(Dated: March 22, 2022)

The elastostatic Green function tensor approach, which was recently used to treat electrostriction in numerical simulation of domain structure formation in cubic ferroelectrics, is reviewed and extended to the crystals of hexagonal and orthorhombic symmetry. The tensorial kernels appearing in the expressions for effective nonlocal interaction of electrostrictive origin are derived explicitly and their physical meaning is illustrated on simple examples. It is argued that the bilinear coupling between the polarization gradients and elastic strain should be systematically included in the Ginzburg-Landau free energy expansion of electrostrictive materials.

I. INTRODUCTION

Technological advancements in ferroelectric materials have triggered interest in the kinetics of domain pattern formation and its description by the time dependent Ginzburg-Landau model. Unlike the standard thermodynamic theory, valid for homogeneous monodomain crystals, the time dependent Ginzburg-Landau model comprises extra terms accounting for the contribution of long-range interactions in the free energy and providing a potential to simulate kinetics of the domain patterns, macroscopic ferroelectric response, the impact of defects, and gives a new insight in the piezoelectric effect. Crucial for this technique, based on a variational derivation of the free-energy density with respect to the polarization, is dealing with the elastic field controlled by the inhomogeneous polarization due the electrostrictive coupling. Indeed, the static and kinetic properties of the domain structure are substantially influenced by elastic strain fields associated with polarization inhomogeneities. For example, it was shown that the electrostrictive interactions are critical to the formation of twin domain structure in prototype ferroelectric material BaTiO$_3$. The standard approach to the problem consists in elimination of the elastic degrees of freedom with the help of the mechanical equilibrium conditions. This leads to an effective interaction term $F_{\text{het}}$ depending explicitly on the order parameter (polarization $\mathbf{P}(\mathbf{x})$) only. Such an effective term is then added to the Landau-Devonshire free energy functional instead of the elastic and the electrostrictive terms. A technical drawback of this approach is that the resulting effective energy term is nonlinear and nonlocal. Moreover, if the real space integration is preserved, the elastic properties of the medium come in the formula through the anisotropic elastostatic Green functions for which only complicated integral expressions are known.

Nevertheless, at least for some purposes, the explicit expressions for anisotropic elastostatic Green functions can be avoided by expressing the interaction $F_{\text{het}}$ in terms of Fourier components of polarization. The Fourier representation is particularly convenient in the case of modulated ferroelectrics, where the polarization has a form of a single plane wave, but it is extremely useful even in the case of 3D domain structures. In the Fourier representation, the elastic properties appear in the expression for $F_{\text{het}}$ through a tensorial kernel $B_{ijkl}(\mathbf{n})$. This tensorial kernel is 4-th order tensor angular function comprising all necessary information about the electrostrictive and the elastic properties of the material. The elastic properties of the medium are introduced in $B_{ijkl}(\mathbf{n})$ solely via the so called elastic Green function tensor, which is a much more simple object than the (real space) elastic Green function itself.

In some cases, the exact form of the tensorial kernel $B_{ijkl}(\mathbf{n})$ could be reasonably approximated by that of elastically isotropic medium. Some time ago, however, the components of $B_{ijkl}(\mathbf{n})$ in general cubic crystals were derived explicitly, and the fully anisotropic $F_{\text{het}}$ was then successfully used in realistic 2D and 3D simulations of domain structure coarsening in perovskite ferroelectrics. Objective of this work is to the extension of this technique, which may be called "elastostatic Green function tensor technique", to the crystals of lower symmetry.

For the sake of clarity, we have introduced the notation and the approach leading to the expressions for effective energy contribution $F_{\text{het}}$ in section II. The explicit expressions known for cubic crystals are generalized to the case of orthorhombic and hexagonal symmetries in section III. The section IV is devoted to the basic electrostriction (without gradient terms). The $F_{\text{het}}$ is expressed in terms of polarization autocorrelation tensor, and the physical meaning of $A_{ijkl}$ tensor introduced in Ref. 3 is discussed in detail. Finally, the role of gradient terms in systematic expansion of electrostrictive energy is elucidated in the Section V.
II. ELIMINATION OF ELASTIC DEGREES OF FREEDOM

The excess Gibbs free energy functional describing an elastically linear ferroelectric in a general polarization and stress state can be expressed as a sum of three terms

\[ F = F_0\{P_i, P_{i,j}\} + F_1\{P_i, P_{i,j}, u_{ij}\} + F_2\{u_{ij}\}, \]  

(1)

where \(P_i, P_{i,j}\) stands for the \(i\)-th cartesian component of the polarization field and for its \(j\)-th spatial derivative, and \(u_{ij}\) is the \(ij\)-component of the (infinitesimal) strain field.

