Models of Membrane Electrostatics

Kevin Cahill

Biophysics Group, Department of Physics & Astronomy, University of New Mexico, Albuquerque, NM 87131 and Physics Department, Fudan University, Shanghai, China 200433

(Dated: May 18, 2012)

I derive formulas for the electrostatic potential of a charge in or near a membrane modeled as one or more dielectric slabs lying between two semi-infinite dielectrics. One can use these formulas in Monte Carlo codes to compute the distribution of ions near cell membranes more accurately than by using Poisson-Boltzmann theory or its linearized version. Here I use them to discuss the electric field of a uniformly charged membrane, the image charges of an ion, the distribution of salt ions near a charged membrane, the energy of a zwitterion near a lipid slab, and the effect of including the phosphate head groups as thin layers of high electric permittivity.

I. CELL MEMBRANES

The plasma membrane of an animal cell and the membranes of the endoplasmic reticulum, the Golgi apparatus, the endosomes, and other membrane-enclosed organelles are lipid bilayers about 5-nm thick studded with proteins. The lipid constituents are mainly phospholipids, sterols, and glycolipids.

Of the four main phospholipids in membranes, three—phosphatidylethanolamine (PE), phosphatidylcholine (PC), and sphingomyelin (SM)—are neutral, and one, phosphatidylserine (PS), is negatively charged. In a living cell, PE and PS are mostly in the outer layer; and the electrostatic potential of the cytosol is 20 to 120 mV lower than that of the extracellular environment.

After pioneering work by Gouy, Chapman, and Wagner, and by Onsager and Samaras, many scientists have studied the electrical properties of cell membranes. This paper presents the exact electrostatic potential due to a charge in or near a membrane in the continuum limit in which the membrane is taken to be one or more dielectric slabs lying between two different infinite dielectric media. Because of the superposition principle, this monopole potential also gives the multipole potential due to any array of charges in or near a membrane.

One can use these formulas to simulate the interactions of ions with other ions and with fixed charges near membranes while modeling water and other neutral molecules as bulk media. For instance, one can use them in Monte Carlo simulations to compute the behavior of salt ions and protons in water near neutral or charged membranes even in the presence of fixed charges of arbitrary geometry. This method is more accurate than the Poisson-Boltzmann mean-field approximation and much more accurate than its linearized version. These formulas also provide a context for and a check on all-atom computer simulations.

As early as 1924, Wagner noted that an ion in water near a lipid slab induces image charges that repel the ion. No mean-field theory can describe this simple effect. But work-arounds are available for the Poisson-Boltzmann theory.

Formulas for the electrostatic potential of a charge in or near a cell membrane modeled as a single slab are derived in section. As pedagogical illustrations of their utility, I use them to compute the electric field of a charged membrane in section and the response of bound charge to an ion in section. In section I use them to simulate the distribution of salt ions near a charged membrane. I discuss the Debye layer in section and the energy of a zwitterion near a lipid slab in section. I calculate the potential of a charge near a membrane modeled as several dielectric layers of different permittivities between two different semi-infinite dielectrics. I use this analysis in section to model a phospholipid bilayer as a lipid layer bounded by two layers of head groups of high electric permittivity. The phosphate head groups cause the membrane to attract rather than to repel ions. I summarize the paper in section.

II. THE POTENTIAL OF A CHARGE IN OR NEAR A LIPID BILAYER

In electrostatic problems, Maxwell’s equations reduce to Gauss’s law which relates the divergence of the electric displacement to the free-charge density (not including the polarization of the medium), and the static form of Faraday’s law which implies that the electric field is the gradient of an electrostatic potential.

Across an interface with normal vector the tangential component of the electric field is continuous

while the normal component of the electric displacement
jumps by the surface density \( \sigma \) of free charge

\[
\mathbf{n} \cdot (\mathbf{D}_2 - \mathbf{D}_1) = \sigma. \tag{2}
\]

In a linear dielectric, the electric displacement \( \mathbf{D} \) is the electric field scaled by the permittivity \( \epsilon \) of the material \( \mathbf{D} = \epsilon \mathbf{E} \).

The lipid bilayer is taken to be flat, extending to infinity in the \( x-y \) plane, and of a thickness \( t \approx 5 \text{ nm} \). The interface between the extracellular salty water and the lipid bilayer is at \( z = 0 \). The permittivity \( \epsilon_\ell \) of the lipid bilayer is about twice that of the vacuum \( \epsilon_\ell \approx 2 \epsilon_0 \); those of the extracellular environment \( \epsilon_w \) and of the cytosol \( \epsilon_c \) are about 80 times \( \epsilon_0 \).

The potential of a charge \( q \) at a point \((0,0,h)\) on the \( z \)-axis is cylindrically symmetric, and so Bessel functions are useful here. In cylindrical coordinates with \( \rho = \sqrt{x^2 + y^2} \), the functions \( J_\ell(k\rho)e^{in\phi}e^{\pm k z} \) form a complete set of solutions of Laplace’s equation, but due to the azimuthal symmetry, we only need the \( n = 0 \) functions \( J_\ell(k\rho)e^{\pm k z} \). We will use them and the relation \[5\]

\[
\frac{1}{\sqrt{\rho^2 + (z-h)^2}} = \int_0^\infty dk \, J_\ell(k\rho) \, e^{-k|z-h|} \tag{3}
\]

to represent the potential of point charge at \((0,0,h)\).

