around the ring artifacts (including negative gray values) that lead to a wrong background color. Interestingly, our algebraic reconstruction method seems to avoid such artifacts which is why the reconstructions appear without any background signal. The reason why the ring artifacts are not produced in our reconstructions may be a consequence of our improved model and the use of an iterative (regularized) reconstruction procedure.

6.3. Influence of amplitude threshold

We further study the influence of the threshold $b$ on the reconstruction quality. In figure 7 we can see how this threshold determines the volume of the LFV used in the discrete imaging equation (19) to model the generation of the MPI signal.

We consider again the example of the phantom given in figure 3, with $f_{\text{ref}} = 100$ Hz, and using the secant approximation scheme with $N = 30$ for the Langevin function. The reconstructions in figure 8 and the line profiles in figure 9 show that the choice of the threshold $b$ has a strong impact on the reconstruction quality in the entire FOV when $b$ is in the range 1 to 4 mT. On the other hand, if $b$ is between 4 and 10 mT only small differences are visible.
on the periphery of the FOV. Thus, in this example a threshold $b$ of 10 mT is sufficient, and a threshold of 4 mT yields already very good results for the central part of the FOV. Note that a smaller threshold is desirable from a computational point of view in order to benefit from a sparser representation of the system matrix $S$. We also remark that for all six thresholds the same reconstruction technique based on the LSQR algorithm with early stopping at 20 iterations was used. Adapting the number of iterations for each $b$ or using additional regularization strategies can improve the reconstruction quality for the single thresholds even further. In this way, a threshold of $b = 3$ might already be sufficient for a reasonable reconstruction or the pincushion artifacts at the boundaries of figures 8(e) and (f) might vanish.
6.4. Discretization effects

In two additional tests, we study discretization effects on the reconstruction. In the first test, we search for the optimal number of equidistant nodes \( N \) for the piecewise approximation of the Langevin function in the tangential approximation scheme on an example with \( f_{\text{rot}} = 100 \text{ Hz} \) and a threshold \( b = 10 \text{ mT} \). The corresponding results are illustrated in figures 10 and 11. It is visible that already for \( N = 8 \) the piecewise approximation of the Langevin function provides acceptable reconstructions.

In a second experiment, we test three different discretization techniques for the Langevin function on an example with \( f_{\text{rot}} = 100 \text{ Hz} \), threshold \( b = 10 \text{ mT} \) and \( N = 30 \) nodes. As shown in figures 12 and 13, all three discretizations provide comparable reconstruction results.

**Figure 12.** Reconstruction with three different discretization schemes. (a) Secant, equidistant; (b) tangent, equidistant; (c) tangent, \( L_1 \)-optimal.
7. Conclusion

We introduced a new 3D modeling framework for MPI that includes classical MPI models based on ideal 1D-FFP and FFL magnetic fields, as well as realistic magnetic field topologies. Via expansions in spherical harmonics, this framework allows to incorporate realistic magnetic fields in the imaging model such that the reconstruction process can be adapted to a given scanner topology. In this sense, our framework can be regarded as a hybrid model-based approach for MPI in which the applied magnetic fields are measured in a preliminary calibration step and then included in the 3D model. A further advantage of our model is that no speed normalisation of the LFV is required (as preprocessing step) during the reconstruction which leads to an improved stability and avoids singularities.

Compared to an ideal FFP or FFL topology, the magnetic fields generated in real MPI scanners have distortions that lead to distorted LFVs. Our model-based approach is able to deal with these distortions and can generally be applied for magnetic fields that are parallel to their velocity field. We showed how this new 3D model can be approximated and discretized numerically in order to obtain a finite system matrix for the reconstruction of the magnetic particles.

