Abstract

Objective

The present study was aimed to determine the differentially expressed proteins (DEPs) between paired samples of cervical cancer (CC) and paracancerous tissue by quantitative proteomics and to examine the effects of DUSP7 expression on tumorigenesis and progression of CC.

Materials and methods

Proteomic profiles of three paired samples of CC and paracancerous tissue were quantitatively analyzed to identify the DEPs. The gene functions of the DEPs were presented based on bioinformatics analysis in combining with bibliographical information. The expression of the DEPs was validated by IHC examination in the CC tissue arrays. The relationship between the DEPs expression and patients’ clinicopathological characteristics and prognosis were evaluated using the Spearman rank correlation test and Kaplan-Meier survival analysis respectively. The effects of the selected DEPs on CC progression were examined in SIHA (human CC cell line) cells.

Results

According to the TMT (Tandem Mass Tags) ratios (≥ 1.5 or ≤ 0.5), a total of 129 proteins were found to be differentially expressed in all 3 pairs of samples with a p value < 0.05. To investigate gene functions of these DEPs in tumor growth and progresssion, Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis was performed. Three DEPs, HRAS, DUSP7, and PLD1, and P-ERK1/2, associated with RAS pathway, were selected for further investigation. Western Blot and IHC staining analyses confirmed the results from quantitative proteomic analysis showing that HRAS, P-ERK1/2, and PLD1 levels were increased whereas DUSP7 level was decreased in CC tissue compared with the paired normal paracancerous tissues. The IHC results from the CC TMA analysis showed that the decreased expression of DUSP7 (P = 0.045 and 0.044, respectively) and increased expression of PLD1 (P = 0.046 and 0.028, respectively) were significantly associated with a tumor size > 2 cm and parametrial infiltration. In addition, the decreased expression of DUSP7 and increased expression of PLD1 and p-ERK1/2 were adversely related to patients’ relapse (P = 0.003, 0.040, and 0.001, respectively) and survival (P = 0.034, 0.001, and 0.006, respectively). The expression of HRAS and p-ERK1/2 was decreased in DUSP7-SIHA cells compared to NC-SIHA cells (P = 0.0003 and 0.0026, respectively). Biological functions in vitro, including invasion, migration, and proliferation, and tumor formation in vivo were decreased in the DUSP7-SIHA cells (all P < 0.05), yet increased in the siDUSP7-SIHA cells (all P < 0.05).

Conclusions

DUSP7 is decreased in cervical cancer tissues compared to normal tissues. Increasing or decreasing DUSP7 expression was found to significantly reduce or enhance the anchorage-independent growth of SIHA cells, respectively. The biological function of DUSP7 is possibly achieved through dephosphorylation of the ERK1/2 and inactivation of the RAS pathway. Up-regulating the expression of DUSP7 may be potential useful for the prevention or treatment of CC.

Introduction
Human cervical carcinoma (CC) ranks as the third most common cancer worldwide and is the most frequent gynecological cancer in developing countries. In developing countries, the incidence and mortality of CC are on the rise. China has approximately 150,000 new cases of CC each year, and CC tends to occur in younger people [1]. CC remains a serious health problem in women. It is crucial to explore the pathogenesis of CC and discover effective therapeutic targets for this lethal disease. The key etiologic role of human papillomavirus (HPV) in the development of CC and its precursors has been well documented convincingly [2], and the use of HPV vaccination in women has the potential to reduce the incidence of CC in the future. However, due to the high price of the vaccine, coverage rates are still low, especially in low- or middle-income countries [3]. Further, viral presence is not sufficient to induce CC [4], suggesting that a distinct molecular mechanism could play a key role in its transformation and progression.

Proteomics is defined as the comprehensive global analysis of a specific proteome, the set of all proteins expressed in a cell or a biological system or organism at a given point in time and under certain conditions. Proteomics has been widely used to identify certain proteins with complex biological functions related to pathogenesis of various diseases including human malignancies [5]. Wang et al. [6] compared the proteomes of the primary tumors of CC patients with and without lymph node metastasis and revealed that patients with high FABP5, HspB1 and MnSOD expression have a high risk of lymph node metastasis and adverse prognosis. By comparing the proteomes of primary CC tissues and corresponding adjacent normal tissues, Zhang et al. [7] found that Notch signaling, viral carcinogenesis, RNA transport, and Jak-STAT signaling play an important role in tumor progression. In these studies, the study group and control group had the same genetic backgrounds. Differentially expressed proteins (DEPs) identified through this manner might reflect the process of tumorigenesis and progression of CC to some extent. However, no further details on the preparation of tissue specimens were provided. In this analysis, the tissue specimens available for proteomic examination were subjected to a stricter pathological evaluation, so that the results would more accurately reflect the factors involved in the invasion and progression of cervical cancer. The protein profiles between paired samples of CC and paracancerous tissues were compared and analyzed, with the goal of providing useful information about diagnostic biomarker or molecular therapeutic targets for patients with CC.

