We present an exhaustive study of Andreev crystals (ACs) – quasi-one-dimensional superconducting wires with a periodic distribution of magnetic regions. The exchange field in these regions is assumed to be much smaller than the Fermi energy. Hence, the transport through the magnetic region can be described within the quasiclassical approximation. In the first part of the paper, by assuming that the separation between the magnetic regions is larger than the coherence length, we derive the effective nearest-neighbour tight-binding equations for ACs with a helical magnetic configuration. The spectrum within the gap of the host superconductor shows a pair of energy-symmetric bands. By increasing the strength of the magnetic impurities in ferromagnetic ACs, these bands cross without interacting. However, in any other helical configuration, there is a value of the magnetic strength at which the bands touch each other, forming a Dirac point. Further increase of the magnetic strength leads to a system with an inverted gap. We study junctions between ACs with inverted spectrum and show that junctions between (anti)ferromagnetic ACs (always) never exhibit bound states at the interface. In the second part, we extend our analysis beyond the nearest-neighbour approximation by solving the Eilenberger equation for infinite and junctions between semi-infinite ACs with collinear magnetization. From the obtained quasiclassical Green functions, we compute the local density of states and the local spin polarization in anti- and ferromagnetic ACs. We show that these junctions may exhibit bound states at the interface and fractionalization of the surface spin polarization.

I. INTRODUCTION

Magnetic defects and regions in a superconductor may lead to bound states that strongly change the local spectrum.1–3 When the magnetic exchange coupling is larger than the Fermi energy and the size of the magnetic region is small compared to the superconducting coherence length, a pair of non-degenerate states with opposite energies appear inside the superconducting gap. These are the so-called Yu-Shiba-Rusinov (YSR) states.1–3 In contrast, if the exchange coupling is small compared to the Fermi energy, μ, a pair of degenerate bound states appear.2,3 The origin of such degeneracy can be understood from a semiclassical perspective: electrons at the Fermi level traveling through the magnetic region are not back-scattered, but they accumulate a phase, Φ. This phase has the opposite sign for electrons/holes and spin up/down. This results in double-degenerate bound states formed by electrons from the Fermi valleys at either +kF or −kF (see Fig. 1A). In a normal metal, the phase accumulated can be gauged out. In contrast, if the host material is a superconductor, the Andreev reflection at the semiclassical impurities leads to the coupling between electrons and holes at the same Fermi valley. This mechanism leads to Andreev bound states inside the superconducting gap. The crossover from the YSR to Andreev limit has been studied in detail in Ref.12.

In a periodic arrangement of magnetic impurities, as for example a chain, the single-impurity bound states hybridize and form bands within the superconducting gap. Such bands have been widely studied for atomic-sized magnetic impurities.11–22 The hybridization of YSR states can lead to topological phases which host Majorana bound states at the ends of the impurity chain. In Ref.22 we proposed the analog of such atomic chains in a mesoscopic structure with lateral dimensions smaller than the superconducting coherence length, ξ0. The magnetic impurities are replaced by semiclassical magnetic regions realized, for example, by the contact to magnetic materials (see the sketch in Fig. 1B). Mesoscopic structures involving superconductors and ferromagnetic materials have been extensively studied, mainly in the diffusive limit, in the context of superconducting spintronics.24–31 Our focus here is from a very different perspective. We consider clean superconducting wires with a periodic array of magnetic regions as a mesoscopic realization of crystals, which we call Andreev crystals (ACs).

Specifically, in this article we present the general theory of ACs, including non-collinear magnetization orientation and arbitrary separation between the magnetic impurities. In a first part we consider chains of impurities with non-collinear magnetization where the magnetic regions are separated by a distance a ≳ ξ0. We solve the nearest-neighbours tight-binding equations of helical ACs, where the exchange field rotates a constant angle 2α.
around a fixed axis between subsequent magnetic impurities, whereas their strength remains constant, $\Phi$. The spectrum of helical ACs for energies within the superconducting gap, $|\epsilon| < |\Delta|$, shows a pair of Andreev bands with symmetric energy with respect to the Fermi level. In ferromagnetic configurations ($\sin \alpha = 0$) the Andreev bands cross without interacting, closing the gap in a finite range of $\Phi$ values around half-integer values of $\Phi/\pi$. Otherwise, the Andreev bands touch each other only at half-integer values of $\Phi/\pi$ forming a Dirac point. In junctions between semi-infinite helical ACs where the rotation, $\alpha$, remains constant all along the chain and the magnetic phase changes from $\Phi_L$ to $\Phi_R$ at the left and right sides of the junction, respectively, states bounded to the interface may appear when $\text{sign}(\tan \Phi_L) \neq \text{sign}(\tan \Phi_R)$. We refer to the junctions fulfilling this condition as inverted junctions of ACs and they maintain similarities with Dirac system with a spatial mass inversion. We show that inverted junctions of (anti)ferromagnetic ACs (always) never support interfacial states and that the range of parameters, $\Phi_{L(R)}$, for which the bound states appear increases as the rotation approaches an antiferromagnetic ordering (i.e., with decreasing value of $|\cos \alpha|$).

In a second part, we present exact calculations of the spectral properties of (anti)ferromagnetic ACs and junctions beyond the tight-binding approximation used in previous works. Specifically, we solve the Eilenberger equation and obtain the quasiclassical Green’s functions (GFs) in different situations. The magnetic regions are described by effective boundary conditions that take into account the spin-dependent jump of the phase, $\Phi$. On the one hand, our solution provides the exact energy and spatial distribution of the density of states and spin polarization of the system. On the other hand, our results demonstrate the validity of the first neighbours’ tight-binding approximation regarding the gap closing in infinite antiferromagnetic ACs at half-integer values of $\Phi/\pi$, the appearance of a pair of states bounded to the interface between two antiferromagnetic ACs with inverted gaps, and the fractionalization of the surface spin polarization in such junctions.

This article is organized as follows: in Sec. II we introduce the model Hamiltonian and the main equations used for the nearest-neighbours tight-binding model (Sec. II A), and the Eilenberger GFs (Sec. II B). In Sec. III we solve the nearest-neighbours tight-binding equations of infinite and junctions between semi-infinite helical ACs, i.e., ACs where the exchange field of the semiclassical impurities form an helix along the wire. In Sec. IV we focus on ACs where the exchange field of all the impurities is collinear. In particular, we solve the Eilenberger equation to obtain the quasiclassical GF of ACs with magnetic impurities following (Sec. IV A) ferromagnetic and (Sec. IV B) antiferromagnetic ordering. In Sec. IV C we present the method to solve the Eilenberger equation in junctions between semi-infinite collinear ACs and we apply it to obtain the quasiclassical GFs in junctions between anti-ferromagnetic ACs. Finally, in Sec. V we summarize the main results of the paper.