The first part \(F_0\{P_i, P_{i,j}\}\) may be further divided into an integral of the basic local Landau free energy density \(f_L\), Ginzburg (gradient) energy density \(f_G\) depending on spatial derivatives of \(\hat{P}(\mathbf{x})\) and the contribution of dipole-dipole interaction \(F_{\text{dip}}\)

\[ F_0\{P_i, P_{i,j}\} = F_{\text{dip}} + \int (f_L + f_G) \, d\mathbf{x}. \]  

(2)

The electrostrictive energy \(F_1\{P_i, P_{i,j}, u_{ij}\}\) can be expressed as an integral over electrostriction density \(f_{\text{es}}\), which is by definition linear in the elastic strain field \(u_{ij}(\mathbf{x})\)

\[ F_1\{P_i, P_{i,j}, u_{ij}\} = \int f_{\text{es}} \, d\mathbf{x}, \quad f_{\text{es}} = -g_{ij}u_{ij}, \]  

(3)

where the leading term in expansion of coefficient \(g_{ij}\)

\[ g_{ij} = g_{ij}(P_i, P_{i,j}) = q_{ijkl}P_kP_l + \ldots \]  

(4)

is just given by the usual electrostriction tensor \(q_{ijkl}\). Note that Einstein summation rule is assumed in the paper.

The last term, the proper elastic energy, is merely a quadratic function of the elastic strain field

\[ F_2\{u_{ij}\} = \int (p_{ij}u_{ij} + f_{\text{ela}}) \, d\mathbf{x}, \quad f_{\text{ela}} = \frac{1}{2}C_{ijkl}u_{ij}u_{kl}. \]  

(5)

In this case the total stress \(\sigma_{ij}(\mathbf{x})\) can be divided in three contributions — thermal stress \(p_{ij}\), describing for example the common thermal dilatation, purely elastic stress \(C_{ijkl}u_{kl}\) and the proper electrostrictive tensile stress field \(g_{ij}\) originating from coupling to the polarization field:

\[ \sigma_{ij}(\mathbf{x}) = \frac{\partial f}{\partial u_{ij}} = p_{ij} + C_{ijkl}u_{kl} - g_{ij} \]  

(6)

In static problems or in dealing with slow processes like domain structure formation, the inhomogeneous elastic strain can often be eliminated by means of static equilibrium conditions. The local stress equilibrium condition \(\sigma_{ij,j} = 0\) can be considered as a second order partial differential equation for displacement field \(\hat{u}(\mathbf{x})\):

\[ C_{ijkl} \frac{\partial^2 u_k}{\partial x_j \partial x_l} = \frac{\partial g_{ij}}{\partial x_j}. \]  

(7)

This condition defines \(\hat{u}(\mathbf{r})\) up to a linear form (homogeneous strain). Let us first consider a macroscopically clamped crystal with a large volume \(V\), where the homogeneous strain is zero. In principle, the solution to the Eq. (7) satisfying

\[ \bar{u}_{ij} \equiv \langle u_{ij}(\mathbf{x})\rangle \equiv \frac{1}{V} \int_V u_{ij}(\mathbf{x}) \, d\mathbf{x} = 0, \]  

(8)

can be found using the corresponding anisotropic elastostatic Green function \(G(\mathbf{x})\) defined by

\[ C_{ijkl} \frac{\partial^2 G_{km}}{\partial x_j \partial x_l} = \delta(\mathbf{x})\delta_{im}, \]  

(9)

where \(\delta(\mathbf{x})\) and \(\delta_{ij}\) are Dirac and Kronecker deltas.