Materials And Methods

Materials and Cell culture

The main materials, including reagents, instruments, and antibodies for western blot (WB) and immunochemistry (IHC), used in this work were showed in supplementary(S)_Tables 1 and 2 respectively. Human CC cell line SIHA was cultured in RPMI-1640 supplemented with 10% fetal bovine serum (FBS) and antibiotics (100 U/ml of penicillin and 100 µg/ml of streptomycin) at 37 °C in a humidified atmosphere in a 5% CO₂ incubator.

Specimen collection of CC and paracancerous tissue

CC and paracancerous tissue samples were all collected from patients who underwent surgery at department of Obstetrics and Gynecology, Beijing Chao-yang Hospital, Capital Medical University. Those who received preoperative chemotherapy or radiotherapy, or had concurrent or successive primary malignancies, were excluded. Patients, with extensive cancerous areas occupying the cervix, were also excluded. Sample were collected according to the "Sandwich" method (Fig. 1-A) and obtained from 3 consecutive sites of suspicious lesions (C1/C2/C3) and normal-looking areas (N1/N2/N3). Specimens at the middle site (C1 and N1) were immediately washed 3 times with ice-cold PBS solution and stored in liquid nitrogen. If the specimens at both ends (C2/C3, N2/N3) were consistently confirmed by pathological examination as cervical invasive carcinoma and normal cervical tissue respectively, then the middle
specimens (C1 and N1) were qualified. A total of 13 pairs of qualified specimens were taken. The cancerous and adjacent normal tissue samples were named C1-13 and N1-13, respectively. Tissue collection was under the approval of Beijing Chao-yang Hospital Ethics Committee and under the patients’ informed consent.

### Proteomic profiles of CC and paracancerous tissue and the identification of DEPs

Three pairs of CC and paracancerous tissue were used for proteomic testing. Samples were ground in liquid nitrogen and dissolved in PBS containing 8 M urea, 1 x protease inhibitor cocktail (Biotool, B14001) and 1 mM PMSF. After sonication for 5 min, the protein concentrations of each sample were measured with the BCA method. Each sample (100 µg) was reduced with 5 mM DTT and alkylated with 12.5 mM iodoacetamide (IAM). After being diluted with PBS to 1.5 M urea, samples were digested with trypsin at a protease/protein ratio of 1:100 overnight at 37 °C. Then, Sep-Pak columns (Waters, MA) were used to desalt the samples. According to the manufacturer's instructions, peptides from each sample were labeled with tandem mass tag (TMT) reagents (Thermo, Pierce Biotechnology). The TMT labeled peptides were desalted by a Sep-Pak column.

A UPLC3000 system (Dionex, CA) with an XBridgeTM BEH300 C18 column (Waters, MA) was used to fractionate the peptides. H₂O adjusted by ammonium hydroxide to a pH of 10 was defined as mobile phase A, and acetonitrile adjusted by ammonium hydroxide to a pH of 10 was defined as mobile phase B. Peptides were separated gradiently as follows: phase B, 8–18%, 30 min; and phase B, 18–32%, 22 min. Peptides at forty-eight fractions were collected, dried with a SpeedVac, combined into 12 fractions, and redissolved in 0.1% formic acid.

For proteomic quantitative analysis, a 120-min gradient step elution at a flow rate of 0.250 µl/min with an EASYnLCII™ integrated nano-HPLC system (Proxeon, Denmark) was used to separate the TMT labeled peptides. This system was directly interfaced with a Q Exactive mass spectrometer. Mobile phase A consisted of only 0.1% formic acid. Mobile phase B consisted of 100% acetonitrile and 0.1% formic acid. Xcalibur 2.1.3 software was used to operate the Q Exactive mass spectrometer in the data-dependent acquisition mode. The generated MS/MS spectra were collected with a data-dependent acquisition method. The isolation window, dynamic exclusion time and normalized collisional energy (NCE) were set to 2-Da width, 60 s and 30, respectively. Quantification was carried out only for proteins with two or more matching unique peptides. The median value of all peptide hits belonging to a protein was defined as the protein ratio. Protein ratio variability was used to evaluate the quantitative precision. The DEPs were identified through this manner. The gene functions of the DEPs were analyzed through bioinformatics analysis in combination with bibliographical information.

The DEPs with a greater likelihood of having a potential role in the pathogenesis and progression of CC were selected in this manner through validation through WB and IHC staining. Expression of the validated DEPs was detected through IHC examination of CC tissue arrays.

