Thermal production of $J/\psi$ within quark gluon plasma is reconsidered. We show that if screening effects are not strong enough, the “in-plasma born” $J/\psi$’s would show up as a peak in the Feynman momentum distribution at $x_F = 0$.

I. INTRODUCTION

Over the past fifteen years charmonium suppression has been considered as one of the best signatures of quark gluon plasma (QGP) formation. Recently this belief was questioned by some works. $J/\psi$ suppression in relativistic heavy ion collisions is based on the following simple argument, presented in the original work by Matsui and Satz [1]. Lattice simulations show that the heavy quark-antiquark potential becomes screened at high enough temperatures. As a consequence, when the range of the potential becomes smaller than the $J/\psi$ Bohr radius the bound state can no longer be formed. On the other hand, detailed simulations [2] of a population of $c\bar{c}$ pairs traversing the plasma suggested that, given the large number of such pairs, the recombination effect of the pairs into charmonium Coulomb bound states is non-negligible and might even lead to an enhancement of $J/\psi$ production. This conclusion received support from the calculations of [3], where a two component model for $J/\psi$ production was proposed.

Taking the existing calculations seriously, it is no longer clear that an overall suppression of the number of $J/\psi$’s will be a signature of QGP. A more detailed analysis is required and a more complex pattern can emerge. In particular, we might have suppression in some regions of the phase space and enhancement in others. Indeed, this is the result of the analysis presented in [4]. In that work the authors study the fate of $c\bar{c}$ pairs produced in the early stage of heavy ion collisions, comparing the case where they have to traverse QGP with the case where they have to traverse ordinary nuclear matter. One of the merits of that paper is to emphasize that very interesting information can be extracted from the scaled momentum ($x_F$) distribution of the produced $J/\psi$'s.

Motivated by these observations, in this work we address the $J/\psi$ Feynman momentum distributions. In some aspects we follow refs. [3] and [4] with one important difference: we include $J/\psi$ production within the plasma. This is usually neglected because the number of $c\bar{c}$ pairs produced in the plasma is believed to be small. However, as it will be discussed in section III, a closer look into the existing estimates shows discrepancies of two orders of magnitude. In [5], for example, it was estimated to be of the order of 1% of the total number of charm quark pairs. In [6], with the inclusion of thermal parton masses this fraction was estimated to reach 20 – 30%. Finally, in [7] this number could, in some cases, be equal to the number of directly produced pairs. No systematic effort was made to reconcile these different estimates mainly because the screening mechanism was believed to destroy all bound states. Therefore in-plasma charm production has been an issue of open charm physics whereas the main focus has always been on hidden charm production and suppression.

Although well established in several lattice calculations [8], the color screening mechanism may be not so effective in real collisions. The existing lattice results are valid for an infinite mass, static, charge-anticharge pair and we know that this is not very close to the real situation, where charges are not so heavy and are moving. Recently, a calculation of the screening effect in moving charges [9] showed that, in this case the screening is not so strong. With the improvements of lattice gauge determinations [8] of the temperature-dependent quark-antiquark potential new calculations of the quarkonium spectrum in QGP were performed. In [10] it was found that at up to temperatures of the order of 1.10 $T_c$ the $J/\psi$ can survive as a bound state in the plasma. At higher temperatures the potential is too shallow to hold a bound charmonium state.

We shall assume that screening is not so strong and, in a narrow temperature window just above the phase transition, will allow for charmonium (Coulomb) bound states which “survive” from QGP. More precisely, we will allow up to one in hundred bound states to survive in the region where they should be screened and destroyed. As it will be seen, these “survivors” tend to escape with $x_F \simeq 0$, thus giving us a new kind of QGP signal. Moreover, this peak at low $x_F$ will fill the dip predicted in [4].
We will consider $J/\psi$ production in nucleus-nucleus collisions by three different mechanisms: i) direct (primordial QCD parton fusion) ii) thermal (statistical coalescence at hadronization) and iii) QGP (in-plasma parton fusion). As already discussed in [3] i) and ii) are just two extreme cases. In realistic simulations, for a fixed number of $c\bar{c}$ pairs and of $J/\psi$'s, these last are gradually destroyed, giving origin to the “regenerated” component ii). In the particular calculation presented in [3], for central collisions and for high enough energies a near to complete replacement of the initial by the final thermal $J/\psi$'s was found. Component iii) was considered long time ago [11], before the work of Matsui and Satz, and then it was left in oblivion. Once produced the charmonium state will suffer interactions with the partons in the plasma, or with hadrons in hot and dense medium and in a later stage with comoving hadrons [12,13].