At the same time, the formal solution for \(k \neq 0\) Fourier components follows immediately from Eq. (7):

\[ \hat{u}(\mathbf{k}) \equiv \langle \hat{u}(\mathbf{x}) \exp(-i\mathbf{k} \cdot \mathbf{x}) \rangle = \frac{i\Omega(\hat{n}) \cdot g(\mathbf{k}) \cdot \mathbf{k}}{k^2}, \]  

(10)
where $\hat{n}$ is the unit vector such that $k = k\hat{n}$,

$$g_{ij}(k) \equiv \langle g_{ij}(x) \exp(-ikx) \rangle$$  \hspace{1cm} (11)

are the Fourier components of the electrostrictive tensile stress field $g_{ij}(x)$ and the Green function tensor $\Omega(\hat{n})$ is the inverse of the Christoffel (acoustical) tensor $\Gamma(\hat{n})$:

$$(\Omega(\hat{n})^{-1})_{ij} = \Gamma_{ijkl}\hat{n}_k\hat{n}_l.$$  \hspace{1cm} (12)

Assuming a Born-Kármán-like boundary conditions on the volume $V$, the inverse Fourier transform provides the heterogeneous strain field as

$$\tilde{u}_{ij}(x) = \sum_{k \neq 0} ik_i u_{ij}(k) \exp(ikx).$$  \hspace{1cm} (13)

The $k$-vectors involved in the summation form a discrete set spread homogeneously over the whole Brillouin zone with density $V/(2\pi)^3$. In fact, only the long wave contributions should be essential (theory assumes smooth inhomogeneity or thick enough domain walls) since otherwise the long wavelength elasticity considered in Eq. (5) is not adequate. By inserting the formal solution Eq. (13) back to Eq. (1), we obtain the searched effective interaction term $F_{\text{het}} = F_1 + F_2$ for a macroscopically clamped system in the form

$$F_{\text{het}} = -\frac{V}{2} \sum_{k \neq 0} \sum_{ijkl} \tilde{u}_i g_{ij}(k) \Omega_{jk}(\hat{n}) g_{kl}(-k) \tilde{u}_l =$$
$$= -\frac{V}{2} \sum_{k \neq 0} \tilde{n} \cdot g(k) \cdot \Omega(\hat{n}) \cdot g(-k) \cdot \tilde{n},$$  \hspace{1cm} (14)

which does not depend on the elastic strain field any more. The integrand (summand) of Eq. (14) is a bilinear form in Fourier transformed tensor components $g_{ij}(k)$. It is thus possible to use the Voigt abbreviated subscript notation for $C_{ijkl}$ and for $g_{ij}$

$$g_1 = g_{11}, \quad g_2 = g_{22}, \quad g_3 = g_{33},$$
$$g_4 = g_{23}, \quad g_5 = g_{13}, \quad g_6 = g_{12},$$  \hspace{1cm} (15)

and rewrite Eq. (14) in a compact form (hereafter the Greek indices go always from 1 to 6)

$$F_{\text{het}} = -\frac{V}{2} \sum_{k \neq 0} g_{\alpha}(k) B_{\alpha\beta}(\hat{n}) g_{\beta}(-k).$$  \hspace{1cm} (16)

The nonlocal character of this effective interaction is better apparent after returning back to the real space:

$$F_{\text{het}} = -\frac{1}{2} \int V \int V \tilde{g}_{ij}(x') \frac{\partial^2 G_{kl}(x' - x'')}{\partial x_j \partial x_m} \tilde{g}_{lm}(x'') \, dx' \, dx''$$  \hspace{1cm} (17)

where $\tilde{g}_{ij} = g_{ij} - \langle g_{ij} \rangle$ is the heterogenous part of electrostrictive field $g_{ij}$. This expression shows that the $B_{\alpha\beta}$ tensorial kernel is actually a Fourier-transformed Hessian of the elastostatic Green function $G(x)$ defined in Eq. (9).