If the charge \( q \) is at \((0,0, h)\) in the water above the membrane \((h > 0)\), then we may write the potentials in the extracellular water \( V_w^w \), in the lipid membrane \( V_\ell^w \), and in the cytosol \( V_c^w \) as

\[
V_w^w(\rho, z) = \int_0^\infty dk \, J_\ell(k\rho) \left[ \frac{q}{4\pi \epsilon_w} e^{-k|z-h|} + u(k) e^{-kz} \right]
\]

\[
V_\ell^w(\rho, z) = \int_0^\infty dk \, J_\ell(k\rho) \left[ m(k) e^{kz} + f(k) e^{-kz} \right]
\]

\[
V_c^w(\rho, z) = \int_0^\infty dk \, J_\ell(k\rho) \, d(k) \, e^{kz}. \tag{4}
\]

Imposing the constraints \[1\&\,2\], writing \( u(k) \) as \( u, m(k) \) as \( m, \) and so forth, and setting \( \beta = qe^{-kh}/4\pi \epsilon_w \) and \( y = e^{2kt} \), we get the four equations

\[
m + f - u = \beta
\]

\[
\epsilon_\ell m - \epsilon_\ell f + \epsilon_w u = \epsilon_w \beta
\]

\[
\epsilon_\ell m - \epsilon_\ell yf - \epsilon_\ell d = 0
\]

\[
m + yf - d = 0. \tag{5}
\]

In terms of the abbreviations

\[
\epsilon_{\ell w} = \frac{1}{2} (\epsilon_w + \epsilon_\ell) \quad \text{and} \quad \epsilon_{\ell c} = \frac{1}{2} (\epsilon_c + \epsilon_\ell)
\]

\[
p = \frac{\epsilon_w - \epsilon_\ell}{\epsilon_w + \epsilon_\ell} \quad \text{and} \quad p' = \frac{\epsilon_c - \epsilon_\ell}{\epsilon_c + \epsilon_\ell}
\]

their solutions are

\[
u(k) = \beta \frac{p - p' / y}{1 - pp' / y}
\]

\[
m(k) = \beta \frac{\epsilon_w}{\epsilon_{\ell w}} \frac{1}{1 - pp' / y}
\]

\[
f(k) = -\beta \frac{\epsilon_w}{\epsilon_{\ell w}} \frac{p' / y}{1 - pp' / y}
\]

\[
d(k) = \beta \frac{\epsilon_w \epsilon_{\ell}}{\epsilon_{\ell w} \epsilon_{\ell c}} \frac{1}{1 - pp' / y}. \tag{7}
\]

Inserting these solutions into the Bessel expansions \[4\] for the potentials, expanding their denominators

\[
\frac{1}{1 - pp' / y} = \sum_{n=0}^\infty (pp')^n e^{-2nkt} \tag{8}
\]

and using the integral \[3\], we find that the potential \( V_w^w(\rho, z) \) in the extracellular water due to a charge \( q \) at \((0,0,h)\) in that water is

\[
V_w^w(\rho, z) = \frac{q}{4\pi \epsilon_w} \left[ \frac{1}{r} + \frac{p}{\sqrt{r^2 + (z + h)^2}} \right]
\]

\[
- p' \frac{1}{\sqrt{r^2 + (z + 2(n+1)t + h)^2}} \tag{9}
\]

in which \( r = \sqrt{\rho^2 + (z-h)^2} \) is the distance to the charge \( q \), and \( \sqrt{r^2 + (z+h)^2} \) is the distance to the principal image charge \( pq \). Similarly, the potential \( V_\ell^w \) in the lipid bilayer is

\[
V_\ell^w(\rho, z) = \frac{q}{4\pi \epsilon_{\ell w}} \sum_{n=0}^\infty (pp')^n \left[ \frac{1}{\sqrt{r^2 + (z - 2nt - h)^2}} \right]
\]

\[
- p' \frac{1}{\sqrt{r^2 + (z + 2(n+1)t + h)^2}} \tag{10}
\]

and the potential \( V_c^w \) in the cytosol is

\[
V_c^w(\rho, z) = \frac{q \epsilon_{\ell c}}{4\pi \epsilon_{\ell w} \epsilon_{\ell c}} \sum_{n=0}^\infty \frac{(pp')^n}{\sqrt{r^2 + (z - 2nt - h)^2}} \tag{11}
\]

If the charge \( q \) is in the lipid bilayer at \((0,0,h)\) with \(-t < h < 0\), then the Bessel representations of the potentials are

\[
V_w^\ell(\rho, z) = \int_0^\infty dk \, J_\ell(k\rho) \, u(k) \, e^{-kz}
\]

\[
V_\ell^\ell(\rho, z) = \int_0^\infty dk \, J_\ell(k\rho) \left[ \frac{q}{4\pi \epsilon_\ell} e^{-k|z-h|} \right]
\]