Before performing detailed calculations one could try to guess the shape of the outgoing $J/\psi$'s $x_F$ distribution in the three mechanisms mentioned above. QCD production has been studied in the past and the naive extrapolation [12,13]. Matsui and Satz, and then it was left in oblivion. Once produced the $c\bar{c}$ bound state will suffer interactions with the plasma or with hadrons in hot and dense medium and in a later stage with comoving hadrons.

The text is organized in the following way: in section II we describe direct production; in sections III and IV we address production in the plasma and final thermal production respectively; in section V we discuss final state interactions; in section VI we present numerical results and in the last section we make some concluding remarks.
II. INITIAL $J/\psi$ PRODUCTION IN NUCLEUS-NUCLEUS COLLISIONS

Nowadays perturbative QCD calculations of $c\bar{c}$ production can be found in textbooks. Nevertheless, we shall, in what follows, give some formulas to introduce the notation, to stress the role played by shadowing and to obtain expressions in terms of $x_F$, the variable of interest. One popular approach to charm production is the color evaporation model [15,18,19]. We are aware of the discrepancies between different implementations of perturbative QCD in charm production [18]. In particular, there is another model, namely the color octet model [20], which gives a more sophisticated description of the hadronization process in terms of non-perturbative matrix elements. While the COM seems to give a very good description of high $p_T$ data ($p_T > 2$ GeV), especially those from the Fermilab Tevatron, it is not so reliable at smaller $p_T$ [21] ($p_T < 2$ GeV), where the bulk of charm production takes place and where we wish to make a comparison between QCD and plasma production. For our purpose of studying the $x_F$ distributions, as can be inferred from the calculations presented in [22], the COM prediction is compatible with a smooth behavior of the cross section $d\sigma/dx_F$ at the origin $x_F \simeq 0$, much like the CEM. Therefore, for simplicity, we shall use this latter model in what follows. Our results will certainly depend on the choice of approach. Inspite of the uncertainties, we will assume that, since we are interested in the low $x_F$ region, pQCD is enough and nonperturbative effects are small, in sharp contrast to what happens at large $x_F$ [23].

In the CEM, charmion is defined kinematically as a $c\bar{c}$ state with mass below the $D\bar{D}$ threshold. In leading order (LO) the cross section is computed with the use of perturbative QCD for the diagrams of the elementary processes $q\bar{q} \rightarrow c\bar{c}$ and $gg \rightarrow c\bar{c}$ convoluted with the parton densities in the projectile and in the target. Calling $x_F$ the fractional momentum of the produced pair (with respect to the momentum of a projectile nucleon in cm frame) and $\sqrt{s}$ the cm energy of a nucleon-nucleon collision, the cross section for production of a $c\bar{c}$ pair with mass $m$ is just given by:

$$
\frac{d\sigma^{pp \rightarrow c\bar{c}}}{dx_F dm^2} = \frac{1}{s \sqrt{x_F} \sqrt{4m^2/s}} H(x_{01},x_{02};m^2) ; \quad x_{01,02} = \frac{1}{2} \left( \pm x_F + \sqrt{x_F^2 + 4m^2/s} \right)
$$

where $x_1$ and $x_2$ are the nucleon momentum fractions carried respectively by partons in the projectile and target. The function $H(x_1,x_2;m^2)$, which represents the convolution of the elementary cross sections and parton densities is given by:

$$
H(x_1,x_2;m^2) = f_q(x_1,m^2) f_g(x_2,m^2) \hat{\sigma}_{gg}(m^2) + \sum_{q=u,d,s} [f_q(x_1,m^2) f_q(x_2,m^2) + f_q(x_1,m^2) f_{q\bar{q}}(x_2,m^2)] \hat{\sigma}_{q\bar{q}}(m^2)
$$

with the parton densities $f_i(x,m^2)$ in the nucleon computed at the scale $m^2 = x_1 x_2 s$.