Finally, the total strain field under general macroscopic equilibrium conditions reads

$$u_{ij}(x) = \tilde{u}_{ij} + \bar{u}_{ij}(x),$$  \hspace{1cm} (18)

where $\tilde{u}_{ij}(x)$ is given by Eq. (13) and $\bar{u}_{ij}$ is the homogeneous component defined by the left hand side of Eq. (8). For example, the free sample condition $\bar{u}_{ij} = 0$ leads to the equilibrium value (see Eq. (8))

$$\bar{u}_{ij} = S_{ijkl}(\tilde{g}_{kl} - p_{kl}),$$  \hspace{1cm} (19)

where $S_{ijkl} = (C^{-1})_{ijkl}$ is the matrix of elastic compliances. Substitution of Eq. (18) back in the original potential in Eq. (8) provides $F_1 + F_2 = F_{\text{het}} + F_{\text{hom}}$ where

$$F_{\text{hom}} = -\frac{V}{2} (\tilde{g}_{\alpha} - p_{\alpha}) S_{\alpha\beta}(\tilde{g}_{\beta} - p_{\beta})$$  \hspace{1cm} (20)

and $F_{\text{het}}$ is just the same as for the case of clamped crystal (Eqs. (14), (17)).
III. ELASTOSTATIC GREEN FUNCTION TENSOR FOR CUBIC, HEXAGONAL AND ORTHORHOMBIC CRYSTALS

Provided that the explicit dependence of the electrostrictive tensile stress \( g_{ij} \) on polarization field appearing in the Eq. (12) is known, the effective energy term \( F_{\text{het}} \) can be calculated from Eq. (13). Obviously, in some cases, it is worth to tackle the problem of calculation of the Green function derivatives appearing in Eq. (17) explicitly, while in other cases it is possible to avoid it, and use Eq. (14) or (16). For example, it was shown [1] that simulations of domain structure coarsening described by the time dependent Ginzburg-Landau equations (including the above effective interaction term \( F_{\text{het}} \)) can be performed entirely in the Fourier space.

In this paragraph, we will concentrate on properties of the elastic Green function tensor \( \Omega_{ij}(\hat{n}) \) and the 6x6 matrix of the tensorial kernel \( B_{\alpha\beta}(\hat{n}) \) appearing in the Eq. (10). In order to avoid numerical inversion of the Christoffel tensor (Eq. (12)) at each wave vector direction \( \hat{n} \), several authors have derived explicit formulas for the cubic symmetry Green function tensor \( \Omega_{ij}(\hat{n}) \). Among them, the approach of the Ref. [3] is the most suitable here since it allows generalization to the case of hexagonal and orthorhombic symmetry. The essential step consists in expressing \( \Gamma_{ij} \) as a sum of diagonal part \( d_j(\hat{n}) \) and a tensorial square of a convenient real vector \( \mathbf{v} \):

\[
\Gamma_{ij}(\hat{n}) = d_j(\hat{n}) \delta_{ij} + v_i v_j.
\] (21)

This is trivial in cubic crystals where obviously:

\[
v_i = (C_{12} + C_{44}) \hat{n}_i,
\] (22)

\[
d_i = C_{44} + (C_{11} - C_{12} + C_{44}) \hat{n}_i^2.
\] (23)

The decomposition is not so straightforward for the crystals of lower symmetry. Nevertheless, for example in the case of orthorhombic elastic medium with

\[
C_{23} > -C_{44}, \quad C_{13} > -C_{55}, \quad C_{12} > -C_{66},
\] (24)

(which is a very weak assumption since practically all known crystals have all the off-diagonal elements \( C_{12}, C_{13} \) and \( C_{23} \) positive), the Christoffel tensor is given by Eq. (22) with

\[
v_1 = \hat{n}_1 \sqrt{\frac{(C_{12} + C_{66})(C_{13} + C_{55})}{C_{23} + C_{44}}},
\]

\[
v_2 = \hat{n}_2 \sqrt{\frac{(C_{23} + C_{44})(C_{12} + C_{66})}{C_{13} + C_{55}}},
\]

\[
v_3 = \hat{n}_3 \sqrt{\frac{(C_{13} + C_{55})(C_{23} + C_{44})}{C_{12} + C_{66}}},
\] (25)

\[
d_1 = C_{11} \hat{n}_1^2 + C_{66} \hat{n}_2^2 + C_{55} \hat{n}_3^2 - v_1^2,
\]

\[
d_2 = C_{44} \hat{n}_1^2 + C_{22} \hat{n}_2^2 + C_{44} \hat{n}_3^2 - v_2^2,
\]

\[
d_3 = C_{55} \hat{n}_1^2 + C_{44} \hat{n}_2^2 + C_{33} \hat{n}_3^2 - v_3^2.
\] (26)