### Tissue microarray (TMA) construction

A TMA was constructed based on the formalin-fixed, paraffin-embedded (FFPE) tumor tissues of CC patients. The inclusion criteria were as follows: (1) CC patients who underwent primary surgery at Beijing Chao-Yang Hospital, Capital Medical University between January 2002 and December 2013. (2) patients with cervical squamous cell carcinoma (SCC) ; and (3) patients who did not receive neoadjuvant chemotherapy and/or radiotherapy before surgery. Clinicopathological information including age at diagnosis, number of pregnancy and deliveries, status of menopause, BMI, tumor history, family history of tumor, histological type, tumor grade, FIGO stage, surgery, intraoperative and postoperative complications, postoperative radiotherapy and chemotherapy, recurrence and death
was collected from the clinical database. FFPE tumor samples were collected from the Department of Pathology Department at our Hospital. Progression-free survival (PFS) was calculated from the date of surgery to tumor recurrence. Patients who lived free from the disease at the last visit were censored. Overall survival (OS) was calculated from the date of diagnosis to patient death or the last follow-up.

TMAs were constructed according to a method described in our previous studies [8, 9]. The slides were reviewed, and the pathological diagnosis of cervical SCC of all the included patients was confirmed by two independent gynecological pathologists, who were blinded to the clinical data. Accurate locations of the tumors were marked on the FFPE samples. Two tissue cores, 1 mm in diameter, were taken from a donor block and placed in a recipient block (10 × 12 arrays) using a manual tissue array instrument. Sequential 4-µm-thick sections were cut from the FFPE TMA blocks and mounted on blank slides.

IHC staining was performed to detect the expression level of the validated DEPs in the CC TMAs. The images of TMA slides were captured using a digital pathological section scanner (Pannoramic MIDI/P250). Pannoramic Viewer 1.15.4 software was used to display the image at 1 to 400 × magnification. Semiquantitative analysis was performed according to the histochemistry score (H-score), which was calculated based on a combination of the scores for the percentage of stained cells and staining intensity. H-score = Σ(percentage [0–100%] × intensity [1–3]) = (percentage of cells with weak intensity × 1) + (percentage of cells with moderate intensity × 2) + (percentage of cells with strong intensity × 3) [8]. The validated DEPs whose expression levels were significantly associated with patients’ clinical outcomes were selected as candidate DEPs for further evaluation.

**Production and transduction of lentiviral particles**

A plasmid encoding a candidate DEP gene was inserted into the pWSLV-08 vector, with Green fluorescent protein (GFP) as the reporter gene. Lentiviral particles containing the candidate DEP gene were transfected into SIHA cells (candidate DEP-SIHA). Then, the cells were cultured and amplified. GFP-positive cells were sorted by flow cytometry (FCM). SIHA cells transfected with a negative control (NC) plasmid (NC-SIHA) were used as a control.

Specific short hairpin RNAs (shRNAs) targeting the candidate DEP gene were designed and synthesized. Separate fragments containing different shRNAs targeting the candidate DEP gene and the scrambled shRNA sequence were each cloned into the GV248 plasmid. The GV248 plasmid and other packaging plasmids were cotransfected into HEK293T cells using Lipofectamine 2000. Candidate DEP SIHA cells were transfected with the viral particles, and the cells were collected 48 h after transfection. Cells with the viral particle containing the most effective shRNA sequence were selected and named sh-candidate DEP-SIHA.

Real-time PCR and WB were used to validate the transfection efficiency at the protein and mRNA levels, respectively. Primers for Real-time PCR were showed in S_Table 3.

**The effect of candidate DEP on the biological function of SIHA**

Based on the reports about the candidate DEPs in the literature, the following experimental procedures were performed on the candidate DEP-SIHA and NC-SIHA, as well as sh-candidate DEP-SIHA and shNC-SIHA cells. The Cell Counting Kit-8 (CCK-8) assay and FCM were used to detect cell proliferation and cell cycle distribution, respectively. A colony formation assay was used to assess colony formation. The migration ability was detected through wound healing and Transwell migration assay. Transwell invasion assays were used to evaluate the invasion ability. Immunofluorescence assays were used to detect the expression of E-cadherin and vimentin in the target cells. The role of the candidate DEP in epithelial-to-mesenchymal transition (EMT) was also evaluated in this manner.

**Xenograft experiments**
All the following procedures were approved by the Animal Research Ethics Committee of Capital Medical University. Ten female nude mice (female BALB/c, 4 weeks of age) were randomly divided into 2 groups (5 mice per group). *Candidate DEP-SIHA/NC-SIHA* (or sh-*candidate DEP-SIHA/shNC-SIHA*) cells were injected subcutaneously into the left or right flanks of nude mice, respectively to compare the tumor formation ability in vivo.