The LO elementary cross sections in terms of the pair invariant mass $(m)$ are given by [24]:

$$
\hat{\sigma}_{gg}(m^2) = \frac{\pi \alpha_s^2(m^2)}{3m^2} \left\{ \left( 1 + \frac{4m_c^2}{m^2} + \frac{m_c^4}{m^4} \right) \ln \left[ \frac{1 + \lambda}{1 - \lambda} \right] - \frac{1}{4} \left( 7 + \frac{31m_c^2}{m^2} \right) \lambda \right\}
$$

$$
\hat{\sigma}_{q\bar{q}}(m^2) = \frac{8\pi \alpha_s^2(m^2)}{27m^2} \left( 1 + \frac{2m_c^2}{m^2} \right) \lambda \quad ; \quad \lambda = \left[ 1 - \frac{4m_c^2}{m^2} \right]^{1/2}
$$

where $m_c$ is the mass of the c quark.

The production cross section of the charmed state $i$ (= $J/\psi$, $\psi'$ or $\chi_c$) $\sigma_i$, is then finally obtained by integrating the free pair cross section $c\bar{c}$ over the invariant mass $m$ starting from the production threshold $2m_c$ up to open charm production threshold $2m_D$:

$$
\frac{d\sigma^{pp \rightarrow J/\psi}}{dx_F} = F_{J/\psi} \int_{2m_c^2}^{4m_D^2} dm^2 \frac{d\sigma^{pp \rightarrow c\bar{c}}}{dx_F dm^2}
$$

where $F_{J/\psi}$ is the fraction of $\sigma^{c\bar{c}}$ which contains the corresponding $c\bar{c}$ resonance.

This model describes well the experimentally measured $x_F$ distribution of hidden charm both with LO and NLO cross sections, provided that $F_i^{LO}$ is defined as $F_i^{NLO} \kappa$, which is equal to the ratio of the NLO and LO cross sections ($F_{J/\psi}^{NLO} \approx 2.54\%$) [25].

3
In what follows we shall use the CEM to study perturbative $J/\psi$ production in nucleus-nucleus collisions at RHIC. As it is well known, in nuclear collisions and in processes involving small values of $x$, shadowing plays an important role (see, for example, [26]). In this case expression (5) is rewritten as:

$$H_{AB}(x_1, x_2; m^2) = AB \left\{ f_g(x_1, m^2) R_g^A(x_1, m^2) f_g(x_2, m^2) R_g^B(x_2, m^2) \sigma_{gg}(m^2) \right. $$

$$+ \sum_{q=u,d,s} \left[ f_q(x_1, m^2) R_q^A(x_1, m^2) f_\bar{q}(x_2, m^2) R_\bar{q}^B(x_2, m^2) \right. $$

$$\left. + f_\bar{q}(x_1, m^2) R_\bar{q}^A(x_1, m^2) f_q(x_2, m^2) R_q^B(x_2, m^2) \right] \sigma_{q\bar{q}}(m^2) \}$$

(9)

where

$$R_i^A(x, m^2) = \frac{f_i^A(x, m^2)}{f_i(x, m^2)}$$

(10)

with $f_i^A(x, m^2)$ being the $i$ parton momentum distribution in a nucleon inside the nucleus $A$. Replacing $H$ by $H_{AB}$ in (4) we obtain the cross section for $c\bar{c}$ production in $A - B$ collisions:

$$\frac{d\sigma_{AB\rightarrow c\bar{c}}}{dx_F} = \kappa \int_{4m_F^2}^{\infty} dm^2 \frac{1}{s \sqrt{x_F^2 + 4m^2/s}} H_{AB}(x_{01}, x_{02}; m^2)$$

(11)

and the $J/\psi$ production cross section as:

$$\frac{d\sigma_{AB\rightarrow J/\psi}}{dx_F} = \kappa F_{J/\psi}^{NLO} \int_{4m_F^2}^{4m_{B}^2} dm^2 \frac{1}{s \sqrt{x_F^2 + 4m^2/s}} H_{AB}(x_{01}, x_{02}; m^2)$$

(12)

In a central $A + A$ collision the number of $J/\psi$'s produced directly is related to the cross section by [27]:

$$\frac{dN_{\text{direct}}^{AA\rightarrow J/\psi}}{dx_F} \approx \frac{1}{\pi R_A^2} \frac{d\sigma_{AA\rightarrow J/\psi}}{dx_F}$$

(13)

where $R_A$ is the radius of nucleus $A$.

The expression above would give the final distribution if there were no absorption due to further interactions with partons in a QGP or hadrons in a comoving fireball. The effect of these final state interactions will be discussed later.