II. THE MODEL AND MAIN EQUATIONS

We consider a superconducting wire of lateral dimensions much smaller than the superconducting coherence length, $\xi_0$. The wire contains magnetic regions located at the points $X_n = na$, where $a$ is the separation between the impurities and $n$ is the impurity index. We assume that the width of the magnetic regions, $d$ is larger than $k_0^{-1}$ and hence can be considered within the semiclassical approach. In addition, we also assume that $d \ll \xi_0$ such that we can treat the magnetic regions as point-like impurities, in the semiclassical scale, with a polarization strength and direction proportional to the corresponding SU(2) magnetic phase

$$\sigma \cdot \Phi_n = \frac{1}{\hbar v_F} \int dx \sigma \cdot h_n(x).$$

Here, $v_F$ is the Fermi velocity, and $h_n(x)$ is the exchange field vector induced by the $n$-th impurity which is assumed to be parallel to the local magnetization of the magnetic region. The Bogoliubov-de Gennes (BdG) Hamiltonian describing the AC reads

$$\hat{H}_{\text{bdg}}^n(x) = -i\hbar v_F \tau_3 \partial_x + \tau_1 \Delta - \hbar v_F \sum_n \sigma \cdot \Phi_n \delta(x - X_n),$$

\[ \text{(2)} \]
where \( \hat{\tau}_i \) are the Pauli matrices spanning the Nambu space (i.e. the electron-hole space), \( \hat{\sigma} \equiv (\hat{\sigma}_1, \hat{\sigma}_2, \hat{\sigma}_3) \) stands for the vector of Pauli matrices that span the spin space and \( \eta = \pm \) refers to the two electron-hole valleys at \( \pm k_F \) (see Fig. 4]). A distinctive feature of semiclassical impurities is that they do not trigger back-scattering processes. This allows us to treat the two Fermi valleys separately and to drop the \( \eta \) index. In the (first order) BdG equation, Eq. (3), the delta functions describe the boundary conditions within the semiclassical approach. Namely, they describe the phase gained by a quasiparticle when it traverses the magnetic region [see Eq. (6) below].

The solution of the BdG equations provides all the spectral information about the crystal. As it will be shown in Sec. II A one can solve this problem analytically under the assumption that magnetic impurities are weakly coupled to each other, \( e^{-a/\xi_0} \ll 1 \). In this limit the system can be described by an effective tight-binding model which provide the spectrum of this system. A drawback of this approach is that to compute observable quantities, such as the local density of states or the local spin density, one has to perform explicit summation over the Bloch momentum. Indeed, for calculation of observables it is more convenient to use the quasiclassical Eilenberger equation\(^{[38]}\). This formalism is presented in Sec. II B. Specifically, we show how to obtain exact analytical expressions for the quasiclassical Green’s functions (GFs) of periodic ACs, and how to access to observables in a rather simple way. Thus, both formalisms presented in Secs. II A and II B are complementary and provides a full description of ACs.

### A. Tight-binding equations

To obtain the spectral properties of an AC one needs to solve the BdG equations,

\[
\hat{H}_{BdG}(x)\hat{\Psi}(x) = \epsilon \hat{\Psi}(x),
\]

where \( \hat{H}_{BdG}(x) \) is the Hamiltonian, Eq. (2), and \( \hat{\Psi}(x) \) is a 4-component spinor in the Nambu\( \times \)spin space. The general solution of Eq. (3) in the region between two neighbouring impurities, \( X_n < x < X_{n+1} \), reads

\[
\hat{\Psi}(x) = B^+_{n+1} e^{\frac{x-x_{n+1}}{\xi}} |+\rangle + B^-_{n} e^{-\frac{x-x_n}{\xi}} |-\rangle.
\]

Here \( \xi \equiv \frac{\hbar v_F}{e} \) is the superconducting coherence length, \( B^+_{n} \) is a 2-component spinor (covering the spin space) that contains the amplitudes of the contributions to the wavefunction that decays from the \( n \)-th impurity into the left (right), and

\[
|\pm\rangle = \frac{e^{\pm i\theta/2}}{\sqrt{2\cos \theta}} \left( \begin{array}{c} 1 \\ \pm i e^{\mp i\theta} \end{array} \right),
\]

are 2-component spinors in the Nambu space, where \( e^{i\theta} = \sqrt{\Delta^2 + \epsilon^2} / \Delta \) is the Andreev factor. Direct product is assumed between the spinors in Nambu and spin spaces.

Within the semiclassical limit, quasiparticles traveling through the \( n \)-th semiclassical impurity do not backscatter, but pick up a phase according to:

\[
\hat{\Psi}(X^n R) = e^{i\tau_n \hat{\sigma} \cdot \Phi_n} \hat{\Psi}(X^n L).
\]

because of \( \tau_3 \) and \( \hat{\sigma} \cdot \Phi_n \), the sign of the accumulated phase is different for electron/holes and spin up/down quasiparticles along the exchange field direction, respectively. Applying these boundary conditions to the general wavefunction in Eq. (6) we obtain the equations for the \( B^\pm \) coefficients, which can be recast into an effective tight-binding model by keeping terms up to first order in \( e^{-a/\xi} \). In particular, in the limit where \( e^{-a/\xi} \ll 1 \), coefficients \( B_n^\pm \) at each site \( n \) can be related to their counterparts, \( B_n^\pm \), as follows:

\[
B^-_n = i \hat{\sigma}_n \frac{\Delta \sin \Phi_n}{\sqrt{\Delta^2 - \epsilon^2}} B^+_n,
\]

where \( \Phi_n \equiv |\Phi_n| \) is the strength of the magnetic phase vector, and we define \( \hat{\sigma}_n \equiv \frac{\Phi_n}{|\Phi_n|} \). It is convenient to introduce the re-scaled coefficients, \( b'_n \equiv \hat{\sigma}_n \sin \Phi_n B^+_n \), which satisfy a tight-binding-like equation

\[
\left( \omega - \hat{\sigma}_n \omega_n \right) b'_n = \hat{\sigma}_{n+1} b'_{n+1} + \hat{\sigma}_n t_n b'_{n-1}.
\]

Here \( \omega \equiv \frac{\epsilon}{\sqrt{\Delta^2 - \epsilon^2}}, \hat{t}_n \equiv -\frac{e^{-a/\xi}}{\sin \Phi_n} \) is the hopping amplitude, and \( \omega_n = \frac{\cos \Phi_n}{\sin \Phi_n} \) is the value of the function \( \omega \) evaluated at the bound state energy in the \( n \)-th impurity, \( \epsilon_n = |\sin \Phi_n| \). In principle, Eq. (8) describes an arbitrary AC with lattice constant \( a \). In Ref.\(^{[38]}\) it was solved for collinear magnetization of the impurities. In Sec. III we analyze helical ACs composed by identical magnetic impurities with an spatially rotating magnetization, forming a helix in the \( y-z \) plane.