\[
V_c^\ell(\rho, z) = \int_0^\infty dk \, J_\ell(k\rho) \, d(k) \, e^{kz}. \tag{12}
\]
With $\gamma = q e^{kh} / 4\pi \epsilon_\ell$ and $x = e^{-2kh}$, the Maxwell constraints \[1 & 2\] give us the equations
\begin{align*}
u - m - f &= \gamma \\
\epsilon_w u + \epsilon r m - \epsilon f &= \epsilon r \gamma \\
d - m - y f &= x \gamma \\
\epsilon_c d - \epsilon \ell m - \epsilon f &= \epsilon \ell x \gamma. \tag{13}
\end{align*}
whose solutions are
\begin{align*}
u(k) &= \frac{\epsilon \ell \beta}{\epsilon_w \ell} \frac{1 - p' x / y}{1 - p' y / y} \\
m(k) &= - p \beta \frac{1 - p' x / y}{1 - p' y / y} \\
f(k) &= - p \beta \frac{x - p}{y} \\
d(k) &= \frac{\epsilon \ell \beta}{\epsilon_c \ell} \frac{x - p}{1 - p' y / y}. \tag{14}
\end{align*}
After putting these solutions into the Bessel expansions \[12\] and using the integral \[3\] and the denominator sum \[8\], one finds that the potential $V^c_\ell$ in the extracellular water due to a charge $q$ at $(0,0,h)$ in the lipid bilayer is
\begin{align*}
V^c_\ell(\rho, z) &= \frac{q}{4\pi \epsilon_\ell} \left[ \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2nt - h)}^n \left( p' \rho^n \right) \right] \\
&- \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2n+1)t + h}^n \left( p' \rho^n \right) \\
&- p \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z - 2nt + h)}^n \left( p' \rho^n \right)
\tag{15}
\end{align*}
The potential $V^c_\ell$ in the lipid bilayer is
\begin{align*}
V^c_\ell(\rho, z) &= \frac{q}{4\pi \epsilon_\ell} \left[ \sum_{n=-\infty}^{\infty} \sqrt{\rho^2 + (z - 2nt - h)}^n \left( p' \rho^n \right) \right] \\
&- \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z - 2nt + h)}^n \left( p' \rho^n \right) \\
&- \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2n+1)t + h}^n \left( p' \rho^n \right)
\tag{16}
\end{align*}
and that $V^c_\ell$ in the cytosol is
\begin{align*}
V^c_\ell(\rho, z) &= \frac{q}{4\pi \epsilon_\ell} \left[ \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2nt - h)}^n \left( p' \rho^n \right) \right] \\
&- \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z - 2nt + h)}^n \left( p' \rho^n \right) \\
&- p \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2nt + h)}^n \left( p' \rho^n \right)
\tag{17}
\end{align*}
Finally and somewhat redundantly, we turn to the case of a charge $q$ in the cytosol at $(0,0,h)$ with $h < -t$. Now the Bessel expansions of the potentials are
\begin{align*}
V^c_w(\rho, z) &= \int_0^\infty dk \ J_0(kp) \ u(k) e^{-kz} \\
V^c_\ell(\rho, z) &= \int_0^\infty dk \ J_0(kp) \ [m(k) e^{kz} + f(k) e^{-kz}] \\
V^c_c(\rho, z) &= \int_0^\infty dk \ J_0(kp) \ \left[ \frac{q}{4\pi \epsilon_w} e^{-k |z - h|} + d(k) \right] e^{kz}.
\tag{18}
\end{align*}
The continuity conditions \[1 & 2\] give us the four equations
\begin{align*}
u - m - f &= 0 \\
\epsilon_w u + \epsilon r m - \epsilon f &= 0 \\
d - m - y f &= - \beta y \\
\epsilon_c d - \epsilon \ell m - \epsilon f &= \beta \epsilon_c y. \tag{19}
\end{align*}
whose solutions are
\begin{align*}
u(k) &= \frac{\epsilon \ell \epsilon_c}{\epsilon_w \ell \epsilon_c} \frac{\beta}{1 - p' y / y} \\
m(k) &= - p \beta \frac{\beta}{1 - p' y / y} \\
f(k) &= - \beta \frac{p'}{1 - p' y / y} \\
d(k) &= \frac{\beta}{1 - p' y / y}.
\tag{20}
\end{align*}
Thus using \[8 & 8\] in \[13\], we find that the potential $V^c_\ell$ in the extracellular water due to a charge $q$ at $(0,0,h)$ in the cytosol is
\begin{align*}
V^c_\ell(\rho, z) &= \frac{q \epsilon_\ell \epsilon_c}{4\pi \epsilon_\ell \epsilon_c} \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2nt - h)}^n \left( p' \rho^n \right) \\
&- p \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2nt + h)}^n \left( p' \rho^n \right)
\tag{21}
\end{align*}
The potential $V^c_\ell$ in the lipid bilayer is
\begin{align*}
V^c_\ell(\rho, z) &= \frac{q}{4\pi \epsilon_\ell} \left[ \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z - h + 2nt)^2}^n \left( p' \rho^n \right) \right] \\
&- p \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z - h - 2nt)^2}^n \left( p' \rho^n \right) \\
&- p \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2nt + h)^2}^n \left( p' \rho^n \right)
\tag{22}
\end{align*}
The potential $V^c_c$ in the cytosol is
\begin{align*}
V^c_c(\rho, z) &= \frac{q}{4\pi \epsilon_c} \left[ \frac{1}{r} + \frac{p'}{\sqrt{r^2 + (z + 2nt + h)^2}} \right] \\
&- p \left( 1 - p^2 \right) \sum_{n=0}^{\infty} \sqrt{\rho^2 + (z + 2nt + h)^2}^n \left( p' \rho^n \right)
\tag{23}
\end{align*}
in which $r$ is the distance to the charge and $\sqrt{r^2 + (z + 2nt + h)^2}$ is the distance to the principal image charge $p'q$.

Inasmuch as $1 - p^2 = \epsilon_w \epsilon_c / \epsilon_w \ell$; the series \[9 & 11\] for the potentials $V^c_w(\rho, z)$, $V^c_\ell(\rho, z)$, and $V^c_c(\rho, z)$ agree with those derived by the method of image charges \[9\]. The first eight terms of the infinite series \[91111117 & 21 \& 23\] give the potentials to within a percent. They are fast.

The first 1000 terms of the series \[91111117\ & 21 & 23\] for the potentials $V^c_w(\rho, z)$, $V^c_\ell(\rho, z)$, and $V^c_c(\rho, z)$ (right curve, red) and \[21 \& 22 \& 23\] for the potentials $V^c_\ell(\rho, z)$, $V^c_w(\rho, z)$, and $V^c_c(\rho, z)$ (left curve, blue) are plotted in Fig. \[1\] \(V\) for $\rho = 1$ nm as a function of the height $z$ (nm) above the phospholipid bilayer for a unit charge
The lipid bilayer is between cytosol lipid bilayer exterior, in the extracellular salty water at (0, 0) in nm; and the permittivities are $\epsilon = 80\epsilon_0$ and $\epsilon_z = 2\epsilon_0$.

$V = |q|$ in the extracellular medium at $(\rho, z) = (0, 1)$ nm (right curve, red) and in the cytosol at $(\rho, z) = (0, -6)$ nm (left curve, blue). The errors due to the truncation of these series at 1000 terms are less than 1 part in $10^{15}$.

The first 1000 terms of the series (15, 16 & 17) for the potentials $V^{\epsilon}_w(\rho, z)$, $V^{\epsilon}_c(\rho, z)$, and $V^{\epsilon}_e(\rho, z)$ are plotted in Fig. 2 (V) for $\rho = 1$ nm as a function of the height $z$ (nm) above the phospholipid bilayer for a unit charge $q = |e|$ in the bilayer at $(\rho, z) = (0, -4.5)$ (left curve, blue), $(0, -2.5)$ (middle curve, magenta), and $(0, -0.5)$ (right curve, red). The lipid bilayer extends from $z = -5$ to $z = 0$ nm and is bounded by thin (black) vertical lines in Figs. 1 & 2. The cytosol lies below $z = -5$ nm. The relative permittivities were taken to be $\epsilon_w = \epsilon_c = 80\epsilon_0$ and $\epsilon_z = 2\epsilon_0$.