Since we are going to compare the total number of initially produced $c\bar{c}$ pairs and $J/\psi$'s with those produced in the plasma it is useful to introduce the compact notation

$$N_{QCD}^{c\bar{c}} = \frac{1}{\pi R_A^2} \int_0^1 dx_F \frac{d\sigma_{AA\rightarrow c\bar{c}}}{dx_F}$$

(14)

for the number of $c\bar{c}$ pairs and

$$N_{QCD}^{J/\psi} = \int_0^1 dx_F \frac{dN_{\text{direct}}^{AA\rightarrow J/\psi}}{dx_F}$$

(15)

for the number of $J/\psi$'s.

Expressions (14) and (15) are calculated with the nuclear parton distributions which take shadowing into account. While this makes calculations more realistic, it also introduces some model dependence in the results. In order to have a baseline for comparisons it is useful to introduce the equivalent definitions of $N_{QCD}^{c\bar{c}}$ and $N_{QCD}^{J/\psi}$ without shadowing. For central $A - A$ collisions these are:

$$N_{QCD}^{c\bar{c}} = T_{AA}(b = 0) \int_0^1 dx_F \frac{d\sigma_{pp\rightarrow c\bar{c}}}{dx_F} \quad \text{(no shadowing)}$$

(16)

and
where \( T_{AA} \) is the usual nuclear overlap function. In Table I we present some quantitative results for (14), (15), (16) and (17). As it can be seen, these numbers change with different choices for the charm quark mass and for the parton distribution. Inclusion of shadowing reduces the number of charm quark pairs and (17). As it can be seen, these numbers change with different choices for the charm quark mass and for the parton densities may change these numbers in 40\% but what changes the most our results is the adopted distribution. Inclusion of shadowing reduces the number of charm quark pairs and (18). As it can be seen, these numbers change with different choices for the charm quark mass and for the parton densities may change these numbers in 40\% but what changes the most our results is the adopted distribution.

In the expression above we have:

\[ \frac{dN^{gg\rightarrow c\bar{c}}}{dt d^3x} = \frac{1}{2(2\pi)^6} g_s^2 \int d^3p_1 d^3p_2 f_g(E_1) f_g(E_2) \hat{\sigma}_{gg}^{LO}(m^2) v_{12} \] (18)

where \( g_s \) is the gluon statistical factor (number of colors \( \times \) number polarization states) \( v_{12} \) is the relative velocity between colliding gluons with energies \( E_1 \) and \( E_2 \) and three momenta \( \vec{p}_1 \) and \( \vec{p}_2 \), \( \hat{\sigma}_{gg}^{LO} \) is the elementary gluon-gluon cross section (6) and \( f_g(E_i) \) the usual thermal distribution function:

\[ f_g(E_i) = \frac{1}{e^{E_i/T} - 1} \] (19)

We now introduce the charm pair four momentum \( p \) with help of the delta function \( \delta^4[p - (p_1 + p_2)] \):

\[ \frac{dN^{gg\rightarrow c\bar{c}}}{d^4p} = \frac{1}{2(2\pi)^6} g_s^2 \int d^3x d^3p_1 d^3p_2 f_g(E_1) f_g(E_2) \hat{\sigma}_{gg}^{LO}(m^2) v_{12} \delta^4[p - (p_1 + p_2)] \] (20)

In the expression above we have:

\[ p_1 \equiv (E_1, \vec{p}_{T_1}, p_{z1}) \quad p_2 \equiv (E_2, \vec{p}_{T_2}, p_{z2}) \quad p \equiv (E, \vec{p}_T, p_z) \] (21)

\[ m^2 = (p_1 + p_2)^2 \quad v_{12} = \frac{m^2}{2 E_1 E_2} \] (22)

where \( m \) is the invariant mass of the pair. We next decompose the delta function into temporal, transverse and longitudinal components.
\[
\frac{dN^{gg\rightarrow c\bar{c}}}{dm^2dp_Tdp_z} = \frac{1}{4(2\pi)^6} g_g^2 \int dtd^3x \frac{1}{E_1} d^3p_1 \frac{1}{E_2} d^3p_2 f_g(E_1) f_g(E_2) \delta_{gg}^{LO}(m^2) m^2 \\
\times \delta[m^2 - (p_1 + p_2)^2] \delta^2[\vec{p}_T - (\vec{p}_{T1} + \vec{p}_{T2})] \delta[p_z - (p_{z1} + p_{z2})]
\]