### B. Eilenberger equation

Because of its simplicity, the tight-binding formulation, Eq. (6), is very useful for describing the spectral properties of ACs. However, one should bear in mind that it has been derived within first-neighbours approximation, and therefore it is valid as long as \( e^{a/\xi} \ll 1 \). To go beyond this approximation we introduce here the Eilenberger equation\(^{[38]}\) from which we can determine the quasiclassical Green’s functions (GFs).

We focus again on point-like semiclassical magnetic impurities. The Eilenberger equation in the regions between the impurities has a simple form:

\[
\hbar v_F \partial_x \hat{g}(x) - \left[ i e \hat{\tau}_3 + \Delta \hat{\tau}_2, \hat{g}(x) \right] = 0.
\]

Here \( \hat{g}(x) \) is the quasiclassical Green’s function (GF), which is a 4\( \times \)4 matrix in the Nambu\( \times \)spin space that satisfies the normalization condition, \( \hat{g}^2 = 1 \). The square brackets stand for the commutation operation. \( \Delta \) is the
superconducting gap, which is assumed to be constant along the superconducting wire. Solving Eq. (9) we obtain the propagation of the GF along the superconducting region,
\[ \hat{g}(x) = \hat{u}(x - x_0)\hat{g}(x_0)\hat{u}(x_0 - x), \]
where the propagator reads,
\[ \hat{u}(x - x_0) = \hat{P}_x e^{i(x-x_0)/\xi} + \hat{P}_e^{-i(x-x_0)/\xi}. \] (11)
Here \( \hat{P}_x \equiv |\pm\rangle \langle \pm| \) are two orthogonal projectors that span the Nambu space, \( |\pm\rangle \) are the basis column vectors of Eq. (5) and
\[ \langle \pm| \equiv \frac{e^{\pm i\theta/2}}{\sqrt{2} \cos \theta} \left( 1 \mp i e^{\mp \theta} \right), \] (12)
are the co-basis row vectors orthonormal to \( |\pm\rangle \).

The inverse of the propagator in Eq. (11) fulfills the relation
\[ \langle \pm| \hat{u}(x) \hat{u}(x') |\pm\rangle = 1, \]
where \( \hat{u}(x) = \hat{\tau}_3 \hat{g}(x) \hat{\tau}_3 \) is the local spin density.

III. HELICAL ANDREEV CRYSTALS

In this section, we study the spectral properties of ACs with a periodic rotation of the magnetization of the magnetic impurities. For this sake, we use the tight-binding approach introduced in Sec. II A. In particular, we focus on an AC consisting of identical magnetic impurities whose magnetization is in the \( y-z \) plane and rotates by a constant angle, \( 2\alpha \) around the \( x \)-axis (see Fig. 1). The magnetic phase vector describing this situation is given by
\[ \hat{\sigma}_n \cdot \hat{\Phi}_n = \Phi e^{-i\xi \alpha n} \hat{\sigma}_3 e^{i\xi \alpha n}, \] (17)
where \( \Phi \) is the strength of the magnetic phase. Its strength is the same in all the impurities. Substituting this expression into Eq. (8) we obtain that
\[ \omega = e^{i\xi \alpha n} \hat{\sigma}_3 \hat{\Phi}_n b_n = \hat{\sigma}_3 \left( b_{n+1} + b_{n-1} \right), \] (18)
where we have defined the coefficients \( b_n \equiv e^{i\xi \alpha (n+\frac{1}{2})} b'_n \). Here \( \omega_0 = \frac{\cos \Phi}{\sin \Phi} \) stands for the energy of the single-impurity levels and \( t = -\frac{e^{-\xi/\xi}}{\sin \Phi} \) is the hopping amplitude. After this redefinition of the coefficients, Eq. (18) reduces to the typical tight-binding system of identical equations, whose solution reads \( b_n = b e^{1/k a} \) and 
\[ \omega = \pm \sqrt{\omega_0^2 \sin^2 \alpha + (\omega_0 \cos \alpha + 2t \cos ka)^2}. \] Here \( k \) is the Bloch momentum, and the spinors \( b \), are obtained from Eq. (18). The Andreev bands are defined by
\[ \frac{\epsilon}{\Delta} = \pm \sqrt{\omega_0^2 \sin^2 \alpha + (\omega_0 \cos \alpha + 2t \cos ka)^2} / (1 + \omega_0^2 \sin^2 \alpha + (\omega_0 \cos \alpha + 2t \cos ka)^2), \] (19)
where \( \epsilon \) has to be evaluated at the energy of the single-impurity level \( \omega_0 \). In Fig. 2a and 2b we show the subgap spectrum of ACs with different values of \( \Phi \) and \( \alpha \). At \( \Phi = 0 \), no bound states appear, and hence there are no Andreev bands. Increasing \( \Phi \), a pair of bands emerge from the coherent peaks and start moving towards the Fermi level, up to a point around \( \Phi = \pi/2 \) where they touch each other, forming a gapless phase. Further increase of \( \Phi \) leads to a gap reopening with inverted Andreev bands. The latter merge with the continuum spectrum at \( \Phi = \pi \). Interestingly, the bands’ inversion also happens when they merge into the continuum and reenter the superconducting gap at \( \Phi = l\pi \), where \( l \) is an integer. Consequently, the spectrum of these ACs is \( \pi \) periodic in \( \Phi \).

As can be seen from the energy spectrum of the bands, Eq. (19), the gap closes only at half-integer values of \( \Phi/2 \).
forming a Dirac point at $ka = \pi/2$ in ACs with any value of $\alpha$ except in those where $\sin \alpha = 0$. This situation corresponds to ferromagnetic ACs, where each of the Andreev bands corresponds to opposite spin species, and hence they do not interact while crossing.