Obviously, the above decomposition can be used also for hexagonal crystals; it is sufficient to put \( C_{55} = C_{44}, C_{22} = C_{11}, C_{23} = C_{13} \) and \( 2C_{66} = C_{11} - C_{12} \).

For arbitrary crystal symmetry, once the explicit expressions for \( v_i \) and \( d_i \) are known, the Green function tensor \( \Omega_{ij} \) is obtained directly using the Lemma from the Appendix:

\[
\Omega_{ij}(\hat{n}) = \frac{\delta_{ij}}{d_j} - \frac{v_i v_j}{d_i d_j} (1 + \sum_{k=1}^{3} \frac{v_k^2}{d_k})^{-1}.
\] (27)

The tensorial kernel \( B_{\alpha\beta} \) then reads

\[
B_{\alpha\beta}(\hat{n}) = \beta_{\alpha\beta} - \theta_{\alpha} \theta_{\beta} (1 + \sum_{k=1}^{3} \frac{v_k^2}{d_k})^{-1},
\] (28)
where
\[
\begin{align*}
\theta_1 &= \dot{n}_1 v_1 / d_1, \quad \theta_2 = \dot{n}_2 v_2 / d_2, \quad \theta_3 = \dot{n}_3 v_3 / d_3, \\
\theta_4 &= \dot{n}_2 v_3 / d_3 + \dot{n}_3 v_2 / d_2, \\
\theta_5 &= \dot{n}_1 v_3 / d_3 + \dot{n}_3 v_1 / d_1, \\
\theta_6 &= \dot{n}_2 v_1 / d_1 + \dot{n}_1 v_2 / d_2,
\end{align*}
\]
(29)

modifies the eq. (4.16) used in Ref. 3 for cubic crystals and the components of the \( \{ \beta_{\alpha \beta} \} \) tensor
\[
\left(\begin{array}{cccc}
\dot{n}_1^2 & 0 & 0 & 0 \\
0 & \dot{n}_2^2 & 0 & 0 \\
0 & 0 & \dot{n}_3^2 & 0 \\
\dot{n}_2 \dot{n}_3 & 0 & 0 & \dot{n}_1^2 \\
\end{array}\right)
\]
(30)
as a function of \( d_i \) simply coincide with those given previously for cubic crystals in eq. (4.15) of Ref. 3.

Let us note that in the rare cases when some of denominators in Eqs. (25) would become zero or negative, the method works equally well, it is sufficient to modify these equations in order to express the Christoffel matrix in the form assumed in Appendix.

IV. BASIC ELECTROSTRICTION IN CRYSTAL OF ARBITRARY SYMMETRY CLASS

In this section, we will assume that the electrostrictive tensile stress \( g_{ij} \) is a bilinear form of polarization components :
\[
g_{ij}(x) = g_{ijkl} P_k(x) P_l(x),
\]
(31)
where \( g_{ijkl} \) is the usual electrostrictive tensor, symmetric both in the first and second pair of indexes. In all crystal symmetry classes, at least some of the components are nonzero. Since it is also the lowest order term in nonpiezoelectric materials, most of the phenomenological models are limited just to that term. In this case, it is convenient to introduce an autocorrelation tensor \( Y_{ij}(k) \)
\[
Y_{ij}(k) = \langle P_i(x) P_j(x) \exp(-i k x) \rangle,
\]
(32)
which is nothing else but convolution of corresponding Fourier components of the polarization field
\[
Y_{ij}(k) = \sum_{k'} P_i(k') P_j(k - k').
\]
(33)
The heterogeneous effective energy term \( F_{\text{het}} \) then read,
\[
F_{\text{het}} = -\frac{V}{2} \sum_{k \neq 0} Y_{\alpha}(k) A_{\alpha \beta}(\hat{n}) Y_{\beta}(-k),
\]
(34)
where \( A_{\alpha \beta}(\hat{n}) = g_{\alpha \beta} B_{\beta r}(\hat{n}) g_{r \delta} \) now depends on both elastic and electrostrictive material constants.