**Statistical analysis**

All statistical analyses were performed using Review Manager 5.3 and SPSS software version 19. A P value of $\leq 0.05$ was considered significant. The relationship between the DEPs expression and patients’ clinicopathological characteristics and prognosis were evaluated through Spearman rank correlation test and Kaplan-Meier survival analysis respectively.

**Study ethics**

Patient records and information were anonymized and de-identified prior to analysis; therefore, consent was not necessary. The study protocol was approved by the ethics committees at Beijing Chao-Yang Hospital.

**Results**

Proteomic profile of CC and paracancerous tissue and the identified DEPs

A total of 7811 proteins were identified in all samples, with less than a 1% false discovery rate (FDR) (S_Table 4). According to the TMT ratios ($\geq 1.5$ or $\leq 0.5$), 129 proteins were found to be differentially expressed in all 3 pairs of samples, with a p value $< 0.05$. The gene function of 97 out of the 129 DEPs, including 89 upregulated and 8 downregulated DEPs, was associated with the pathogenesis and progression of tumors (Table 1).

* TMT: Tandem Mass Tags; C1, C2, C3: cervical cancer tissue; N1, N2, N3: paired paracancerous tissue.
To investigate the functions of the DEP-related genes in signal transduction in tumor cells, Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis was performed. Three DEPs—HRAS, DUSP7, and PLD1—are RAS pathway components. ERK, also a RAS pathway component, was not included in the DEPs. Total ERK is not necessarily highly expressed in human malignancies \[10\]; however, persistent ERK1/2 activation through phosphorylation ultimately promotes cell proliferation and malignant transformation \[11\]. The interaction of HRAS, DUSP7, PLD1, and phosphorylated ERK1/2 (p-ERK1/2) is illustrated in Fig. 2. These four genes were thus selected for further verification. WB and IHC staining analyses confirmed the results of the quantitative proteomic analysis that the levels of HRAS, PLD1, and p-ERK1/2 were increased, whereas DUSP7 level was decreased in CC tissue compared with the paired normal paracancerous tissue (Fig. 1-B and C).

### TMA construction and patients’ clinicopathological information
During the study period, a total of 102 patients’ FFPE samples were included in the TMA (Table 2, Fig. 1-D). The mean age of patients at diagnosis was 44.7 (Range: 24–78) years old. The mean diameter of the tumors was 2.9 (Range: 0.3–5.5) cm, including 38 (37.3%) cases of tumors with a tumor size < 2 cm. Tumors were grade II in 16 cases and grade III in 86 cases. Lymph-vascular space invasion (LVSI) was detected in about one-fourth of patients. Uterine isthmus involvement was identified in 4 (3.9%) cases. Parametrial and vaginal invasion were identified in 11 cases and 12 (11.8%) cases, respectively. Positive lymph node involvement was identified in 18 (17.7%) cases. Postoperative adjuvant radiotherapy was administered in 68 (6.7%) cases. The mean follow-up period was 64.6 (Range: 8-136) months, during which time 14 (13.7%) women relapsed after a mean relapse interval of 26.1 (Range: 5–90) months. At the last contact, 10 patients died of the disease. The 5-year relapse-free survival rate was 86.9%, and the 5-year overall survival rate was 90.5%.
Table 2
The clinicopathological features of 102 patients with cervical cancer

| Parameters                  | Number of patients | %  | Parameters                  | Number of patients | %  |
|-----------------------------|--------------------|----|-----------------------------|--------------------|----|
| Age (Mean;range)            | 44.7 ± 11.1; 24–78 |     | Parametrial invasion        |                    |    |
| ≤ 45                        | 57                 | 55.9 | +                          | 11                 | 10.8 |

The expression of DUSP7, PLD1 and p-Erk1/2 in CC TMA

The IHC results from the CC TMA analysis showed that the decreased expression of DUSP7 (P = 0.045 and 0.044, respectively) and increased expression of PLD1 (P = 0.046 and 0.028, respectively) were significantly associated with a tumor size > 2 cm and parametrial infiltration (Table 3). In addition, the decreased expression of DUSP7 and increased expression of PLD1 and p-ERK1/2 were adversely related to patients’ relapse (P = 0.003, 0.040, and 0.001, respectively; Fig. 3) and survival (P = 0.034, 0.001, and 0.006, respectively). DUSP7 was selected as the candidate gene and was evaluated in further experiments.

