Running title: Risk factors in COVID-19 patients with hypertension
ABSTRACT

**Background:** While hypertension is the most common comorbid condition in patients with coronavirus disease (COVID-19) in Korea, there is a lack of studies investigating risk factors in COVID-19 patients with hypertension in Korea. In this study, we aimed to examine the effects risk factors in hypertensive Korean COVID-19 patients.

**Methods:** We selected patients from the database of the project #OpenData4Covid19. This information was linked to their 3-year historical healthcare data. The severity of the disease was classified into five levels. We also clustered the levels into two grades.

**Results:** The risk factors associated with COVID-19 severity were old age, diabetes mellitus, cerebrovascular disease, chronic obstructive pulmonary disease (COPD), malignancy, and renal replacement therapy. The use of ACE inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) both before and after a diagnosis of COVID-19 were not associated with COVID-19 severity. A multivariate analysis revealed that old age, male sex, diabetes mellitus, and renal replacement therapy were risk factors for severe COVID-19.

**Conclusion:** The results suggest that in hypertensive patients with COVID-19, older age, male sex, a diagnosis of diabetes mellitus, and renal replacement therapy were risk factors for a severe clinical course. In addition, the use of ARBs and ACEIs before or after COVID-19 infection did not affect a patient’s risk of contracting COVID-19 nor did it contribute to a worse prognosis for the disease. These results highlighted that precautions should be considered for hypertensive patients with those risk factors and do not support discontinuation of ARBs and ACEIs during COVID-19 pandemic.

**Keyword:** COVID-19, Hypertension, Angiotensin receptor blocker (ARB), Angiotensin converting enzyme inhibitor (ACEI)
INTRODUCTION

Among laboratory-confirmed cases of coronavirus disease (COVID-19), patients with underlying disease such as hypertension, diabetes, cardiovascular disease, respiratory disease, and malignancy have a poorer clinical outcome. In 2016, the percentage of the Korean population that was diagnosed with hypertension was 29.1%. Due to its high prevalence, hypertension is the condition most comorbid with COVID-19 in Korea. While hypertension is a known prognostic indicator of disease severity and mortality in COVID 19, it is not clear whether this link is due to the actual hypertensive condition itself, the presence of other comorbidities, or the type of anti-hypertensive treatment regimen being followed.

There is also a debate concerning the role played by the angiotensin-converting enzyme 2 (ACE2) in the pathogenesis of COVID 19; angiotensin receptor blockers are the most frequently used monotherapy drugs in Korea. The debate centers around the effect of RAS modulators such as ACE inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) on severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infectivity. One school of thought is that these RAS modulators increase the risk of developing severe COVID-19, since ACE2 facilitates the entry of SARS-CoV-2 into the cell. Another school of thought is that these RAS modulators improve the clinical outcome of COVID-19 by regulating the immune function and attenuating the inflammatory response.

In this study, we assessed the effects of RAS modulators and other risk factors in COVID-19 patients with hypertension in Korea.
METHODS

Patient selection and classification

We selected patients selected from the database of the project #OpenData4Covid19, a global research collaboration on COVID-19, hosted jointly by the Ministry of Health and Welfare of Korea and the Health Insurance Review and Assessment Service (HIRA). The database contained information on the insurance benefit claims sent to HIRA including the data of all the patients that claimed for a COVID-19 test. This information was linked to their 3-year historical healthcare data. From January 3 to May 15, 2020, 234,427 individuals were tested for COVID-19, and 75,527 were diagnosed with hypertension. Of the 13,116 individuals that were on RAS modulators, 331 had a laboratory-confirmed COVID-19 diagnosis. Of the 62,411 individuals that were not on any RAS modulators, 1,580 had a laboratory-confirmed COVID-19 diagnosis. A flow-chart of patient selection is presented in Figure 1. This study was approved by the Institutional Review Board of Chungbuk National University Hospital (2020-04-015-001).