Let us now assume that the sample contains a single planar domain wall perpendicular to a fixed direction \( \hat{n}_0 \). Then, we can keep only \( P_i(k) \) and \( Y_{\alpha}(k) \) with \( k \parallel \hat{n}_0 \) so that \( A_{\alpha \beta}(\hat{n}) = A_{\alpha \beta}(\hat{n}_0) \) can be taken in front of the summation symbol in Eq. (34).
\[
F_{\text{het}} = -\frac{V}{2} A_{\alpha \beta}(\hat{n}_0) \left[ \sum_k Y_{\alpha}(k) Y_{\beta}(k) - Y_{\alpha}(0) Y_{\beta}(0) \right].
\]
(35)
Let us further assume, for example, a 180° domain wall with \( P_1, P_3 = 0 \), so that only \( Y_2(k) \) contributes. The Einstein summation in the above expression then reduces to a single term
\[
F_{\text{het}} = -\frac{V}{2} A_{22}(\hat{n}_0) \left[ \langle P_1^4 \rangle - \langle P_1^2 \rangle^2 \right],
\]
(36)
where \( \langle \rangle \) stands for the spatial average as defined in Eq. (8).

Since the polarization field comes in Eq. (34) via spatial mean square deviation of \( P_2^2 \), it is apparent that the nonzero contributions to \( F_{\text{het}} \) comes only from the region in the vicinity of the domain wall. Our example thus allows to give a clear interpretation to the \( A_{5,3}(\hat{n}_0) \) tensor function. For a fixed domain wall profile, its angular dependence defines, how the electrostrictive reduction of domain wall energy varies with domain wall orientation \( \hat{n}_0 \), and its tensorial components distinguish various type of domain walls according to the associated change in polarization direction. Obviously, in a well-coarsened domain pattern, where the polarization inhomogeneities are limited to the domain wall regions, the \( F_{\text{het}} \) become again effectively local functional, but depending on density, type and orientation of domain walls.

Incommensurate structures with modulated polarization represent another transparent case of 1D inhomogeneity where Eq. (35) holds. Actually, it was shown that the \( F_{\text{rel}} \) term is essential for explanation of the dielectric anomalies of incommensurate ferroelectric NaNO\(_2\). In the ideal case of uniaxial sinusoidal modulation with \( P_1, P_3 = 0 \) and wave vector \( \mathbf{k}_0 \parallel \hat{n}_0 \), there is only a single nonzero pair of Fourier components of polarization \( \{ P_2(\mathbf{k}_0), P_2(-\mathbf{k}_0) \} \) so that
\[
F_{\text{het}} = -V A_{2,2}(\hat{n}_0) [P_1(\mathbf{k}_0) P_1(-\mathbf{k}_0)]^2 ,
\]
(37)
As noted previously, this expression does not depend explicitly on modulation wave vector, and thus it does not vanish in \( \mathbf{k}_0 \to 0 \) limit. In fact, this observation is not so surprising in the present context, since it follows from the fact that the volume ratio between “domain walls” and “domains” is fixed by sinusoidal profile of the modulation. Naturally, if one assumes that with decreasing \( \mathbf{k}_0 \) the modulation becomes of a more and more “rectangular” shape, the “gap” between the energy of homogeneous and modulated ferroelectric would vanish in \( \mathbf{k}_0 \to 0 \) limit.

Finally, let us note that in the case of 1D inhomogeneity with a fixed direction \( \hat{n}_0 \), the first term on the right hand side of Eqs. (35) and (36) can be actually interpreted as a local term, merely renormalizing 4-th order terms in the Landau-Devonshire potential \( F_L \). At the same time, the second term, although non-local, depends on polarization in the same way as the \( F_{\text{hom}} \).