To obtain the final magnetic particle distribution, we solved the linear system of equations (see section 5.4) iteratively using a finite number of LSQR iterations and no further tuning. This was sufficient to evaluate the enhanced reconstruction properties of our proposed model, leaves however room for further improvements. In particular, a combined optimization of the various parameters of the model, of the discretization strategy, and the early stopping of the LSQR solver might improve the reconstruction even further. Moreover, the incorporation of more advanced regularization techniques, as for instance TV-regularization, is likely to have an additional positive effect on the reconstruction quality of our model.
Table 3. Spherical harmonics encoding of an ideal magnetic field topology generating a 3D Lissajous FFP.

| Coil name | $B_1$ | $B_2$ | $B_3$ | Time dependent part |
|-----------|-------|-------|-------|---------------------|
| Selection | $c_{11}^1 = -g$ | $c_{11}^2 = -g$ | $c_{10}^3 = 2g$ | $1 \sin 2\pi f_xt$ |

Appendix A

A.1. Magnetic field topology for an ideal 3D-FFP along a Lissajous trajectory

As an important example of a magnetic field topology in MPI, we give a mathematical description of the building elements of the magnetic field $\mathbf{B}(\mathbf{r}, t)$ in the original Philips design [32]. In this field topology an FFP along a 3D-Lissajous trajectory inside a cuboid domain is created. The spherical harmonic coefficients of the involved drive and selection fields are summarized in table 3. Here, the constant $g$ denotes the gradient strength of the selection field, $d_x, d_y, d_z$, and $f_x, f_y, f_z$ the amplitudes and frequencies of the time-dependent drive field. The entire magnetic field $\mathbf{B}(\mathbf{r}, t)$ to generate the 3D-FFP on the Lissajous curve is then given by

$$\mathbf{B}(\mathbf{r}, t) = \mathbf{B}_{\text{Selection}}(\mathbf{r}) + \mathbf{B}_{\text{x-drive}}(\mathbf{r}) \sin 2\pi f_xt$$
$$+ \mathbf{B}_{\text{y-drive}}(\mathbf{r}) \sin 2\pi f_y t + \mathbf{B}_{\text{z-drive}}(\mathbf{r}) \sin 2\pi f_z t$$
$$= g \begin{pmatrix} -x \\ -y \\ 2z \end{pmatrix} + \begin{pmatrix} d_x \sin 2\pi f_xt \\ d_y \sin 2\pi f_y t \\ d_z \sin 2\pi f_z t \end{pmatrix}. \quad (20)$$

The vector field $\mathbf{B}(\mathbf{r}, t)$ is curl- and divergence free with the potential function

$$\varphi_B(\mathbf{r}, t) = g(z^2 - \frac{x^2}{2} - \frac{y^2}{2}) + d_x x \sin(2\pi f_xt) + d_y y \sin(2\pi f_y t) + d_z z \sin(2\pi f_z t).$$

The FFP $r_{\text{FFP}}(t)$ itself is the point in $\mathbb{R}^3$ at which the magnetic field $\mathbf{B}(\mathbf{r}, t)$ vanishes, i.e., $\mathbf{B}(r_{\text{FFP}}(t), t) = 0$. In this example, we have

$$r_{\text{FFP}}(t) = \left( \frac{d_x}{g} \sin 2\pi f_xt, \frac{d_y}{g} \sin 2\pi f_y t, -\frac{d_z}{2g} \sin 2\pi f_z t \right).$$

In particular, the FFP moves along a Lissajous trajectory inside the cuboid domain $[-\frac{|d_x|}{g}, \frac{|d_x|}{g}] \times [-\frac{|d_y|}{g}, \frac{|d_y|}{g}] \times [-\frac{|d_z|}{2g}, \frac{|d_z|}{2g}] \subset \mathbb{R}^3$. For Lissajous FFP topologies, model-based reconstruction approaches in 3D or 2D have limitations due to the complex magnetization behavior of SPIONs. The reconstruction of the particle density for Lissajous FFP topologies is therefore usually performed by measuring the system responses in a rather time-consuming calibration procedure [10, 12, 32].
A.2. Magnetic field topology for an ideal 1D-FFP along line segments