In Ref. [23] it was shown that a junction between two antiferromagnetic ACs with inverted gaps presents states bounded do the interface. This corresponds to the situation where $\cos \alpha = 0$ all along the structure and the sign of $\omega_0$ changes across the junction. It becomes interesting, then, to study if those bound states survive for arbitrary values of $\alpha$. To do so, we consider a junction between two different chains where the rotation parameter between the impurities remains constant, $\alpha$, but their magnetic phases change from the AC on the left, $\Phi_L$, to the one on the right $\Phi_R$. The tight-binding equations of such a system read

$$\left[\omega - e^{i\pi \mathcal{S} \omega_0 \mathcal{L}} \beta_n \right] b_n = \beta_{n+1} + 3 \beta_n b_{n-1}, \quad (20)$$

where $\omega_0$ and $t_n$ are defined below Eq. (8). The magnetic phase is $\Phi_L$ for $n < 0$ and $\Phi_R$ for $n \geq 0$. We can write for the left and right ACs, $b_n = b_{L} + e^{-i\pi \mathcal{L} \Phi_L(n)} + b_{R} - e^{i\pi \mathcal{L} \Phi_R(n)}$, respectively, where $q_{\Phi_L(R)}(n)$ is determined by the solution of the eigenvalue equation, Eq. (20), with positive imaginary part:

$$\cos q_{\Phi_L(R)}(n) = \frac{-\omega_0 \alpha \cos \pm i \sqrt{\omega_0 \alpha^2 - \omega^2}}{2(\omega_0 \alpha^2 - \omega^2)}. \quad (21)$$

According to this expression, bound states can only appear at energies with $\omega^2 < \omega_0 \alpha^2$, i.e., at energies within the gap formed by the Andreev bands of both ACs [c.f Eq. (19)]. The corresponding eigenvectors are given by

$$b_{L(R)}(n) = \left( \frac{1}{i e^{\pm i \gamma_{\Phi_L(R)}}} \right) \omega_0 \alpha^2,$$

where

$$\omega_{\Phi_L(R)}^2 = \frac{\omega_0^2 \alpha^2}{\omega_0 \alpha^2 - \omega^2}. \quad (23)$$

From the above results we find that bound states exist for those energies satisfying following determinant equation:

$$\begin{vmatrix}
    t_L & t_L e^{i\gamma_L} & t_R & t_R e^{-i\gamma_R} \\
    t_L e^{-i\gamma_L} & e^{i\gamma_L} & t_R e^{i\gamma_R} & e^{i\gamma_R} \\
    t_R e^{-i\gamma_R} & e^{-i\gamma_R} & t_R e^{-i\gamma_R} & e^{-i\gamma_R} \\
    e^{i\gamma_L} e^{i\gamma_R} & e^{i\gamma_L} & e^{-i\gamma_R} & e^{-i\gamma_R} \\
\end{vmatrix} = 0. \quad (24)$$

One can check that this equation has solutions only when

$$\text{sign}(\omega_0) = -\text{sign}(\omega_0 R).$$

Therefore, the bound states can only appear in junctions between ACs with inverted gaps. This is a necessary but not sufficient condition. Namely, the presence of the interface state in inverted junctions depends on the magnetic rotation along the crystal described by $\alpha$; whereas for antiferromagnetic alignment of the impurities ($\cos \alpha = 0$) the interface state appears in any inverted junction, for ferromagnetic ACs ($\sin \alpha = 0$) it never does. For any other value of $\alpha$ the existence of the bound state depends on $\Phi_L$ and $\Phi_R$ as explained below.

The determinant equation, Eq. (24), can be reduced to a compact equation in the anti-symmetric configuration with $\Phi_R = -\Phi_L$. In this situation we can define $\gamma_L = \gamma_R$ and $q_{\Phi_L(R)}(n) = (\pm \gamma + i n), \lambda$, where $k$ and $\lambda$ are real numbers determined by Eq. (21). For $\lambda > 0$, the condition for the existence of the bound state reads

$$\sin^2 \gamma \cosh^2 \lambda - \sin^2 \kappa = 0. \quad (25)$$
In Fig. 3 we show the dependence of the positive energy bound states with $\alpha$ in anti-symmetric junctions of ACs with fixed value of $a = 2\xi_0$ and different strengths of the magnetic impurities, $\Phi \equiv \Phi_R = -\Phi_L$. With shaded areas we show the energies within the positive-energy Andreev band is situated in the infinite AC [Eq. (19)]. The dotted lines correspond to energy values for which $\omega^2 = \omega_0^2 \sin^2 \alpha$ and they indicate the maximum possible energy of a bound state [Eq. (23)]. Close to the gap-closing point, $\cos \Phi \ll 1$, the interfacial states are present at any value of $\alpha$, excluding ferromagnetic ordering of the impurities, $\sin \alpha = 0$. As the size of the gap between the Andreev bands increases, the range of $\alpha$ values for which the pair of bound states exist shrinks around those values corresponding to an antiferromagnetic ordering of the magnetic impurities, $\cos \alpha = 0$.

The existence or not of the bound state in anti-symmetric junctions of ACs can be understood from the relative position of the maximum-energy condition for the bound state (the dotted line in Fig. 3) and the positive-energy solution of Eq. (25). When $\cos \alpha \approx 0$ the maximum-energy condition locates very close to the bottom of the Andreev band and, consequently, the $\omega$ value that solves Eq. (25) almost always fulfills that $\omega^2 < \omega_0^2 \sin^2 \alpha$. When $\sin \alpha \approx 0$, by contrast, the dotted lines in Fig. 3 approach the center of the gap, $\omega = 0$. Thus, the solution to Eq. (25) only meets the bound state existence condition, $\omega^2 < \omega_0^2 \sin^2 \alpha$, when the borders of the gap are also very close to the Fermi energy, i.e., when $\cos \Phi \approx 0$. These considerations are also applicable in general junctions between helical ACs, in which case the energy of the bound state solves Eq. (24) and its existence condition is given by $\omega^2 < \min(\omega^2_{OL}, \omega^2_{OR}) \sin^2 \alpha$.

As a summary of this section, for a given value of the rotation angle $\alpha$ we can classify ACs in two groups depending on whether an interfacial state appears upon the formation of a junction between two chains with inverted gaps. These two groups are best exemplified by (anti-)ferromagnetic ACs inverted junctions in which interfacial bound states (always) never appear. In the next section we focus on these two types of junctions and study in more detail their spatial properties.

**IV. COLLINEAR ANDREEV CRYSTALS**

In this section we extend the study of (anti-)ferromagnetic ACs beyond the first neighbours tight-binding approximation used in previous sections. To do so, we solve the Eilenberger equation to obtain the quasiclassical GFs, $\tilde{g}(x)$, following the procedure discussed in Sec. 1IB. From the knowledge of $\tilde{g}(x)$ we can obtain the local density of states and magnetization of ACs and junctions.