### Establishment of stable DUSP7 knockdown and overexpression cells

Stable DUSP7 overexpressing cell lines were established by transducing SIHA cells with Lv-DUSP7 and were named DUSP7-SIHA cells (Fig. 4-A and B).

The qRT-PCR results showed that the DUSP7 mRNA level in DUSP7-SIHA cells was significantly higher than that in NC-SIHA cells (42.52 vs. 1, P < 0.0001; Fig. 4-C). Three specific shRNAs targeting DUSP7 were designed and synthesized. The qRT-PCR results showed that the silencing efficiencies of these shRNAs were 55%, 54% and 47% (All P < 0.0001) when siNC was used as a reference. Cells infected the most effective (55%) shRNA sequence (GCAUCAAGUAUAUCCUCAATT) were named siDUSP7-SIHA and used for subsequent experiments. The WB results indicated that the DUSP7 expression level in Dusp7-SIHA cells was significantly higher than that in NC-SIHA and wild-type SIHA cells. In contrast, DUSP7 expression was significantly down-regulated in siDUSP7-SIHA cells compared to Dusp7-SIHA and wild-type SIHA cells (Fig. 4-D and E).

### The effect of DUSP7 on the biological function of SIHA cells

The CCK-8 assay growth curves showed that DUSP7-SIHA cells proliferated significantly slower than NC-SIHA cells, based on a clear delay in the doubling time (47.72 ± 1.14 h vs. 23.99 ± 0.47 h, P = 0.0001; Fig. 5-A). Cell cycle analysis indicated that the DUSP7-SIHA cells displayed a concomitant decrease in the percentage of cells in S phase (37.71 ± 0.53% vs. 46.96 ± 0.59%, P < 0.0001) and a significant increase in the percentage of cells in G0/G1 phase (52.50 ± 3.49% vs. 44.04 ± 0.71%, P = 0.0473), suggesting that inhibited proliferation of DUSP7-SIHA cells might be due to the arrest of DNA synthesis (Fig. 5-B). Colony formation assays showed that the number of colonies formed by DUSP7-SIHA cells was significantly less than that formed by NC-SIHA cells (44.67 ± 9.0 vs. 75.33 ± 14.47, P = 0.0121; Fig. 5-C). In the Matrigel invasion/migration assay, DUSP7-SIHA cells demonstrated a significantly weaker ability to invade and migrate through the membrane than control cells (P = 0.0207 and 0.0059, respectively; Fig. 6-A). Wound healing assays showed that the migration area of DUSP7-SIHA cells was significantly smaller than that of NC-SIHA cells (P = 0.049; Fig. 6-B). Additionally, E-cadherin expression was significantly increased but vimentin expression was...
significantly reduced in DUSP7-SIHA cells, which demonstrated that overexpression of DUSP7 has a potential role in inhibiting the EMT process of SIHA cells (Fig. 7).

In contrast, the CCK-8 assay growth curves showed that the doubling time of siDUSP7-SIHA cells was significantly shorter than that of siNC-SIHA cells (49.12 ± 1.14 h vs. 64.14 ± 0.47 h, P = 0.0001; Fig. 5-A). Cell cycle analysis indicated that siDUSP7-SIHA cells displayed a concomitant increase in the percentage of cells in S phase (49.54 ± 1.53% vs. 46.4 ± 0.97%, P = 0.019) and a significant decrease in the percentage of cells in G0/G1 phase (41.8 ± 0.38% vs. 45.2 ± 0.80%, P = 0.020; Fig. 5-B). Colony formation assays showed that the number of colonies formed by siDUSP7-SIHA cells was significantly greater than that formed by siNC-SIHA cells (13.33 ± 3.4 vs. 30.33 ± 16.50, P = 0.049; Fig. 5-C). In the Matrigel invasion/migration assay, siDUSP7-SIHA cells demonstrated a greater ability to invade and migrate through the membrane than control cells (P = 0.0007 and 0.0426, respectively; Fig. 6-A). Wound healing assays showed that the migration area of siDUSP7-SIHA cells was larger than that of siNC-SIHA cells (P = 0.0313; Fig. 6-B). Additionally, E-cadherin expression was significantly reduced, while vimentin expression was increased in siDUSP7-SIHA cells (Fig. 7).

The role of DUSP7 in tumor formation in vivo

After subcutaneous injection, DUSP7-SIHA tumors were observed much later than NC-SIHA tumors (13 ± 4 vs 6 ± 1 days; P = 0.0122; Fig. 8-A). On the study end date, the DUSP7-SIHA tumors were significantly smaller than NC-SIHA tumors (0.74 ± 0.38 vs 3.25 ± 1.68 cm³; P = 0.0183). In contrast, siDUSP7-SIHA tumors were observed much earlier than siNC-SIHA tumors (7 ± 1 vs 12 ± 2 days; P = 0.0303). On the study end date, the siDUSP7-SIHA tumors were significantly larger than the siNC-SIHA tumors (3.66 ± 1.33 vs 0.75 ± 0.41 cm³; P = 0.0201).