Figs. 1 & 2 show that the potentials fall off sharply as they cross the lipid bilayer. The reason for this effect is a build-up of bound charge in the water near the lipid bilayer due to the high electric permittivities of the extracellular environment $\epsilon_w$ and of the cytosol $\epsilon_c$.

In sections VIII & IX I will extend this derivation to the case of several dielectric slabs. This generalization will allow us to add two layers of high-permittivity dielectric that will represent the head groups of the phospholipids.

### III. A SURFACE CHARGE ON A MEMBRANE

As a pedagogical application of the formulas of the preceding section, let us consider a uniform charge density $\sigma$ on the surface of a lipid bilayer of thickness $t$. To avoid minus signs, I will put the charge density on the extracellular leaflet. After doing the computation, I will translate the result to the case of phosphatidylserine on the cytosolic leaflet.

Maxwell’s jump equation [2] tells us that the electric displacement $D_w$ in the water differs by $\sigma$ from its value $D_t$ in the lipid, which in turn is the same as its value $D_c$ in the cytosol. So we have two equations $D_w = D_t + \sigma$ and $D_t = D_c$ for three unknowns. We can use the electrostatic potentials of section III to resolve this ambiguity.

The electrostatic potential $V^{\omega}_c(\rho, z)$ due to a point charge at $(0, 0, h)$ as given by (19) is equal to the electrostatic potential $V^{\omega}_w(0, z)$ due to a point charge at $(\rho, h)$. Thus setting the height $h$ in (19) equal to zero, and differentiating with respect to $z$, we find for the $z$-component of the electric field at $(0, 0, 0)$ due to a charge $q$ at $(\rho, 0)$

$$E_z(0, z) = \left. -\frac{\partial}{\partial z} V^{\omega}_w(\rho, z) \right|_{h=0}$$

or

$$E_z(0, z) = \frac{q}{4\pi \epsilon_w} \left[ \frac{(1+p)z}{r^3} + p'(1-p^2) \sum_{n=1}^{\infty} \frac{([p^2+(z+2nt)^2]^{1/2} - [p^2+(z+2nt)^2]^{1/2})}{r^3} \right]$$
in which \( r = \sqrt{\rho^2 + z^2} \) and \( z \geq 0 \). Replacing the charge \( q \) by \( \sigma 2\pi \rho d\rho \) and integrating over \( \rho \) from \( \rho = 0 \) to \( \rho = \infty \), we have

\[
E_z(\sigma) = \frac{2\pi \sigma}{4\pi \epsilon_w} \left[ 1 + p - p'(1 - p^2) \sum_{n=0}^{\infty} (pp')^n \right].
\] (26)

The dependence upon the variables \( z \) and \( t \) has dropped out. Doing the sum and using the definitions (6) of \( p \) and \( p' \), we get

\[
E_z(\sigma) = \frac{\sigma}{2\epsilon_w} \left[ \frac{1 + p - p'(1 - p^2)}{1 - pp'} \right] = \frac{\sigma}{2\epsilon_w} \left[ \frac{1 + p}{1 - pp'} - 1 \right].
\] (27)

The field points in the \( \hat{z} \) direction.

In the limiting case in which the electric permittivity of the extracellular medium is the same as that of the cytosol, \( \epsilon_w = \epsilon_c \), the electric field is \( E_w(\sigma) = \sigma / 2\epsilon_w \).

We may apply similar reasoning to the formula (11) for the potential \( V_e'(\rho, z) \) in the cytosol due to a charge \( q \) in the extracellular water at a height \( h \) above the membrane. If we keep in mind that the quantity \( z - 2nt - h \) is negative, then we find for the electric field in the cytosol of a surface-charge density \( \sigma \) at \( h = 0 \)

\[
E_c(\sigma) = -\frac{\sigma}{\epsilon_w + \epsilon_c}.
\] (28)

Since there is no surface charge between the cytosol and the membrane, it follows from Maxwell’s jump equation (2) that \( D_\ell = \epsilon_\ell E_\ell = D_c = \epsilon_c E_c \), and so the electric field in the membrane is proportional to that in the cytosol

\[
E_\ell(\sigma) = \frac{\epsilon_c}{\epsilon_\ell} E_c(\sigma).
\] (29)

Our formula (28) for \( E_c(\sigma) \) now gives \( E_\ell(\sigma) \) as

\[
E_\ell(\sigma) = -\frac{\sigma \epsilon_c}{\epsilon_\ell(\epsilon_w + \epsilon_c)}.
\] (30)

The jump in the displacement \( D \) across the layer of surface charge is

\[
D_w - D_\ell = \frac{\sigma \epsilon_w}{(\epsilon_w + \epsilon_c)} + \frac{\sigma \epsilon_c}{\epsilon_\ell(\epsilon_w + \epsilon_c)} = \sigma
\] (31)
in agreement with Maxwell’s equation (2).

If the layer of surface charge of density, like that of phosphatidylserine, lies on the cytosolic leaflet at \( z = -\ell \), then the electric fields are

\[
E_w(\sigma) = \frac{\sigma}{\epsilon_w + \epsilon_c},
\]

\[
E_\ell(\sigma) = \frac{\sigma \epsilon_w}{\epsilon_\ell(\epsilon_w + \epsilon_c)},
\]

\[
E_c(\sigma) = -\frac{\sigma}{\epsilon_w + \epsilon_c}.
\] (32)

IV. IMAGE CHARGES

As noted by Wagner [2], a charge \( q \) in or near a membrane polarizes the membrane and the surrounding water. The potential formulas (9–11), (15–17), and (21–23) represent these bound charges as infinitely many mirror charges. The mirror charges affect the behavior of ions near an interface between two dielectrics in ways that mean-field theories can’t describe.

For instance, a charge \( q \) in the lipid bilayer induces mirror charges in the cytosol and in the extracellular environment. These induced charges are of opposite sign, and they attract the charge \( q \) in the lipid membrane. We can be more precise about this attraction if in the formula (13) for \( V_e'(\rho, z) \), we use \( V_e'(z) \) to represent the self-potential \( V_e'(0, 0) \) without the \( z \)-independent, infinite, \( n = 0 \) term of the first sum

\[
V_e'(z) = \frac{q}{4\pi \epsilon_\ell} \left[ \frac{\ln(1 - pp')}{t} \right] - \sum_{n=0}^{\infty} \frac{p (pp')^n}{|2z - 2n t|} - \frac{pp'(pp')^n}{|2z + 2(n + 1) t|}.
\] (33)

Keeping only the first term in each sum and using \( C \) for the constant log term, we recognize two image charges

\[
V_e'(z) \approx \frac{q}{4\pi \epsilon_\ell} \left( C - \frac{p}{|2z|} - \frac{pp'}{|2z + 2 t|} \right)
\] (34)
familiar from freshman physics. They attract the charge \( q \) no matter what its sign. Water is better than lipid at attracting charges.