Specifically, we consider chains of magnetic impurities located at $X_n = na$, with an arbitrary separation between the impurities $a$. Here $n$ is an integer. We assume that all magnetizations, and hence the exchange fields, are aligned along the $z$ axis. Because of the collinear alignment of the exchange field we can treat the two spin degrees of freedom separately, $\sigma = \pm$, thus reducing the size of the GFs involved from $4 \times 4$ (in Nambu space) to $2 \times 2$ matrices in Nambu space. It follows from Eq. (10) and the normalization condition, $[\tilde{g}(x)]^2 = 1$, that within the region between two subsequent impurities, $X_n < x < X_{n+1}$, the quasiclassical GF for a single spin projection, $\sigma$, can be written in terms of two independent constants, $b_{\sigma n}$ and $c_{\sigma n}$:

$$
\hat{g}_\sigma(x) = \sqrt{1 - e^{-2a/\xi}b_{\sigma n}c_{\sigma n}g^0 + b_{\sigma n}e^{2(x-X_{n+1})/\xi} |+\rangle \langle +| + c_{\sigma n}e^{-2(x-X_n)/\xi} |\mp\rangle \langle \mp|}.
$$

Here $g^0 \equiv \hat{P}_+ - \hat{P}_- = \Delta^2 \hat{\tau}_3 + i \tau_3$ is the GF of an homogeneous BCS superconductor. Equation (26) is the representation of the GF in the basis where the BCS propagator, Eq. (11), is diagonal.

According to Eq. (13), the GFs at the left and right side of the $n$-th impurity are connected by the boundary condition

$$
\hat{g}_\sigma(X_n^R) = e^{i\sigma \tau_3 \Phi_n} \hat{g}_\sigma(X_n^L) e^{-i\sigma \tau_3 \Phi_n},
$$

where the direction to which the exchange field is pointing along the quantization axis is determined by the sign of the magnetic phase, $\Phi_n$. Ferromagnetic ACs are described by a sequence of identical magnetic impurities with associated magnetic phases of $\Phi_n = \Phi$, whereas in antiferromagnetic ACs $\Phi_n = (-1)^n \Phi$. In the next sections we study these two types of ACs and junctions between them.
Figure 4. Local density of states, $\nu_\epsilon$, of spin-up electrons in ferromagnetic ACs with different separation between and strengths of the magnetic impurities, $a$ and $\Phi$, respectively (see the title above each panel).

A. Ferromagnetic ACs

In a ferromagnetic AC the unit cell contains a single magnetic impurity, so the $\sigma$-spin projection of the chain propagator, Eq. (14), reads

$$\hat{S}_{F\sigma} \equiv \hat{u}(a)e^{i\sigma \tau_3 \Phi}. \quad (28)$$

Here $\hat{u}(a)$ is the BCS propagator given in Eq. (11). The operator $\hat{S}_{F\sigma}$ describes the propagation of the quasiclassical GF from the left side of impurity $n$ to the left side of impurity $n+1$, $\hat{g}_\sigma(X_n^L) = \hat{S}_{F\sigma}\hat{g}_\sigma(X_n^L)\hat{S}_{F\sigma}^{-1}$.

To determine the quasiclassical GF we need to obtain the parameters $b$ and $c$ in Eq. (26). The periodicity of $\hat{g}_\sigma$ over the unit cell, leads to $b_{\sigma n} = b_\sigma$ and $c_{\sigma n} = c_\sigma$. These expressions together with $\hat{S}_{F\sigma}\hat{g}_\sigma(X_n^L)\hat{S}_{F\sigma}^{-1} = \hat{g}_\sigma(X_n^L)$ result in

$$b_\sigma = c_\sigma = \frac{\frac{a}{\xi} \left( \langle | e^{i\sigma \tau_3 \Phi} | - \rangle \right)}{\sqrt{\left( \frac{\frac{a}{\xi} \left( \langle | e^{i\sigma \tau_3 \Phi} | + \rangle \right) + \frac{2}{\xi} \left( \langle | e^{i\sigma \tau_3 \Phi} | - \rangle \right) \right)^2 - 1}}. \quad (29)$$

After substitution of these values in Eq. (26) one obtains the quasiclassical GF in the magnetic regions all along the chain and, with it, the local density of states (LDOS) and the local spin density [Eqs. (15) and (16), respectively].

In Fig. 4 we show the LDOS for a single spin species of different ferromagnetic ACs, $\nu_\epsilon(\epsilon)$. The LDOS of the opposite spin species can be obtained from the relation $\nu_\epsilon(\epsilon) = \nu_{-\epsilon}(-\epsilon)$. The different panels in Fig. 4 correspond to different values of separation and strength of the magnetic impurities, $a$ and $\Phi$, respectively. Within the superconducting gap, $|\epsilon| < |\Delta|$, the position of the Andreev band depends on $\Phi$ and its width increases by decreasing $a$. For energies larger than $\Delta$ the continuum gets split by small gaps whose widths depend on $\Phi$, $a$ and the energy at which they lay. The origin of the gaps lay on the lifting of degeneracies between electronic states that differ by the reciprocal lattice vector in periodic crystals, studied in many textbooks. At integer values of $\Phi/\pi$ the small gaps at the continuum close, whereas their width is maximum for half-integer values of $\Phi/\pi$. In the same way as it happens with the Andreev band, the width of these small gaps increases with decreasing $a$. The size of the gaps reduces by increasing the energy with respect to the Fermi level.

B. Antiferromagnetic ACs

In antiferromagnetic ACs the unit cell contains two identical magnetic impurities pointing in opposite directions. The chain propagator [Eq. (14)] that describes the evolution of the GF from the left interface of one magnetic impurity to the left interface of the equivalent impurity in the next unit cell reads,

$$\hat{S}_{A\sigma} \equiv \hat{u}(a)e^{-i\sigma \tau_3 \Phi}\hat{u}(a)e^{i\sigma \tau_3 \Phi}. \quad (30)$$

The unit cell consists now of two superconducting regions with two different sets of independent parameters, namely, $b_{\sigma 0} = b_{\sigma(2n)}$, $c_{\sigma 0} = c_{\sigma(2n)}$, and $b_{\sigma 1} = b_{\sigma(2n+1)}$, $c_{\sigma 1} = c_{\sigma(2n+1)}$. Here $n$ is the impurity index. The boundary condition for the impurity located between these two superconducting sections, Eq. (27), leads to the following relation between the set of parameters:

$$b_{\sigma 1} = c_{\sigma 0}, \quad c_{\sigma 1} = b_{\sigma 0}. \quad (31)$$

Additionally, from the periodicity of the GF, $\hat{S}_{A\sigma}\hat{g}_\sigma(X_{2n}^L)\hat{S}_{A\sigma}^{-1} = \hat{g}_\sigma(X_{2n}^L)$, we obtain the expressions for

$$b_{\sigma 0} = \langle \tilde{-} | e^{i\sigma \tau_3 \Phi} | - \rangle D_\sigma, \quad (32)$$
$$c_{\sigma 0} = -\langle \tilde{+} | e^{i\sigma \tau_3 \Phi} | + \rangle D_\sigma, \quad (33)$$