V. GRADIENT ELECTROSTRICTION

Since the elastostatic Green function tensor technique described in section II was developed for dealing with inhomogeneous polarization configurations, it is natural to include in the free energy expansion terms depending on spatial derivations of polarization. In principle, consistent free energy expansion may require such terms not only in the expansion of \( F_0 \), but also in the expansion of \( F_1 \). Thus, instead of Eq. (35), one may need to assume (in a crystal with centrosymmetric paraelectric phase):
\[
g_{ij} = q_{ijkl} P_k P_l + r_{ijkl} \frac{\partial P_k}{\partial x_i} + s_{ijklmn} \frac{\partial P_k}{\partial x_i} \frac{\partial P_m}{\partial x_n} + \ldots
\]
(38)
Let us demonstrate the role of this gradient electrostriction terms in the case of uniaxial \((P_1, P_3 = 0)\) ferroelectric with orthorhombic paraelectric phase. Due to the choice of easy polarization direction and the obvious symmetry constraints, all nonzero terms in \( g_{ij}(\mathbf{x}) \) expansion up to the second order in \( P = P_2 \) and \( P_j = \partial P/\partial x_j \) can be easily enumerated and conveniently expressed using Voigt notation:
\[
g_1 = q_{12} P^2 + r_{12} P_2 + s_{12} P_2^2 ,
g_2 = q_{22} P^2 + r_{22} P_2 + s_{22} P_2^2 ,
g_3 = q_{32} P^2 + r_{32} P_2 + s_{32} P_2^2 ,
g_4 = r_{44} P_3 + s_{44} P_3 P_2 ,
g_5 = s_{564} P_3 P_3 ,
g_6 = s_{66} P_1 + s_{66} P_1 P_2 .
\]
(39)
The Fourier components \( g_{\alpha}(\mathbf{k}) \) then read
\[
g_1(\mathbf{k}) = (q_{12} - s_{12} k_2^2) Y(\mathbf{k}) - i r_{12} k_2 P(\mathbf{k}) ,
g_2(\mathbf{k}) = (q_{22} - s_{22} k_2^2) Y(\mathbf{k}) - i r_{22} k_2 P(\mathbf{k}) ,
g_3(\mathbf{k}) = (q_{32} - s_{32} k_2^2) Y(\mathbf{k}) - i r_{32} k_2 P(\mathbf{k}) ,
g_4(\mathbf{k}) = - i r_{44} k_3 P(\mathbf{k}) - s_{44} k_3 k_2 Y(\mathbf{k}) ,
g_5(\mathbf{k}) = - s_{564} k_1 k_3 Y(\mathbf{k}) ,
g_6(\mathbf{k}) = - i r_{66} k_1 P(\mathbf{k}) - s_{66} k_1 k_2 Y(\mathbf{k}) ,
\]
(40)
where we have used autocorrelation tensor component $Y(\mathbf{k}) = Y_2(\mathbf{k})$ defined previously in Eq. (32).

The effective interaction $F_{\text{het}}$ can be now evaluated from Eq. (42). Let us examine the case of 1D inhomogeneity where only $P(\mathbf{k})$ with $\mathbf{k} \parallel \mathbf{n}_1$ parallel to the crystallographic axis $x_1$ is nonzero. Then, the only nonzero components of the $B_{\alpha\beta}(\mathbf{n}_1)$ tensorial kernel (Eq. (28)) are

$$B_{11}(\mathbf{n}_1) = \frac{1}{C_{11}}, \quad B_{55}(\mathbf{n}_1) = \frac{1}{C_{55}}, \quad B_{66}(\mathbf{n}_1) = \frac{1}{C_{66}},$$

(41)

and the $F_{\text{het}}$ then reduces to sum of two terms

$$F_{\text{het}1} = -\frac{V}{2} \sum_{k_1 \neq 0} \left( \frac{q_{12} - s_{12}k_1^2}{C_{11}} \right) Y(k_1)Y(-k_1),$$

(42)

and

$$F_{\text{het}2} = -\frac{V}{2} \sum_{k_1 \neq 0} \frac{r_{66}^2 k_1^2}{C_{66}} P(k_1)P(-k_1).$$

(43)

The first term has the same form as the expression in Eq. (44), except for the fact that the $s_{\alpha\beta\gamma}$ coupling makes the generalized $A_{\alpha\beta}$ tensor dependent also on the modulus of the $\mathbf{k}$ vector. Therefore, the $s_{\alpha\beta\gamma}$ tensor terms in Eq. (38) can be safely neglected (unless the problem under study is drastically sensitive to the inhomogeneity lengthscale, as for example at lock-in phase transition in type-II incommensurate systems).