Making use of the identity
\[
\frac{1}{2E_i} d^3p_i = \int d^3p \delta(p_i^2) \theta(E_i) = \int dE_i dp_T dp_z \delta[E_i^2 - p_i^2 - p_{z1}^2] \theta(E_i)
\]

we arrive at:
\[
\frac{dN^{gg\rightarrow c\bar{c}}}{dm^2dp_Tdp_z} = \frac{1}{4(2\pi)^6} g_g^2 \int dtd^3x \int_0^\infty dE_1 \int_{-\infty}^{\infty} dp_T \int_{-\infty}^{\infty} dp_z \delta[E_i^2 - p_i^2 - p_{z1}^2] \theta(E_i)
\times \int_0^\infty dE_2 \int_{-\infty}^{\infty} dp_T \int_{-\infty}^{\infty} dp_z \delta[E_2^2 - p_t^2 - p_{z2}^2] \theta(E_2) f_g(E_1) f_g(E_2)
\times \delta_{gg}^{LO}(m^2) \delta[m^2 - (p_1 + p_2)^2] \delta^2[\vec{p}_T - (\vec{p}_{T1} + \vec{p}_{T2})] \delta[p_z - (p_{z1} + p_{z2})]
\]

Integrating in \(p_z, p_T, p_{T1}\) and \(E_1\) and defining \(\beta\) as the angle between \(\vec{p}_T\) and \(\vec{p}_{T1}\), we finally obtain:
\[
\frac{dN^{gg\rightarrow c\bar{c}}}{dp_z} = \frac{\pi}{4(2\pi)^6} g_g^2 \int_{4m^2}^{\infty} dm^2 \int_0^{\infty} dp_T \int_0^{2\pi} d\beta \int dtd^3x \int_{-\infty}^{\infty} dE_1 \int_{-\infty}^{\infty} dp_z f_g(E_1) f_g(E - E_1)
\times \delta_{gg}^{LO}(m^2) \frac{m^2}{E} \delta[m^2 - 2EE_1 + 2p_T(E_1^2 - p_{z1}^2)^{1/2} \cos(\beta) + 2p_zp_{z1}]
\times \theta(E_1) \theta(E - E_1)
\]

where \(E, H(h_{1,2})\) and \(h_{1,2}\) are given by:
\[
E = [m^2 + p_T^2 + p_{z1}^2]^{1/2} ; \quad H(h_{1,2}) = 2p_z - \frac{2p_T \cos(\beta)}{(E_1^2 - h_{1,2}^2)^{1/2}} h_{1,2}
\]
\[
h_{1,2} = \frac{1}{2} \frac{1}{p_T^2 + p_{z1}^2 \cos^2(\beta)} \left\{ p_z(2EE_1 - m^2) \mp \{p_T^2 \cos^2(\beta)
\times \delta^4(E_1^2 \{p_T^2 \cos^2(\beta) + p_{z1}^2 - (m^2 - 2EE_1^2)\})^{1/2} \right)}
\]

In the first line of (26) we have \(\delta[m^2 - 2EE_1 + 2p_T(E_1^2 - p_{z1}^2)^{1/2} \cos(\beta) + 2p_zp_{z1}]\). It is easy to see that taking either \(E_1 \approx p_z\) or \(E_1 >> p_z\) and using the \(\delta\) function to perform the integral in \(p_z\), we obtain a factor \(1/p_z\). This factor survives and, at the end, gives the \(1/x_F\) structure (3) mentioned in the introduction. The actual numerical calculation involves no approximation and has a similar behavior. Notice that, because of the kinematical cuts in the invariant mass integral, we are now restricting the result to the rate to charmonium states. A similar expression can be derived for \(c\bar{c}\) production originating from quark-antiquark annihilation:
\[
\frac{dN^{q\bar{q}\rightarrow c\bar{c}}}{dp_z} = \frac{\pi}{2(2\pi)^6} g_{q\bar{q}}^2 \delta_{q\bar{q}} \sum_{q=u,d,s} \int_{4m^2}^{\infty} dm^2 \int_0^{\infty} dp_T \int_0^{2\pi} d\beta \int dtd^3x \int_{-\infty}^{\infty} dE_1 f_q(E_1) f_{\bar{q}}(E - E_1)
\times \delta_{q\bar{q}}^{LO}(m^2) \frac{m^2}{E} \left[ \frac{1}{|H(h_1)|} \theta(E_1^2 - h_1^2) + \frac{1}{|H(h_2)|} \theta(E_1^2 - h_2^2) \right] \theta(E_1) \theta(E - E_1)
\]
\[ f_{q,q}(E_1) = \frac{1}{e^{E_1/T} + 1} \] (30)