where
Substitution of these expressions into Eq. (28) determines the quasiclassical GF. From it we obtain the LDOS for a single spin species shown in Fig. 5 for different values of \( \Phi \) around the gap closing point, \( \Phi = \pi/2 \). The separation between impurities is set to \( a = 2\xi_0 \). For energies within the superconducting gap a pair of Andreev bands appear at symmetric energy ranges with respect to the Fermi level. As it was predicted in previous calculations under the first-neighbours tight-binding approximation (Ref. 23 and Sec. III), these two bands touch each other only at half-integer values of \( \Phi/\pi \) closing the gap around the Fermi level (see Fig. 5). Moreover, the Andreev bands touch the continuum only when \( \Phi/\pi \) is an integer: situations where the LDOS of the antiferromagnetic AC coincides with that of a pristine superconductor because the phase difference obtained by electrons and holes after propagation across an impurity is a multiple of 2\( \pi \). Within the Andreev bands, the LDOS is larger around the position of the magnetic impurities and around the energies of the single-impurity level. For energies larger than the superconducting gap, \( |\epsilon| > |\Delta| \), we observe an interference pattern and the splitting of the continuum due to the opening of small gaps. The dependence of the width of the small gaps on \( \Phi, a \) and \( \epsilon \) is the same as the one observed in ferromagnetic ACs (see the last paragraph of Sec. IV A).

C. Junctions of collinear ACs

As discussed in Section III, inverted junctions of antiferromagnetic ACs host a pair of states bounded to the interface. Moreover, inverted of antiferromagnetic ACs may present fractionalization of the surface spin polarization per Fermi valley. In this section we show that this result holds beyond the tight-binding approximation used above, by solving the Eilenberger equation in junctions of ACs. Although we focus our analysis on junctions between antiferromagnetic ACs, the mathematical procedure presented here is general and can be applied to obtain the quasiclassical GFs in junctions between any type of collinear ACs.

We start by defining the \( \sigma \)-spin projection of the chain propagators of the left(right) ACs, \( \hat{S}_{L(R)\sigma} \), as the operator that propagates the GFs through a unit cell of the crystal, Eq. (14). The chain propagator is given by Eq. (28) in ferromagnetic and by Eq. (30) in antiferromagnetic ACs. Solving the eigenvalue problem of these operators we find a set of vectors for which the chain propagator is diagonal,

\[
\hat{S}_{L(R)\sigma} |\lambda_{L(R)\sigma}^\pm \rangle = e^{\pm \lambda_{L(R)\sigma}} |\lambda_{L(R)\sigma}^\pm \rangle .
\]

Because \( \hat{S}_{L(R)\sigma} \) is, in general, not Hermitian, the left-eigenvectors that form the co-basis

\[
(\lambda_{L(R)\sigma}^\pm | \hat{S}_{L(R)\sigma} = e^{\pm \lambda_{L(R)\sigma}} (\lambda_{L(R)\sigma}^\pm |)
\]

are not related by Hermitian conjugation to the right-eigenvectors in Eq. (35). The eigenvectors can be represented as exponentials with arguments of opposite sign because \( \det(\hat{S}_{L(R)\sigma}) = 1 \). In ferromagnetic and antiferromagnetic ACs \( \lambda_\sigma \) is purely imaginary (real) for energies where the infinite chain’s spectrum shows (does not show) states. Similarly to the description of the propagation within the superconducting region between two subsequent impurities, Eq. (10), the propagation of the spin-polarized GFs through the reference points of differ-
The transition between plateaus is rounded due to the continuity of projectors that it multiplies corresponds to the quasi-classical GF and the subtraction of impurity Andreev states, \( \omega_\parallel \), has the same sign at both sides of the junction. The spectrum exhibits a transition area around the interface where the size of the gap between the Andreev bands changes, but no bound states appear. When \( \Phi_L = \pi/2 \) (middle panel of Fig. 6) the gap on the left side of the junction closes, whereas the gap on the right remains open. Further increasing of \( \Phi_L \) leads to a reopening of the left gap, as shown on the right panel of Fig. 6. One can clearly see how spin-polarized bound states appear around the interface as a consequence of the gap inversion. Interestingly, these bound states are not restricted to the gap between the low-energy Andreev bands, but appear inside all gaps in the spectrum.

From the quasiclassical GF of the junction, we can also compute the spin of the system by integrating Eq. (16) over \( x \). We consider the zero-temperature case. As it is well known, quasiclassical GFs only describes the physics close to the Fermi surface and, hence, to obtain the total spin density one has to add the Pauli paramagnetic term. Namely, the Pauli paramagnetic contribution of each magnetic impurity is given by \( \frac{\Phi_0}{\pi} \) in units of \( \hbar/2 \). The resulting total value depends on the way the ACs terminate. As we are dealing with an infinite system, it is calculated from the average over all possible ending configurations of the chain. This is equivalent to the so-called sliding window average method (see, for example, Sec. 4.5 of Ref. [23]) and it results in a Pauli paramagnetic contribution of \( \frac{\Phi_0 - \Phi_R}{\pi} \) that has to be added to the integrated magnetization density of Eq. (16).
In Fig. 7 we show the contribution of a single Fermi valley to the surface spin polarization at $T = 0$ of a junction between two antiferromagnetic ACs as a function of $\Phi_L$. We set $a = 0.1\lambda_0$ and $\Phi_R = 0.4\pi$, although any other value of $a$ and $-\pi/2 < \Phi_R < \pi/2$ give the same results. The magnetization per Fermi valley can only take half-integer values of the electronic spin, which indicates fractionalization of the surface spin per electron-hole valley. The contribution from both Fermi valleys are equal and, hence, the total surface magnetization equals to an integer value of $h/2$. Choice of $\Phi_R$ outside the range $-\pi/2 < \Phi_R < \pi/2$ would shift the ladder-like curve in Fig. 7 some steps up or down due to the Pauli paramagnetic contribution (see previous paragraph). In Fig. 7 the smooth transition between plateaus is a consequence of the small imaginary positive number that we add to the energy, $\epsilon + i\Gamma$, with $\Gamma = 10^{-3}\Delta$, in order to avoid numerical problems. $\Gamma$ is known as Dynes parameter and models the effect of inelastic scattering which leads to a broadening of the coherent peaks peaks in the spectrum. In absence of inelastic processes, $\Gamma = 0$ and the magnetization shows sharp steps.