We merged the COVID-19 medical insurance claim data with the patient data and excluded cases of COVID-19 re-infection. The severity of the disease was classified into five levels: mild, moderate, severe, critical, and death. Each level of severity was defined according to the health insurance procedure code. Mild cases were defined by the lack of need for oxygen, moderate cases required oxygen therapy (M0040), severe cases required mechanical ventilation (M0850, M0857, M0858, M0860, M5830, M5850, M5857, M5858, M5860), and critical cases required extracorporeal membrane oxygenation (ECMO) (O1903, O1904). We also clustered the levels into two grades. Moderate, severe, critical, and death levels were clustered as Severe grade 1, while severe, critical, and death levels were clustered as Severe grade 2.

Comorbidities was identified using the International Classification of Disease, 10th revision (ICD-10) codes: hypertension I10, diabetes mellitus E10-E14, cardiovascular disease (I11-I13), cerebrovascular
disease (I60-I69), ischemic heart disease (I20-I25), and chronic obstructive pulmonary disease (J440, J441, J448, J449).

We used expanded benefit coverage codes or specific exemption codes for rare incurable diseases to identify malignancy (V193) and renal replacement therapy (V001, V003, V005). The use of ACEI and ARB was identified by their specific ATC code: angiotensin-converting enzyme (ACE) inhibitors (C09AA, C09BA, C09BB, C09Bx) and angiotensin-receptor II blockers (C09CA, C09DA, C09DB, C09DX).

We defined exposure to antihypertensive medication before diagnosis of COVID-19 as at least one prescription of antihypertensive medication from January 1, 2020 until the diagnosis of COVID-19. This information was obtained from inpatient and outpatient prescription records of antihypertensive medication.

**Statistical Analyses**

Univariate analysis was performed using a chi-square test. Multivariate analysis was performed using logistic regression to evaluate the association between selected clinical characteristics and a likelihood of a positive test for COVID-19/COVID-19 severity. SAS Enterprise Guide Software version 6.1 (SAS Institute Inc, Cary, NC) was used for these analyses, and a $P$ value of less than .05 was considered statistically significant.
RESULTS

Table 1 reports the characteristics of the study population of patients tested for COVID-19. Until 15th May, 2020, a total of 234,427 patients were tested for COVID-19 and 7,590 (3.2%) had a positive result. Among the patients tested for COVID-19, 75,527 (32.2%) had a history of hypertension; of these, 1,911 (2.5%) were COVID-19-positive and 13,116 (17.4%) patients took ACE inhibitors or ARBs. Patients with hypertension were likely to be older and have more comorbidities than those without.

Compared to patients who tested negative for COVID-19, those that tested positive were more likely to be younger (OR: 80.67) and women (OR 56.63) (Table 2). COVID-19 was confirmed more frequently in people without comorbidities, such as diabetes mellitus, cerebrovascular diseases, ischemic heart disease, COPD, malignancy, and renal replacement therapy. Use of ACEI or ARB was not different between two groups.

Multivariate analysis revealed that laboratory confirmed cases were less prevalent in males and individuals with cerebrovascular disease, ischemic heart disease, chronic obstructive pulmonary disease, malignancy, and renal replacement therapy (Table 3). Compared to the <60 years age group, confirmed COVID-19 cases were more frequent in the 61-69 years age group; however, they were less frequent in the ≥80 years age group.