Correlation between DUSP7 expression and the Ras pathway

The expression of HRAS and p-ERK1/2 was decreased in DUSP7-SIHA cells compared to NC-SIHA cells (P = 0.0003 and 0.0026, respectively; Fig. 8-B). In contrast, the expression of HRAS and p-ERK1/2 was significantly upregulated in shDUSP7-SIHA cells compared to control cells (P = 0.034 and 0.0026, respectively). The difference in the expression level of PLD1 between the two cell groups was not statistically significant (P = 0.0947 and 0.307, respectively).

Discussion

Proteomics, as the leading technology in the postgenomic era, plays an important role in screening diagnostic and therapeutic markers for many human malignancies [5]. In this analysis, the "sandwich" sampling method was adopted to ensure the accuracy of the histopathological results of the sampling. Cervical SCC and paired adjacent cervical tissues with the same genetic backgrounds and high comparability were used as the experimental and control groups, respectively. DEPs identified in this way could relatively objectively reflect the process of tumorigenesis and progression of CC. In this study, a total of 7811 proteins were identified through quantitative proteomics. The number of proteins identified in this study was large, and the quality of proteome detection was satisfactory.

In this study, 97 out of 129 DEPs were found to be related to tumorigenesis and the development of human malignancies, including 88 upregulated and 8 downregulated proteins. KEGG pathway analysis showed that 3 DEPs—HRAS, DUSP7, and PLD1—are RAS pathway components. WB and IHC staining analyses consistently confirmed the results of the quantitative proteomic analysis indicating that the HRAS, P-ERK1/2, and PLD1 levels were increased while the DUSP7 level was decreased in CC tissue compared with the paired normal paracancerous tissue. The RAS/RAF/ERK1/2 signaling pathway which involves members of the mitogen-activated protein kinase (MAPK) family, is pivotal in cell signaling networks [12]. The RAS/RAF/MEK/ERK pathway can trigger a series of cascade reactions,
namely, protein phosphorylation, amplification of upstream molecular signals and transduction of the signal into the nucleus, thus activating transcription, promoting gene expression, and stimulating infinite cell [12]. RAS has 4 isoforms: HRAS, NRAS, KRAS4A and KRAS4B[13]. HRAS gene overexpression can specifically activate RAF/MEK/ERK and accelerate the G1/S phase transformation of CC cells [14]. MEK/ERK activation is associated with CC cell resistance to cisplatin [15]. However, when a large number of phosphorylated ERKs accumulate in the nucleus, the use of the MEK-specific blocker U0126 cannot reverse the resistance response of ovarian cancer cells to cisplatin [16]. Exploring the regulatory mechanism of ERK1/2 and reversing its phosphorylation are future areas of focus for oncologists.

Based on our data, the decreased expression of DUSP7 and increased expression of PLD1 were significantly associated with a tumor size > 2 cm and parametrial infiltration. In addition, increased expression of p-ERK1/2 and PLD1 and decreased expression of DUSP7 in the CC tissue array were adversely related to patients’ relapse and survival. These results indicate that both DUSP7 and PLD1 have important regulatory roles in the tumorigenic effect of p-ERK1/2 in CC. DUSP7 is a member of the dual specificity phosphatase (DUSP) family. As a negative regulator of MAPK, DUSPs are involved in cell growth, differentiation, proliferation, migration, apoptosis and tumor formation [17, 18]. Many studies have confirmed that DUSPs are related to tumorigenesis and development. DUSP4 is considered a candidate tumor suppressor gene, and its deletion is related to the occurrence of breast cancer, rectal cancer, thyroid cancer and other tumors [19–21]. DUSP6 is expressed at low levels in the tumor tissues of many human malignancies, including ovarian cancer and endometrial cancer [22–24]. DUSP1 plays different roles in human tumorigenesis: it acts cancer-promoting factor in lung cancer, and leukemia [25–27], and as a tumor suppressor in head and neck SCC, prostate cancer, and urothelial bladder cancer [28–30].