V. CONCLUSIONS

In conclusion, we have presented an exhaustive study of ACs. We have studied the spectral properties of infinite helical ACs and junctions between them. For energies within the superconducting gap, the spectrum of helical ACs exhibits a pair of energy-symmetric Andreev bands with respect to the Fermi level. In ferromagnetic ACs ($\sin \alpha = 0$) the gap between the Andreev bands close in a finite range of $\Phi$ values around half-integer values of $\Phi/\pi$. The range of $\Phi$ values for which the gap remains closed increasing with decreasing separation between impurities, $a$. Otherwise, $\sin \alpha \neq 0$, the gap closes only at half-integer values of $\Phi/\pi$, forming a Dirac point. Inverted junctions of helical ACs may present a pair of states bounded to the interface. These states (always) never appear in inverted junctions of (anti)ferromagnetic ACs, whereas they more likely appear as the rotation of the ACs forming the inverted junction approaches an antiferromagnetic configuration (i.e., with decreasing value of $|\cos \alpha|$).

On the other hand, we show a method to solve the Eilenberger equation of infinite and junctions between semi-infinite ACs. Because (anti)ferromagnetic ACs best exemplify the (existence) absence of interfacial states in inverted junctions between them, we apply this method to compute the full quasiclassical GFs of chains and junctions with collinear magnetization of the impurities. Our calculations are exact and generalizes the results of Ref. [23] for arbitrary distance between the impurities, namely, that the gap around the Fermi level in antiferromagnetic ACs only closes at half-integer values of $\Phi/\pi$ and that junctions between different antiferromagnetic ACs exhibit states bounded to the interface when the gap gets inverted through the junction. From the quasiclassical GFs we calculate the surface spin polarization and show that such inverted junctions show fractionalization of the surface spin. The method that we present to solve the Eilenberger equation of collinear ACs and junctions between them can be generalized for more complex magnetic configurations.

Overall, our results suggest the use of superconductor-ferromagnetic structures to realize crystals of a mesoscopic scale. We predict a diversity of properties of such Andreev Crystals, as gap inversion and edge states, that can be proved by state-of-the-art spectroscopic techniques.

Appendix A: Quasiclassical GF in a junction between antiferromagnetic ACs

We consider a junction between two antiferromagnetic ACs, where the separation between impurities, $a$, remains constant, but their strength changes from one chain to the other one ($\Phi_L$ and $\Phi_R$ in the left and right AC, respectively). Both chains meet at $x = 0$. The chain propagator of each chain is given by Eq. (30), substituting $\Phi$ by $\Phi_L$ and $\Phi_R$ in the left and right AC, respectively. The set of eigenvalues and left- and right-eigenvectors of the chain propagator in the left (right) AC that fulfill,

$$\tilde{S}_{L(R)\sigma} |\lambda^\pm_{L(R)\sigma}\rangle = e^{\pm \lambda_{L(R)\sigma}} |\lambda^\pm_{L(R)\sigma}\rangle,$$

$$\langle \lambda^\pm_{L(R)\sigma}\rangle |\tilde{S}_{L(R)\sigma}\rangle = e^{\pm \lambda_{L(R)\sigma}} \langle \lambda^\pm_{L(R)\sigma}\rangle,$$

(A1)
\[
e^{\pm \lambda_L(R) \sigma} = 1 + 2 \left( \langle + | e^{i\sigma \tau_3 \Phi_L(R)} | + \rangle \langle - | e^{i\sigma \tau_3 \Phi_L(R)} | - \rangle \sinh^2 \frac{a}{\xi} \right) \pm 2 \left( \langle + | e^{i\sigma \tau_3 \Phi_L(R)} | + \rangle \langle - | e^{i\sigma \tau_3 \Phi_L(R)} | - \rangle \sinh^2 \frac{a}{\xi} \right)^{1/2}, \tag{A2}
\]
and,
\[
\langle \lambda^\pm_L(R) \sigma \rangle = \frac{d^+_L(R) \sigma}{\lambda^+_L(R) \sigma} \quad \text{and} \quad |\lambda^+_L(R) \sigma\rangle = \frac{1}{d^+_L(R) \sigma} \langle \lambda^+_L(R) \sigma |d^+_L(R) \sigma\rangle, \tag{A3}
\]
where,
\[
d^+_L(R) \sigma = \frac{e^{+ \lambda_L(R) \sigma} - 1 - (e^{2\lambda_L(R) \sigma} - 1) \langle + | e^{i\sigma \tau_3 \Phi_L(R)} | + \rangle \langle - | e^{i\sigma \tau_3 \Phi_L(R)} | - \rangle}{(e^{2\lambda_L(R) \sigma} - 1) \langle + | e^{i\sigma \tau_3 \Phi_L(R)} | + \rangle \langle - | e^{i\sigma \tau_3 \Phi_L(R)} | - \rangle}, \tag{A4}
\]
\[
d^+_L(R) \sigma = \frac{e^{+ \lambda_L(R) \sigma} - 1 + (1 - e^{-2\lambda_L(R) \sigma}) \langle - | e^{i\sigma \tau_3 \Phi_L(R)} | - \rangle \langle + | e^{i\sigma \tau_3 \Phi_L(R)} | + \rangle}{(1 - e^{-2\lambda_L(R) \sigma}) \langle + | e^{i\sigma \tau_3 \Phi_L(R)} | + \rangle \langle - | e^{i\sigma \tau_3 \Phi_L(R)} | - \rangle}, \tag{A5}
\]
\[
c^+_L(R) \sigma = \sqrt{\frac{\pm (e^{2\lambda_L(R) \sigma} - 1) \langle - | e^{i\sigma \tau_3 \Phi_L(R)} | - \rangle \langle + | e^{i\sigma \tau_3 \Phi_L(R)} | + \rangle}{2 \sinh \lambda_L(R) \sigma}}. \tag{A6}
\]
Here \(\xi = \frac{\hbar v_F}{\Delta x^2} \) is the superconducting coherence length. Note that \(d^+_L(R) \sigma = d^+_R(R) \sigma\).

We can parametrize the value of the quasiclassical GF at the equivalent points of the chain in terms of the eigenvectors of the chain propagator, Eq. (A3), as follows:
\[
\tilde{g}_\sigma(X^L_{2m}) = \sqrt{1 - v_{x\sigma} w_{x\sigma} \left( |\lambda^+_\sigma\rangle \langle \lambda^+_\sigma | - |\lambda^-_{x\sigma}\rangle \langle \lambda^-_{x\sigma}| \right)} + v_{x\sigma} e^{2\lambda_{x\sigma} m} |\lambda^+_\sigma\rangle \langle \lambda^-_{x\sigma}| + w_{x\sigma} e^{-2\lambda_{x\sigma} m} |\lambda^-_{x\sigma}\rangle \langle \lambda^+_\sigma|. \tag{A7}
\]
Here, \(m\) is the unit cell index, \(X^L_{2m}\) stands for the left interface of the magnetic impurity located at \(X_{2m} = 2ma\) and the sub-index \(s\) label the left (L) and right (R) crystal. The unit cells forming the left and right AC are those labeled by \(n \leq 0\) and \(m > 0\), respectively.