To generate an FFP that moves along a line segment in $\mathbb{R}^3$, we can apply the field

$$B(r, t) = g \begin{pmatrix} -x \\ -y \\ 2z \end{pmatrix} + \begin{pmatrix} d_x \\ d_y \\ d_z \end{pmatrix} \sin 2\pi f_d t.$$ 

This field can be generated in the same way as the magnetic field (20) for the 3D-FFP by using the same drive-field frequency $f_d = f_e = f_0 = f_e$ in all coordinates. The position of the FFP is then given as

$$\mathbf{r}_{\text{FFP}}(t) = v \sin(2\pi f_d t), \quad \text{with} \quad v = \begin{pmatrix} d_x \\ d_y \\ d_z \end{pmatrix}.$$ 

The FFP is now moving in the 1D line segment $\mathbb{L}_v = \{ r = sv | s \in [-1, 1] \}$. Such a 1D-FFP topology is generally used for 1D-MPI imaging, see [5, 8, 25].

A.3. The 1D-MPI imaging equation for an FFP along a line segment

As a final example of the general theory developed in this article, we show that the well-known 1D-MPI reconstruction formula for a 1D-FFP moving on an interval or a line segment in $\mathbb{R}^3$ can be deduced from theorem 4.1. In appendix A.2 above, we have already seen that the magnetic field $B(r, t) = g(-x, -y, 2z) + (d_x, d_y, d_z) \sin 2\pi f_d t$ leads to the FFP $\mathbf{r}_{\text{FFP}}(t) = v \sin(2\pi f_d t)$ oscillating on the line segment $\mathbb{L}_v = \{ r = sv | s \in [-1, 1] \}$ in direction $v = \left(\frac{d_x}{g}, \frac{d_y}{g}, \frac{d_z}{2g}\right)$. For all points $r$ in this line segment $\mathbb{L}_v$, the magnetic field $B(r, t)$ is parallel to its velocity field $\frac{\partial}{\partial t}B(r, t)$. Therefore, if the support $\text{supp } c = \Omega \subset \mathbb{R}^3$ of the particle concentration is located in a close volume around the line segment $\mathbb{L}_v$ we can use the simplified imaging equation (9) as a model for the MPI signal generation process. Using the gradient matrix $G = \text{diag}(-g, -g, 2g)$, we can write equation (9) as

$$u_c(t) = 2\pi\mu_0 f_d \cos(2\pi f_d t) \int_{\Omega} \langle \mathbf{g}_c(r), Gv \rangle \overline{\mu'(G(t - \mathbf{r}_{\text{FFP}}(t)))} c(r) \, dr.$$ 

Assuming that the coil sensitivity is constant $\mathbf{g}_c(r) = \mathbf{g}_c$, this equation simplifies to the 1D-MPI model

$$u_c(t) = 2\pi\mu_0 f_d \cos(2\pi f_d t) \langle \mathbf{g}_c, Gv \rangle \left( c * \overline{\mu'}(G(t - \mathbf{r}_{\text{FFP}}(t)))\right),$$

(21)

where $c * \overline{\mu'}(G(t - \mathbf{r}_{\text{FFP}}(t)))$ denotes the convolution of the particle concentration $c$ with the function $\overline{\mu'}(G(t - \mathbf{r}_{\text{FFP}}(t)))$. If the Langevin model of magnetization is used, we can further express $\overline{\mu'}$ in terms of the derivative (4) of the Langevin function.

Remark 4. Although the convolution defined in (21) is defined in terms of a three dimensional integral, the model in (21) is conceptually a one-dimensional model for the reconstruction of the particle concentration $c$ along the line segment $\mathbb{L}_v$. In a more idealized setting, we can also restrict the particle concentration $c$ to the line $\{ r = sv | s \in \mathbb{R} \}$ and formulate the model (21) in terms of a one dimensional convolution along this line. This 1D model was first formulated in [25]. In [5], a profound mathematical analysis of the corresponding imaging operator was conducted.