Univariate analysis of risk factors associated with COVID-19 severity revealed that old age, diabetes mellitus, cerebrovascular disease, COPD, malignancy, and renal replacement therapy were significant risk factors for severe COVID-19 (Table 4). Use of ACEI or ARB before or after diagnosis of COVID-19 was not associated with the severity of COVID-19. Multivariate analysis revealed that old age, male sex, diabetes mellitus, and renal replacement therapy were risk factors for severity of COVID-19 (Table 5).
DISCUSSION

Being older and of the male sex have been described as risk factors for a highly severe disease course in patients with COVID-19. In China, case fatality rate (CFR) for those ≥80 years of age was 14.8% and in Korea, it was 14%. The CFR was also much higher in regions with collapsed health care systems. A recent study showed that men had a higher case of fatality that was independent of age. This finding is thought to be due reasons such as gender specific life behavior patterns or sex differences in immune responses. Another report from China indicated that ACE2 levels which are correlated with organ failure are higher in men than women. Caution should be taken to treat COVID-19 patient with diabetes mellitus, since patients with diabetes mellitus have a poorer prognosis especially when metabolic complications of pre-existing diabetes are observed. In our study of hypertensive patients with COVID-19, older age, male sex, a diagnosis of diabetes mellitus, and renal replacement therapy were risk factor for a more severe clinical prognosis for the disease.

While recent studies have implicated the presence of comorbidities as well as pro-inflammatory and pro-coagulative states in severe COVID-19 outcomes, SARS-CoV-2 itself also has a negative effect on beta cell functions, precipitating acute metabolic complications. Patients on dialysis have depressed immune systems and usually have other comorbidities. A meta-analysis has shown that chronic kidney disease (CKD) seems to be associated with an enhanced risk of severe COVID-19 infection. These patients are also at a higher risk of contracting COVID-19, since the in-center hemodialysis units are often very densely populated. Our data indicated that patients on dialysis are at greater risk of severe COVID-19 infection.

There are conflicting reports on the effects of ARBs or ACEIs on the clinical results of patients with COVID-19. While clinical evidence indicates that these drugs can protect the lung from pneumonia and reduce SARS-CoV-2 -induced lung injury, other researchers recommend discontinuing their use.
on the grounds that their use may enhance the risk of COVID-19. This is based on experimental findings that ARBs upregulate ACE and may thus enhance viral uptake and increase its virulence.\(^4\)

SARS-CoV-2 uses the ACE2 receptor for entry into the cell, and there have been concerns about whether these RAS modulators can upregulate the ACE2 receptor and modify susceptibility to COVID-19.\(^17\)

Current research has demonstrated that use of either ACEIs or ARBs does not increase the likelihood of a positive test, and experts recommend that ACEI and ARB treatment regimens not be withdrawn.\(^18\) The prevailing consensus is that being on either an ARB or ACEI treatment protocol, is not associated with a higher risk of testing positive for COVID-19. After adjusting age, sex and comorbidities, our study confirms that the use of ARBs and ACEIs is not associated with a greater severity of COVID-19 and supports the view that patients on ACEI or ARB treatment regimens should continue their medication as prescribed.

Our study has four limitations. First, the findings cannot be generalized to the general population due to the inhomogeneity of the study population. From February 18 until May 15, 2020 the large number of COVID-19 cases in Korea stemmed from a religious group in the Daegu and Gyeongbuk provinces and we were not able to correlate data regarding religion, contact with a confirmed case, and real area of residence. Therefore, in our study, the COVID-19 exposure risk and the susceptibility to COVID-19 may be biased. Second, we were not able to analyze laboratory data and data regarding antiviral and steroid usage. Third, the severity of cases was identified and analyzed for all cases. Therefore, the level of severity may have been underestimated, because many of the open cases could end in death. Fourth, actual drug exposure to RAS modulators could not be quantified since the electronic health data did not include detailed data regarding patient compliance and the dose of the medication used.
In conclusion, we found that in hypertensive patients with COVID-19, older age, male sex, a diagnosis of diabetes mellitus, and renal replacement therapy were risk factors for a severe clinical course. In addition, the use of ARBs and ACEIs before or after COVID-19 infection did not affect a patient’s risk of contracting COVID-19 nor did it contribute to a worse prognosis. To prioritize at-risk populations and allocate resource, precautions should be considered for hypertensive patients with those risk factors and our data do not support discontinuation of ARBs and ACEIs during COVID-19 pandemic.