For energies at which \(|e^{\pm \lambda_L(R) \sigma}| = 1\), Eq. (A7) describes modes that propagate all along the structure. Otherwise, it describes exponentially decaying states by setting either \(v_{L(R) \sigma}\) or \(w_{L(R) \sigma}\) to zero to ensure commensurability of \(g^\sigma\) at the infinities. Which one is set to zero depends on whether \(|e^{\pm \lambda_L(R) \sigma}| > 1\) or \(|e^{\pm \lambda_L(R) \sigma}| < 1\). Indeed, numerical analysis of Eq. (A2) shows that \(|e^{\pm \lambda_L(R) \sigma}| \leq 1\) and, therefore, we can set \(v_{L \sigma} = 0\) and \(w_{R \sigma} = 0\). To obtain the remaining two parameters we require continuity of Eq. (A7) across the junction, which yields
\[
v_{L \sigma} = \frac{d_{L \sigma}^+ d_{R \sigma}^- - d_{R \sigma}^+ d_{L \sigma}^-}{d_{R \sigma}^+ d_{L \sigma}^-}, \quad v_{R \sigma} = \frac{d_{R \sigma}^+ d_{L \sigma}^- - d_{L \sigma}^+ d_{R \sigma}^-}{d_{R \sigma}^+ d_{L \sigma}^-}. \tag{A8}
\]
Here \(d^+_L(R) \sigma\) is given by Eq. (A4).

Substituting Eq. (A8) into Eq. (A7) we get the value of the quasiclassical GF at the left interface of every second magnetic impurity, \(X^L_{2n}\). To obtain \(g^\sigma(x)\) at every point inside the unit cell, hence, we have to propagate it from \(X^L_{2n}\) to \(x\) by means of the BCS propagator, Eq. (10), when the propagation is across the superconducting regions, and the propagation-like boundary conditions, (13), to connect the GFs at the left and right interfaces of each impurity. Such a propagation allows us writing the quasiclassical GF all along the space as follows:
\[
\tilde{g}_\sigma(x) = \begin{cases} 
\mathcal{B}^0_{\sigma} \langle - | \langle \lambda^-_\sigma | - \rangle \langle + | \langle \lambda^+_\sigma | + \rangle \rangle + \mathcal{B}^+_{\sigma} e^{2x_{2m-1}^L x_{2m+1}^L} \langle - | \langle \lambda^-_\sigma | - \rangle \langle + | \langle \lambda^+_\sigma | + \rangle \rangle \quad & \text{if } X_{2n-2} < x < X_{2n-1}, \\
\mathcal{A}^0_{\sigma} \langle - | \langle \lambda^-_\sigma | - \rangle \langle + | \langle \lambda^+_\sigma | + \rangle \rangle + \mathcal{A}^+_{\sigma} e^{2x_{2m-1}^L x_{2m+1}^L} \langle - | \langle \lambda^-_\sigma | - \rangle \langle + | \langle \lambda^+_\sigma | + \rangle \rangle \quad & \text{if } X_{2n-1} < x < X_{2n},
\end{cases} \tag{A9}
\]
where \( |\pm \rangle \) and \( \langle \pm | \) are the right- and left-eigenvectors of the BCS propagator given by Eqs. [5] and [12], respectively. The expressions of the remaining constants depend on the side of the juction. The \( A \) constants in the AC on the left (\( m \leq 0 \)) read:

\[
A_{m\sigma}^0 = (c_{L\sigma}^+)^2 \left[ d_{L\sigma}^- + d_{L\sigma}^+ + i w_{L\sigma} e^{-2\lambda_{L\sigma} m} d_{L\sigma}^- \right], \tag{A10}
\]

\[
A_{m\sigma}^+ = (c_{L\sigma}^+)^2 \left[ 2 + i w_{L\sigma} e^{-2\lambda_{L\sigma} m} \right], \tag{A11}
\]

\[
A_{m\sigma}^- = -(c_{L\sigma}^+)^2 d_{L\sigma}^- \left[ 2d_{L\sigma}^+ + i w_{L\sigma} e^{-2\lambda_{L\sigma} m} d_{L\sigma}^- \right], \tag{A12}
\]

whereas in the right chain (\( m > 0 \)) they read:

\[
A_{m\sigma}^0 = (c_{R\sigma}^+)^2 \left[ d_{R\sigma}^- + d_{R\sigma}^+ + i v_{R\sigma} e^{2\lambda_{R\sigma} m} d_{R\sigma}^- \right], \tag{A13}
\]

\[
A_{m\sigma}^+ = (c_{R\sigma}^+)^2 \left[ 2 + i v_{R\sigma} e^{2\lambda_{R\sigma} m} \right], \tag{A14}
\]

\[
A_{m\sigma}^- = -(c_{R\sigma}^+)^2 d_{R\sigma}^- \left[ 2d_{R\sigma}^+ + i v_{R\sigma} e^{2\lambda_{R\sigma} m} d_{R\sigma}^- \right]. \tag{A15}
\]

The remaining expressions for the \( B \)-s are given in terms of the \( A \)-s shown in Eqs. [A10]–[A15] and read:

\[
B_{m\sigma}^0 = \left( 1 + 2 \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle \langle - | e^{i \sigma \tau_3 \Phi_\sigma | + \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle - e^{\frac{2\xi}{\tau}} \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle} \right) A_{m\sigma}^0 + e^{-\frac{2\xi}{\tau}} \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle}^2 A_{m\sigma}^+, \tag{A16}
\]

\[
B_{m\sigma}^+ = 2 \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | + \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | + \rangle - e^{\frac{2\xi}{\tau}} \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | + \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle \rangle A_{m\sigma}^0 + e^{-\frac{2\xi}{\tau}} \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | + \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | + \rangle}^2 A_{m\sigma}^-, \tag{A17}
\]

\[
B_{m\sigma}^- = -2 \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle \langle - | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle - e^{\frac{2\xi}{\tau}} \langle \pm | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle \langle + | e^{i \sigma \tau_3 \Phi_\sigma | - \rangle}^2 A_{m\sigma}^-, \tag{A18}
\]

where \( \Phi_\sigma = \Phi_\lambda \) when \( m \leq 0 \) (i.e., in the left side of the juction) and \( \Phi_\sigma = \Phi_\sigma \) otherwise. Equations [A9]–[A18] provide the quasiclassical GF for the \( \sigma \) spin component of a junction between two antiferromagnetic ACs at any position, \( x \), from which we can directly calculate observables like the local density of states, Eq. [15], or the local spin density, Eq. [16].