Similarly, a charge \( q \) in the extracellular water induces a mirror charge in the lipid and others in the cytosol. The mirror charge in the lipid is of the same sign and, being closer, repels the charge \( q \). We can describe this repulsion in terms of the formula (14) for \( V_e'(\rho, z) \) if we use \( V_e'(z) \) to mean \( V_e'(0, 0) \) without the \( z \)-independent, infinite term \( 1 / r \)

\[
V_e'(z) = \frac{q}{4\pi \epsilon_\ell} \left[ \frac{p}{|2z|} \right] - \frac{\epsilon_\ell}{\epsilon_w} \sum_{n=1}^{\infty} \frac{p^{n-1}p^n}{|2z + 2n t|}.
\] (35)

The first term is the potential of the textbook mirror charge

\[
V_e'(z) \approx \frac{q}{4\pi \epsilon_\ell} \frac{p}{|2z|}.
\] (36)

An ion of charge \( q \) in this potential has an energy proportional to \( q^2 p \), which is positive for both cations and anions. A lipid membrane therefore repels both cations and anions; the water attracts the ion more than the lipid does. In a mean-field theory, such as unpatched Poisson-Boltzmann theory, every particle responds to the same potential \( V(x) \), so the force \( qE(x) = -q \nabla V(x) \) is proportional to the charge \( q \) of the ion and therefore must be opposite for cations and anions. Mean-field theories can’t describe why a lipid membrane repels both cations and anions.
V. IONS NEAR A CHARGED MEMBRANE

One can use the formulas of Sec. II in a Monte Carlo code to compute the distribution of salt ions near a charged membrane. Here I present the result of such a simulation of the distributions of potassium and chloride ions near a membrane of a vesicle whose inner leaflet contains phosphatidylserine (PS) at a level of 4 percent, which is about that of the plasma membrane of a liver cell.

In the simulation, I let the potassium and chloride ions move according to a Metropolis algorithm within a box whose width and length were 50 nm and whose height was 10 nm. I took the potassium concentration to be 150 mM so as to allow for a 10 mM concentration of sodium ions. The box contained 2258 $K^+$ ions. The bottom of the box was covered by a uniform negative surface charge density whose total charge was $-143|e|$ corresponding to 4373 chloride ions at a molar density of 4%. I used 2115 $Cl^-$ ions to make the whole system neutral; these chloride ions played the role of the whole ensemble of anionic cell constituents.

To mitigate edge effects, I surrounded the box with eight identical boxes into which I mirrored all 4373 ions. So there were 39357 ions in nine identical boxes. All the boxes had the same uniform surface-charge density due to the presence of the PSs at a level of 4%. To strictly enforce periodic boundary conditions, one should use Ewald sums, but I did not do this because they would have slowed the code down and because liquids are not crystals. Since the maximum step size in the $z$-direction was only 1 Å; the error due to using only eight boxes of mirrored ions altered the energy difference $\Delta E$ of a Monte Carlo move by less than 0.064 $kT$, usually about 0.016 $kT$, far less than the thermal noise.

In my Monte Carlo code, I used the constant $|e|$ for the electric field $E_z(\sigma)$ of the surface charge of phosphatidylserines, the series for the self-potential $V^w_\sigma(z)$ arising from the response of the bound charge to an ion of charge $q$, and the sum for the electrostatic potential $V^w(\rho, z)$ due to a charge in the extracellular water near a membrane. In this way, I took exact account of the fields of the charges of the problem while treating the neutral molecules of the extracellular environment, the membrane, and the cytosol as bulk dielectric media. The simulations consisted of eight separate runs in which 23,000 sweeps were allowed for thermalization. Four of the runs collected data for an additional 50,000 sweeps; the other four for an additional 9,000 sweeps.

In Poisson-Boltzmann theory, all charges respond to a common potential $V$ that obeys Poisson’s equation with a charge density that respects the Boltzmann dis-
Relevance of Debye Layer for a K⁺ Ion

FIG. 5. (Color online) For a potassium ion, the sum \( V_w^p(z) + V_v(z) \) of the electrostatic potential \( V_w^p(z) \) due to the induced mirror charges and that \( V_v(z) = -\sigma |z|/(\epsilon_w + \epsilon_c) \) due to the electric field of a lipid bilayer whose cytosolic leaflet is charged to a phosphatidylserine mole percent of 4% (red solid curve) or 20% (blue, dot-long-dash curve) is plotted against the distance \( |z| \) (nm) from the leaflet. The uncorrected linear potentials \( V_v(z) \) of the two surface-charge densities, 4% (blue dots) and 20% (red dashes), appear as straight lines.

where \( V = 0 \) are then

\[
K_{GC}(z) = e^{-eV(z)/kT} \quad \text{and} \quad Cl_{GC}(z) = e^{eV(z)/kT}. \tag{40}
\]

In Fig. 4 I have plotted my Monte Carlo predictions for the relative concentrations of potassium ions \( \rho_K(z)/\bar{\rho}_K \) (red solid curve) and of chloride ions \( \rho_{Cl}(z)/\bar{\rho}_{Cl} \) (blue dashed curve) as functions of the distance \( z \) from the charged membrane. The Gouy-Chapman predictions \cite{40} for the normalized potassium \( K_{GC}(z) \) (red, dot-dash) and chloride \( Cl_{GC}(z) \) (blue, dots) concentrations also are plotted there. The solid \( K^+ \) and dashed \( Cl^- \) Monte Carlo concentrations correctly drop sharply for respectively \( z < 1 \) and \( z < 2 \) nm due to the repulsion by the induced image charges as discussed in Section \( \text{IV} \). These concentrations are much lower than the Gouy-Chapman predictions. The Gouy-Chapman-Poisson-Boltzmann potassium concentration actually rises monotonically when the \( K^+ \) is less than 4 nm from the membrane. (The behavior of both \( \rho_K(z)/\bar{\rho}_K \) and \( \rho_{Cl}(z)/\bar{\rho}_{Cl} \) for \( z > 9 \) nm is an artifact due to the absence of ions at \( z > 10 \) nm in the simulation.)