In order to account for expansion effects we shall assume that the system cools down following Bjorken hydrodynamics, in which temperature and proper time are related by [30]:

\[ \frac{T(\tau)}{T_0} = \left( \frac{\tau_0}{\tau} \right)^{1/3} \] (31)

where \( T_0 \) is the initial temperature and \( \tau_0 \) is the thermalization time, which marks the beginning of the hydrodynamical expansion. With the help of this relation we can perform the following change of variables:

\[ dtd^3x = dx_\perp \tau dy d\tau = -3 dV \tau_0 T_0^4 T^{-4} dT \quad \Rightarrow \quad \int dtd^3x = 3 \int_{T^\prime}^{T_0} \tau_0 T_0^3 T^{-4} V(T) dT \] (32)

Finally we introduce the energy scale \( \sqrt{\mathcal{S}} \) (the invariant energy of a single nucleon-nucleon collision):

\[ p_z = x_F \sqrt{\mathcal{S}} \] (33)

Expressions (26) and (29) can thus be rewritten as:

\[
\frac{dN^{gg\rightarrow c\bar{c}}}{dx_F} = \frac{3\pi}{8(2\pi)^6} g_s^2 \sqrt{\mathcal{S}} \kappa \int_{4m_c^2}^{\infty} dm^2 \int_0^{2\pi} dp_T^2 \int_0^{\pi} d\beta \int_{T^\prime}^{T_0} \tau_0 T_0^3 T^{-4} V(T) dT \int_0^{\infty} E dE_1 \\
\times f_q(E_1) f_{q}(E - E_1) \delta_{gq}^{LO}(m^2) \frac{m^2}{E} \left[ \frac{1}{|H(h_1)|} \theta(E_1^2 - h_1^2) + \frac{1}{|H(h_2)|} \theta(E_1^2 - h_2^2) \right] \\
\times \theta(E_1) \theta(E - E_1) 
\] (34)

\[
\frac{dN^{q\bar{q}\rightarrow c\bar{c}}}{dx_F} = \frac{3\pi}{4(2\pi)^6} g_s^2 \sqrt{\mathcal{S}} \kappa \sum_{g = u, d, s} \int_{4m_c^2}^{\infty} dm^2 \int_0^{2\pi} dp_T^2 \int_0^{T_0} \tau_0 T_0^3 T^{-4} V(T) dT \int_0^{\infty} E dE_1 \\
\times f_q(E_1) f_{q}(E - E_1) \delta_{qg}^{LO}(m^2) \frac{m^2}{E} \left[ \frac{1}{|H(h_1)|} \theta(E_1^2 - h_1^2) + \frac{1}{|H(h_2)|} \theta(E_1^2 - h_2^2) \right] \\
\times \theta(E_1) \theta(E - E_1) 
\] (35)

The volume of the system evolves in time according to:

\[ V(\tau) = V_0 \frac{\tau}{\tau_0} \quad \Rightarrow \quad V(T) = V_0 \left( \frac{T_0}{T} \right)^3 \] (36)

where \( V_0 = \pi R_A^2 \tau_0, R_A = (1.18 A^{1/3} - 0.45) \) fm and the \( \kappa \) factor was introduced explicitly.

Summing Eqs. (34) and (35) and integrating over \( x_F \) we obtain the total number of in-plasma produced \( c\bar{c} \) pairs, which we call \( N_{QGP}^{c\bar{c}} \).