DUSP7 gene is located on human chromosome 3p21 [31]. DUSP7 has a MAP kinase-binding domain/kinase-acting region that can specifically bind to p-ERK1/2, thus leading to its dephosphorylation. In this way, DUSP7 can promote the meiosis of oocytes [32], the loss of pluripotency in embryonic stem cells [15], and the differentiation of T cell [33]. Cooperation with DUSP6 and DUSP9 promotes the development of the middle ear and outer ear in mice [34]. However, the role of DUSP7 in the development of human tumors is still poorly understood and controversial. In 2003, Nissenbaum and his colleagues [35–37] found that DUSP7 was upregulated in peripheral blood mononuclear cells and bone marrow in patients with acute leukemia. However, a more recent study demonstrated that DUSP7 is a tumor suppressor gene. DUSP7 deletion has been identified in a variety of human mesothelioma cells [38] and tumor tissues [39]. DUSP7 activation can effectively block the cell cycle of (human or mouse) BRCA2-deficient cells and significantly inhibit proliferative activity [40]. Ham et al. [41] demonstrated that constitutive DUP6 and DUSP7 expression is inversely related to the expression of inducible DUSPs and the phosphorylation of ERK1/2 in lipopolysaccharide (LPS)-stimulated microglia. DUSP7 downregulation is associated with poor survival in patients with breast cancer [42]. However, the relationship between DUSP7 and tumorigenesis of CC has not been reported in the literature. In this analysis, high expression of DUSP7 significantly inhibited the proliferation, invasion and migration ability and EMT process of SIHA cervical cancer cells. The tumorigenesis ability of SIHA cells in nude mice was also inhibited in this way. In contrast, when DUSP7 expression was decreased, the anchorage-independent growth of SIHA cells was significantly increased. In addition, when DUSP7 mRNA levels were up- or downregulated, the expression of HRAS and p-ERK1/2 in SIHA cells was significantly reduced or increased, respectively. ERK inactivation arrested cells at late G1 phase and not prevented cells from entering S phase and from transitioning from G2 to M phase [43, 44]. Persistent ERK 1/2 phosphorylation is the key for signal transmission from surface receptors to the nucleus, and its continuous activation ultimately promotes cell proliferation and malignant transformation [45]. These data indicated that the biological function of DUSP7 is possibly achieved through dephosphorylation of ERK1/2 and inactivation of the RAS pathway. The expression level of PLD1 is not affected by the upregulation or
downregulation of DUSP7, and the effect of PLD1 on the progression of cervical cancer is not dependent on the activity status of DUSP7. The related mechanism remains unclear and warrants additional research.

**Conclusions**

DUSP7 is decreased in cervical cancer tissues compared to normal tissues. Increasing or decreasing DUSP7 expression was found to significantly reduce or enhance the anchorage-independent growth of SIHA cells, respectively. The biological function of DUSP7 is possibly achieved through dephosphorylation of ERK1/2 and inactivation of the RAS pathway. Upregulating the expression of DUSP7 may be useful for the prevention or treatment of CC.

Figures
Figure 1

The collection of cervical cancer (CC) and paired paracancerous tissue samples, the expression of differentially expressed proteins (DEPs), and the construction of CC tissue microarrays (TMA). Sample were collected according to the "Sandwich" method and obtained from 3 consecutive sites of suspicious lesions (C1/C2/C3) and normal-looking areas (N1/N2/N3). If the specimens at both ends (C2/C3, N2/N3) were consistently confirmed by pathological examination as cervical invasive carcinoma and normal cervical tissue respectively, then the middle specimens (C1 and N1) were qualified (Fig 1-A). Western Blot (Fig 1-B) and IHC (Fig 1-C) staining analyses consistently confirmed the results of the quantitative proteomic analysis that DEPs—HRAS, P-ERK1/2, and PLD1 levels were increased, whereas DUSP7 level was decreased in CC tissue compared with the paired normal paracancerous tissue. A total of 102 patients’ FFPE samples were included in the TMA (Fig 1-D).
Figure 2

The interaction of HRAS, DUSP7, PLD1, and phosphorylated ERK1/2 (p-ERK1/2).
The expression of DUSP7, PLD1 and p-Erk1/2 in CC TMA. The IHC results from the CC TMA analysis showed that the decreased expression of DUSP7 and increased expression of PLD1 and p-ERK1/2 were adversely related to patients’ relapse (P=0.003, 0.040, and 0.001, respectively; Fig 3) and survival (P=0.034, 0.001, and 0.006, respectively).
Figure 4

Establishment of stable DUSP7 knockdown and overexpression cell. Stable DUSP7 overexpressing cell lines were established by transducing SIHA cells with Lv-DUSP7 and were named DUSP7-SIHA cells (Fig 4-A and B). The qRT-PCR results showed that the DUSP7 mRNA level in DUSP7-SIHA cells was significantly higher than that in NC-SIHA cells (42.52 vs. 1, P<0.0001; Fig 4-C). Three specific shRNAs targeting DUSP7 were designed and synthesized. The qRT-PCR results showed that the silencing efficiencies of these shRNAs were 55%, 54% and 47% (All P < 0.0001) when siNC was used as a reference. Cells infected the most effective (55%) shRNA sequence (GCAUCAAGUAUAUCCUCAATT) were named siDUSP7-SIHA and used for subsequent experiments. The WB results indicated that the DUSP7 expression level in Dusp7-SIHA cells was significantly higher than that in NC-SIHA and wild-
type SIHA cells. In contrast, DUSP7 expression was significantly down-regulated in siDUSP7-SIHA cells compared to Dusp7-SIHA and wild-type SIHA cells (Fig 4-D and E).