In Fig. 4 I have plotted my Monte Carlo predictions for the average total potential that a \( K^+ \) ion (solid, red) or a \( Cl^- \) ion (dashed, blue) feels due to the surface charge of the phosphatidylserines, to the other ions, and to its polarization of the three dielectrics. The induced bound charge sharply raises the potential felt by the potassium ion for \( z < 1 \) nm and lowers that felt by a chloride ion for \( z < 2 \) nm. The dot-dash magenta curve represents the potential due to the surface-charge layer of PSs and to all the ions (including the bound charges they induce) but without the image charges of equation \cite{35}. These three potentials differ significantly over the whole range in which the Gouy-Chapman concentrations differ from their bulk values. (The dip in the three potentials for \( z > 9 \) nm is an artifact due to the absence of ions at \( z > 10 \) nm.)

In the related papers \cite{4,4}, I neglected the self-potential.

VI. VALIDITY OF THE DEBYE LAYER

We have seen in the last two sections that mean-field theory cannot account for the behavior of ions near an interface between two dielectrics with two very different permittivities. Does this mean that the usual interpretation of the Debye layer is incorrect?

The answer depends upon the difference between the two permittivities and upon the magnitude of the surface-charge density. An image charge is proportional to the ratio of the difference of the two permittivities to their sum. So if the dielectrics have similar permittivities, then the induced charges will be weak, and the image-charge correction to a mean-field Debye layer will be small. Similarly, a high surface-charge density will dominate the field due to the induced bound charges un-
VII. A ZWITTERION

Let us consider a simple model of a zwitterionic molecule in salty water above an uncharged lipid bilayer. The toy zwitterion is just a point charge $q'$ at $r'$ and another $q''$ at $r''$. The charges are separated by $s = r' - r''$ which makes an angle $\theta$ with the vertical $\hat{z}$ so that $\hat{z} \cdot s = s \cos \theta$ where $s$ is the distance between the charges $s = \sqrt{s'^2}$. The square of the horizontal distance between the charges is $s^2 = (x' - x'')^2 + (y' - y'')^2 = z'^2 \sin^2 \theta$.

Let us consider a simple model of a zwitterionic molecule in salty water above an uncharged lipid bilayer. In Fig. 5 I have plotted for a $K^+$ ion both their sum $V_w(z) + V_r(z)$ and the potential $V_r(z)$. For the surface-charge density $\sigma$ of a 4 mole-percent concentration of phosphatidylserine, as on the cytosolic leaflet of a liver cell, the sum $V_w(z) + V_r(z)$ (red solid curve) differs from the surface-charge potential $V_r(z)$ (red dashed straight line) for $z < 2$ nm. But for a higher mole percent of 20%, the relative difference between the sum $V_w(z) + V_r(z)$ (blue dot-long-dash curve) and $V_r(z)$ (blue dotted straight line) is somewhat less. The importance of the image-charge correction increases as the surface-charge density falls. It is therefore particularly important in the case of an uncharged membrane, such as the outer leaflet of the plasma membrane.

FIG. 6. (Color online) The energy of a zwitterion in salty water a distance $z$ from a lipid slab. The four lower, solid curves describe a molecule consisting of a point charge $q' = |e|$ separated by 0.5 nm from a charge $q'' = -|e|$; the four upper, dashed curves are for a molecule consisting of a point charge $q' = 2|e|$ separated by 2 nm from a charge $q'' = -|e|$. Within each quartet the molecules from right to left make angles of 0, 30, 60, and 90 degrees with the vertical.

This interaction is unchanged when we interchange the locations of the two charges, and $z' + z'' = 2z$. So

$$E(r', r'') = E(r'', r') = q' q'' u(z, \theta, s)$$

where

$$v(z, \theta, s) = \frac{1}{4\pi \varepsilon_w} \left[ \frac{1}{z^2} + \frac{p}{\sqrt{s^2 \sin^2 \theta + (z + 2nt)^2}} \right].$$

The total electrostatic energy of the molecule is then

$$E(z, \theta) = q' q'' u(z + \frac{1}{2} s \cos \theta) + q'' q u(z - \frac{1}{2} s \cos \theta) + 2 q' q'' v(z, \theta, s).$$

In Fig. 6 I plot the energy of the model zwitterion when it is z nm away from a plasma membrane considered as a lipid slab with salty water on both sides. The four lower, solid curves are for a point charge $q' = |e|$ separated by 0.5 nm from a charge $q'' = -|e|$; the four upper, dashed curves are for a point charge $q' = 2|e|$ separated by 2 nm from a charge $q'' = -|e|$. The lipid slab repels the molecules.

One may find the energy of a more realistic zwitterion by integrating the two-charge formula over a suitable charge distribution.

less the ions are very close to the interface. Thus the validity of the Debye layer depends on the relative magnitudes of the self-potential $V_w(z) \approx q z / 8 \pi \varepsilon_w |z|$ due to the image-charge correction and the potential $V_r(z) = -\sigma |z| / (\varepsilon_w + \varepsilon_s)$ due to the electric field of the phosphatidylserines. In Fig. 5 I have plotted for a $K^+$ ion both their sum $V_w(z) + V_r(z)$ and the potential $V_r(z)$. For the surface-charge density $\sigma$ of a 4 mole-percent concentration of phosphatidylserine, as on the cytosolic leaflet of a liver cell, the sum $V_w(z) + V_r(z)$ (red solid curve) differs from the surface-charge potential $V_r(z)$ (red dashed straight line) for $z < 2$ nm. But for a higher mole percent of 20%, the relative difference between the sum $V_w(z) + V_r(z)$ (blue dot-long-dash curve) and $V_r(z)$ (blue dotted straight line) is somewhat less. The importance of the image-charge correction increases as the surface-charge density falls. It is therefore particularly important in the case of an uncharged membrane, such as the outer leaflet of the plasma membrane.
 VIII. SEVERAL DIELECTRIC LAYERS

We may extend our derivation of the electric potential of a charge in a material of three dielectrics to the case of several dielectrics. One biological application is to a phospholipid bilayer considered as a layer of lipids bounded by two thin layers of head groups. These three layers with the extracellular water and the cytosol pose a five-dielectric problem.