The second term given by Eq. (44) can be straightforwardly transformed to

$$F_{\text{het}2} = -\frac{1}{2} \frac{r_{66}^2}{C_{66}} \int_V \left( \frac{\partial P(\mathbf{x})}{\partial x_1} \right)^2 \, d\mathbf{x},$$

(44)

so that it is apparent that this term renormalize the coefficient of the lowest order gradient term in the “Ginzburg part” $f_C$ of the free-energy expansion (Eq. (1)). The experimental studies of bilinear coupling between soft mode and acoustic branches by Brillouin and inelastic neutron scattering techniques show that the $r_{ijkl}$ coupling term in Eq. (38) may indeed cause an important renormalization of the Ginzburg term. Probably, more pronounced effects are expected in crystals with a small Ginzburg term. It is even believed that in some crystals this gradient electrostriction compensate the Ginzburg term completely what leads to the appearance of incommensurate modulated structure.

Unfortunately, in the general 3D case, the effect of the the $r_{ijkl}$ coupling term does not reduce to a simple renormalization of coefficients in the Ginzburg free energy and the full anisotropy of $B_{\alpha\beta}(\mathbf{n})$ tensorial kernel should be taken into account.

VI. CONCLUSION

The presented elastostatic Green function tensor technique concerns with the simulation of the ferroelectric domain pattern being a cutting edge problem both in theory of phase transitions and technological applications. We have found that this technique, applied recently to electrostriction in ferroelectrics with a cubic paraelectric phase can be straightforwardly generalized to hexagonal and orthorhombic crystals. The contribution of this approach is most valuable for orthorhombic crystals since they are far from isotropy and the closed formulas for elastostatic Green functions are known only for a few very special limit cases. Unfortunately, the method outlined here is not very convenient for tetragonal, trigonal and monoclinic symmetries since the $\mathbf{v}$ vector used in decomposition of the Christoffel matrix would have nontrivial angular dependence. We are not aware of any elegant method for inversion of Christoffel matrix in such cases.

The essential effect of the nonlocal, nonlinear and anisotropic effective interaction term $F_{\text{het}}$ consists in reduction of domain wall energies in function of their orientation and the associated change of polarization vector. This information is conveniently contained in the tensor $A_{\alpha\beta}(\mathbf{n})$ introduced in Eq. (14). Polar diagrams of the $A_{\alpha\beta}(\mathbf{n})$ tensorial components may thus be quite instructive for understanding the behavior of a particular system.

Finally, the bilinear coupling between the polarization gradients and elastic strain should not be overlooked in the realistic simulations. The values of the corresponding tensorial coefficients $r_{ijkl}$ can be determined for example with the help Brillouin and inelastic neutron scattering techniques.

APPENDIX

Let us suppose that a finite regular real symmetrical matrix $A$ can be written sum of a diagonal part $D$ and a real multiple of a tensorial (dyadic) square $v \otimes v$ of a real vector $v$ as

$$A_{ij} = (D + \lambda v \otimes v)_{ij} = d_j \delta_{ij} + \lambda v_i v_j,$$

where $\lambda$ is real. Let $w_i \equiv v_i / d_i$. Then, the matrix inverse to $A$ reads

$$A^{-1} = D^{-1} - \frac{\lambda w \otimes w}{1 + \lambda v \cdot w},$$

provided that the right hand side of Eq. (46) exists. This can be easily proven by multiplication of expression in Eq. (45) and Eq. (46).

In the case of orthorhombic, hexagonal and cubic crystals, the above result allows to find compact explicit expressions for the corresponding elastostatic Green function tensors. For example in Eqs. (21) and (27), we have applied the Eq. (46) with $\lambda = 1$.