Figure 5

The effect of DUSP7 on the biological function of SIHA cells (1) The CCK-8 assay growth curves showed that DUSP7-SIHA cells proliferated significantly slower than NC-SIHA cells, based on a clear delay in the doubling time (47.72±1.14 h vs. 23.99±0.47 h, P=0.0001; Fig 5-A). Cell cycle analysis indicated that the DUSP7-SIHA cells displayed a concomitant decrease in the percentage of cells in S phase (37.71±0.53% vs. 46.96±0.59%, P<0.0001) and a significant increase in the percentage of cells in G0/G1 phase (52.50±3.49% vs. 44.04±0.71%, P=0.0473; Fig 5-B). Colony formation assays showed that the number of colonies formed by DUSP7-SIHA cells was significantly less than that formed by NC-SIHA cells (44.67±9.0 vs. 75.33±14.47, P=0.0121; Fig 5-C). In contrast, the CCK-8 assay
growth curves showed that the doubling time of siDUSP7-SIHA cells was significantly shorter than that of siNC-SIHA cells (49.12±1.14 h vs. 64.14±0.47 h, P=0.0001; Fig 5-A). Cell cycle analysis indicated that siDUSP7-SIHA cells displayed a concomitant increase in the percentage of cells in S phase (49.54±1.53% vs. 46.4±0.97%, P=0.019) and a significant decrease in the percentage of cells in G0/G1 phase (41.8±0.38% vs. 45.2±0.80%, P=0.020; Fig 5-B). Colony formation assays showed that the number of colonies formed by siDUSP7-SIHA cells was significantly greater than that formed by siNC-SIHA cells (13.33±3.4 vs. 30.33±16.50, P=0.049; Fig 5-C).

Figure 6

The effect of DUSP7 on the biological function of SIHA cells (2) In the Matrigel invasion/migration assay, DUSP7-SIHA cells demonstrated a significantly weaker ability to invade and migrate through the membrane than control cells (P=0.0207 and 0.0059, respectively; Fig 6-A). Wound healing assays showed that the migration area of DUSP7-SIHA cells was significantly smaller than that of NC-SIHA cells (P=0.049; Fig 6-B). In contrast, DUSP7-SIHA cells demonstrated a significantly weaker ability to invade and migrate through the membrane than control cells. 
(P=0.0207 and 0.0059, respectively; Fig 6-A). The migration area of DUSP7-SIHA cells was significantly smaller than that of NC-SIHA cells (P=0.049; Fig 6-B).

Figure 7

The effect of DUSP7 on the EMT process of SIHA cells (3) E-cadherin expression was significantly increased but vimentin expression was significantly reduced in DUSP7-SIHA cells. In contrast, E-cadherin expression was significantly reduced, while vimentin expression was increased in siDUSP7-SIHA cells.
The role of DUSP7 in tumor formation in vivo and the correlation between DUSP7 expression and the Ras pathway. After subcutaneous injection, DUSP7-SIHA tumors were observed much later than NC-SIHA tumors (13±4 vs 6±1 days; P=0.0122; Fig 8-A). On the study end date, the DUSP7-SIHA tumors were significantly smaller than NC-SIHA tumors (0.74±0.38 vs 3.25±1.68 cm3; P=0.0183). In contrast, siDUSP7-SIHA tumors were observed much earlier than siNC-SIHA tumors (7±1 vs 12±2 days; P=0.0303). On the study end date, the siDUSP7-SIHA tumors were significantly larger than the siNC-SIHA tumors (3.66±1.33 vs 0.75±0.41 cm3; P=0.0201). The expression of HRAS and p-ERK1/2 was decreased in DUSP7-SIHA cells compared to NC-SIHA cells (P=0.0003 and 0.0026, respectively; Fig 8-B). In contrast, the expression of HRAS and p-ERK1/2 was significantly upregulated in shDUSP7-SIHA cells compared to control cells (P= 0.034 and 0.0026, respectively). The difference in the expression level of PLD1 between the two cell groups was not statistically significant (P=0.0947 and 0.307, respectively).