Let us first consider the case of four dielectric layers with the charge $q$ in the first layer of permittivity $\epsilon_w$ in the region $z > 0$. Instead of the three potentials $V_0$, we have four

$$V_w^u (\rho, z) = \int_0^\infty dk J_0(kp) \left[ \frac{q}{4\pi\epsilon_w} e^{-k|z-h|} + u(k) e^{-kz} \right]$$

$$V_1^b (\rho, z) = \int_0^\infty dk J_0(kp) \left[ m_1(k) e^{kz} + f_1(k) e^{-kz} \right]$$

$$V_2^b (\rho, z) = \int_0^\infty dk J_0(kp) \left[ m_2(k) e^{kz} + f_2(k) e^{-kz} \right]$$

$$V_c^w (\rho, z) = \int_0^\infty dk J_0(kp) d(k) e^{kz}$$

in which the first internal layer of permittivity $\epsilon_1$ fills the region $-t_1 < z < 0$ while the second internal layer of permittivity $\epsilon_2$ fills the region $-t_1 - t_2 < z < -t_1$. The constraints $1$ and $2$ give six equations

$$m_1 + f_1 - u = \beta$$

$$\epsilon_1 m_1 - \epsilon_1 f_1 + \epsilon_w u = \epsilon_w \beta$$

$$m_1 + y_1 f_1 - m_2 - y_1 f_2 = 0$$

$$\epsilon_1 m_1 - \epsilon_1 y_1 f_1 - \epsilon_2 m_2 + \epsilon_2 y_1 f_2 = 0$$

$$m_2 + y_2 f_2 - d = 0$$

$$\epsilon_2 m_2 - \epsilon_2 y_2 f_2 - \epsilon_c d = 0$$

in which $y_1(k) = \exp(2kt_1)$ and $y_2(k) = \exp(2kt_2)$, while as in $1$, the parameter $\beta(k) = q \exp(-kh)/4\pi\epsilon_w$ represents the charge at $z = h > 0$. The functions $m_1(k)$ and $f_1(k)$ determine $m_2(k)$ and $f_2(k)$ as

$$m_2 = ((\epsilon_2 + 1) m_1 + (\epsilon_2 - \epsilon_1) y_1 f_1) / 2 \epsilon_2$$

$$f_2 = ((\epsilon_2 - 1) m_1 / y_1 + (\epsilon_2 + 1) f_1) / 2 \epsilon_2.$$ (47)

We now address the problem of a charge $q$ in a semi-infinite region of permittivity $\epsilon_w$ at a height $h$ above $n$ internal layers of permittivity $\epsilon_i$ and thickness $t_i$ which in turn are above a semi-infinite region of permittivity $\epsilon_c$. In the $i$th internal layer, the potential is

$$V_i^w (\rho, z) = \int_0^\infty dk J_0(kp) \left[ m_i(k) e^{kz} + f_i(k) e^{-kz} \right]$$

while the first and fourth equations of the set $15$ describe the potentials in the two semi-infinite regions. The functions $m_i(k)$ and $f_i(k)$ determine those $m_{i+1}(k)$ and $f_{i+1}(k)$ of the next layer by matrix multiplication. If

$$p_i = \frac{\epsilon_i + 1 - \epsilon_i}{\epsilon_i + \epsilon_1}$$

$$\tau_i = \frac{\epsilon_i + 1 + \epsilon_i}{2}$$

then

$$\begin{align*}
(m_{i+1}) &= \frac{1}{2\epsilon_{i+1}} \left( \begin{array}{c} \epsilon_{i+1} + \epsilon_i \\ \epsilon_{i+1} - \epsilon_i \end{array} \right) \frac{f_i}{y_1} \\
(f_{i+1}) &= \frac{\tau_i}{\epsilon_{i+1}} \left( \begin{array}{c} 1 \\ p_i/y_1 \end{array} \right) \frac{m_i}{f_i}
\end{align*}$$

(50)

in which $y_0 = 1$ and $y_i = \exp(2k(t_i + \cdots + t_1))$ for $i > 0$.

IX. THREE DIELECTRIC LAYERS

A phospholipid bilayer consists of a layer of phosphate head groups, a (double) layer of lipids, and a second layer of phosphate head groups. In this section, we will apply the formulas of section VIII to the problem of a charge $q$ at a height $h$ above such a bilayer. There are now three slabs and two semi-infinite regions. We must compute $E^{(3)}$. I get

$$E_{21}^{(3)} = \rho_0 + \rho_1 + \rho_2 + \frac{\rho_0 \rho_1 \rho_2 \rho_3}{y_1} + \frac{\rho_3}{y_3} \left( 1 + \rho_0 \rho_1 y_1 + \rho_0 \rho_2 y_2 + \rho_1 \rho_2 y_1 y_2 y_3 \right)$$

(54)

and

$$E_{22}^{(3)} = 1 + \frac{\rho_0 \rho_3}{y_1} + \frac{\rho_0 \rho_2}{y_2} + \frac{\rho_1 \rho_3}{y_3} + \rho_0 \rho_1 y_1 + \rho_2 \rho_3 y_2 + \frac{\rho_0 \rho_1 \rho_3}{y_1}.$$ (55)

Stern and Feller $14$, Nymeyer and Zhou $15$, and Baker $16$ have estimated the relative electric permittivity of phospholipid membranes as being 1 from 0 to 10 $\text{Å}$ from the center, 4 from 10 to 15 $\text{Å}$, 180 from 15 to 20 $\text{Å}$, 210 from 20 to 25 $\text{Å}$, and like bulk water beyond 25 $\text{Å}$. I will approximate their results by using 2 from 0 to 15 $\text{Å}$ and 195 from 15 to 25 $\text{Å}$ and will take the relative permittivities of the cytosol and of the extra-cellular environment to be 80. These approximations greatly simplify...
FIG. 7. (Color online) The potential $V_w^\omega(\rho, z)$ [V, 59] at the point $(\rho, z)$ due to a charge $q = |e|$ on the z-axis at $(0,h)$ above a three-slab phospholipid bilayer that is neutral (lowest, solid, blue) or has a 4 mole-percent layer of phosphatidylserine on its cytosolic leaflet (upper, solid, red). Both $\rho$ and $h$ are 1 nm. The potential of a charge above a single neutral lipid slab without head groups is plotted as a dashed magenta curve to illustrate the effect of the layers of head groups.

The key function $u(k)$ then is by (58) the ratio

$$u(k) = -\frac{q}{4\pi\epsilon_w} e^{-kh} \left[ p_0 + p_1 (1 + p_0^2) (e^{-2kt} - e^{-8kt}) + p_0 p_1^2 e^{-4kt} - p_0^2 p_1^2 e^{-6kt} \right]$$

and

$$E_{21}^{(3)} = p_0 + p_1 (e^{-2kt} - e^{-8kt}) - p_0 p_1^2 e^{-6kt}$$

$$E_{22}^{(3)} = 1 + p_0 p_1 (e^{-2kt} - e^{-8kt}) - p_0^2 e^{-6kt}$$

The potential $V_w^\omega(\rho, z)$ of a charge above a single neutral lipid slab is negatively charged by phosphatidylserine at 4 mole percent. Without the outer polar slabs, the potential is purely repulsive (dashed magenta).

The key function $u(k)$ then is by (58) the ratio

$$u(k) = -\frac{q}{4\pi\epsilon_w} e^{-kh} \left[ p_0 + p_1 (1 + p_0^2) (e^{-2kt} - e^{-8kt}) + p_0 p_1^2 e^{-4kt} - p_0^2 p_1^2 e^{-6kt} \right]$$

and

$$E_{21}^{(3)} = p_0 + p_1 (e^{-2kt} - e^{-8kt}) - p_0 p_1^2 e^{-6kt}$$

$$E_{22}^{(3)} = 1 + p_0 p_1 (e^{-2kt} - e^{-8kt}) - p_0^2 e^{-6kt}$$

Figure 8 plots this potential $V_w^\omega(\rho, z)$ for $\rho = 1$ nm and $0 \leq z \leq 5$ nm for the case of a unit positive charge $q = |e|$ on the z-axis at height $h = 1$ nm above a three-slab phospholipid bilayer that is neutral (lowest curve, solid, blue) or has a 4 mole-percent layer of phosphatidyserine on its cytosolic leaflet (upper curve, solid, red). The electric field of the PSs is taken from (52) to be $E_w(\sigma) = |\sigma|/(\epsilon_w + \epsilon_e)$ in which $\sigma$ is negative. To illustrate the effect of the layers of head groups with very high electric...
permittivity, I have replotted the potential \([V_w(z)]\) of Fig. 3 due to the same charge but above a single naked, neutral lipid slab as a dashed magenta curve. The head-group dipoles lower the potential \(V_w(u, z)\) in their vicinity.

We also can use the ratio \(u(k)\) to compute the self-interaction of a charge \(q\) with our three slab model of the phospholipid bilayer. The potential felt by the charge in the salty water due to all the image charges its presence induces in the three slabs and in the cytosol is

\[
V_w(z) = \int_0^\infty u(k) e^{-kz} \, dk
\]

in which \(u(k)\) is the ratio \([58]\) but with the height \(h\) of the charge \(q\) replaced by \(z\). The potential felt by the charge \(q\) at \(z\) then is

\[
V_w(z) = -\frac{q}{4\pi e_0} \int_0^\infty e^{-2kz/\ell} \left[ p_0 + p_0 p_1^2 e^{-4k} - p_0 e^{-10k} + p_1 (1 + p_0^2) (e^{-2k} - e^{-8k}) - p_0 p_1^2 e^{-6k} \right] \left[ 1 + p_0^2 p_1^2 e^{-4k} - p_0^2 e^{-10k} + 2p_0 p_1 (e^{-2k} - e^{-8k}) - p_1^2 e^{-6k} \right] \, dk
\]

in which the parameter \(\ell\) is one nm.

Figure 5 plots the electric potential felt by an ion of charge \(|e|\) near a phospholipid bilayer modeled as a lipid slab bounded by two thin polar slabs. The lowest (solid, blue) curve is for a neutral membrane; the upper (solid, red) curve is for a membrane whose cytosolic leaflet is negatively charged by phosphatidylserines at 4 mole percent represented as in Fig. 7. The two thin layers of phosphate head groups make the potential felt by an ion near a neutral phospholipid bilayer attractive rather than repulsive. Without the outer polar slabs, the potential \([58]\) is purely repulsive (dashed magenta). The head groups attract to the membrane ions that a naked lipid slab would repel. If the membrane has phosphatidylserines on its cytosolic leaflet, then it strongly attracts positive ions that it otherwise would repel. Apparently the phosphate head groups facilitate many physiological processes, such as the docking of ligands and the translocation and endocytosis of positive ions and cell-penetrating peptides.

**X. SUMMARY**

I derived the electrostatic potential of a charge in or near a lipid bilayer in section III and used it in section IV to compute the electric field of a uniformly charged membrane and in section IV to describe the effects of image charges. In section V I used the results of sections III IV in a Monte Carlo computation of the distribution of ions near a charged membrane. I discussed the validity of the Debye layer in section VI and computed the energy of a zwitterion near a lipid slab in section VII. In section VIII I calculated the potential of a charge near a membrane modeled as several dielectric layers of different permittivities between two different semi-infinite dielectrics. I used this analysis in section IX to model a phospholipid bilayer as a lipid layer bounded by two layers of high electric permittivity. The phosphate head groups cause a neutral membrane to attract rather than to repel ions.

**ACKNOWLEDGMENTS**

I am grateful to Nathan Baker, Leonid Chernomordik, Charles Cherqui, David Dunlap, Scott Feller, Kamran Melikov, Michael Wilson, Adrian Parsegian, Sudhakar Prasad, Harry Stern, and David Waxman for helpful conversations; to Susan Atlas, Bernard Becker, Vaibhav Madhok, Samantha Schwartz, James Thomas, and Toby Tolley for useful comments; and to the two referees for constructive criticism.