B. Comparison with other works

We shall now compare the number of \( c\bar{c} \) obtained in this work with the number of charmed pairs obtained in other works. There are some known papers on the subject [5–7,32,33]. From the reading of these papers, we conclude that there are large discrepancies in the numbers and in the way to obtain them. The sources of these discrepancies are:

a) initial temperature of the plasma, \( T_0 \) (ranging from 300 MeV to 550 MeV)
b) degree of parton equilibration (described by the fugacity factors)
c) initial volume and/or thermalization time, \( V_0 \) and \( \tau_0 \)
d) total energy contained in the fireball
e) use or not of a \( \kappa \) factor (=2) in computing thermal rates
f) use or not of temperature dependent \( \alpha_s \)
g) mass of the charm quark \( m_c \) (going from 1.2 to 1.5 GeV)
Depending on the choices that one has to make in dealing with a) → h) the final value of in-plasma produced $c\bar{c}$ pairs can change by orders of magnitude, going roughly from $N_{QGP}^{c\bar{c}} = 0.02$ in [5] to up 15 in [32]. In a comprehensive analysis this same variation was found in [7]. In [6], the authors arrive to the conclusion that in-plasma production was only a factor two smaller than the initial production. However in that paper the factor $\kappa = 2$ was not included in calculation. If it were, then $N_{QGP}^{c\bar{c}} \simeq N_{QCD}^{c\bar{c}}$.

The list of uncertainties given above is not unique and could be enlarged. Each of the items implies taking a decision or making an assumption. Since the list is already large it seems that a high precision calculation is hopeless. In fact the situation is not so bad since our knowledge will increase both because of new experimental results and because of lattice results. RHIC data will impose severe constraints on items from a) to d). For example, taking together data from all the four collaborations, we may expect to know with sufficient accuracy the rapidity distribution of charged particles, from which we can have a good knowledge of the total energy contained in the fireball (item d)). The global analysis of data on rapidity, $p_T$ spectra, abundancies, elliptic flow and HBT interferometry, will eventually rule out several initial conditions used in hydrodynamical models and we will have much less uncertainty in the initial temperature of the plasma. On the theoretical side, the perturbative QCD analysis of other processes like, for example, $J/\psi$ photoproduction or $J/\psi$ production in $e^-e^+$ collisions may significantly reduce the uncertainty in the charm quark mass (item g)). Lattice calculations at finite temperature will hopefully reduce the freedom in the choices of items f) and h). A review of what we may learn in the field in a near future can be found in the summary talk presented by Pisarski in the last Quark Matter meeting [34].

We have explicitly investigated the effect of changing the mass of the quark $c$ and the differences which arise when we use the coupling constant running with $m^2$:

$$\alpha_s(m^2) = \frac{12\pi}{(33 - 2N_F)\ln \frac{m^2}{\Lambda_{QCD}^2}}$$

(37)

or with $T$ [6]:

$$\alpha_s(T) = \frac{6\pi}{(33 - 2N_F)\ln \frac{\Lambda_T^2}{m_s^2}}$$

(38)

where $N_F = 3$, $\Lambda_{QCD} = 230$ MeV and $\Lambda_{\overline{MS}} = 80$ MeV.

In Table II we present our results for the number of “in-plasma born” $c\bar{c}$ pairs for different values of couplings and charm quark masses. All the calculations were done with an initial plasma temperature of $T_0 = 550$ MeV, $\alpha_s(M^2)$ and $\alpha_s(T)$ are given by (37) and (38) respectively. The numbers inside parenthesis correspond to the choice $\kappa = 1$. Otherwise the numbers were obtained with $\kappa = 2$.

The fourth line of Table II shows that our results may change by a factor 30 depending on the inputs used. Since there is no strongly preferred value for the $c$ quark mass, neither for $\kappa$ or for the functional form of $\alpha_s$, we are not able to a priori discard any of these choices and our final results will reflect these uncertainties. In some cases a direct comparison with other works is possible. For example, in the second column, comparing the numbers in parenthesis, we notice that we obtain nearly five times more pairs than in [6]. A similar excess is observed comparing the numbers in parenthesis in the fourth column. Comparing our work with Ref. [6] we can see that the pair production mechanism is quite similar but the treatment given to the plasma expansion is different. Whereas we have used the standard Bjorken hydrodynamics, in Ref. [6] a new hydrodynamical model was introduced. Comparing the details of both approaches we concluded that in Ref. [6] the expansion and cooling of the system is much faster than in Bjorken hydrodynamics. Consequently the system stops much earlier to create $c\bar{c}$ pairs and the final yield will be smaller. We think that the expansion of the plasma must be included in any serious calculation, but hydrodynamics is in itself a very complex subject. A prudent strategy, which we adopt here, is to study the desired effect (charm production) first with the most standard and simple hydrodynamical model and then, as a second step, plug the charm production formalism into a state-of-the-art hydrodynamical code. We will leave this last step for the future. The comparison of the other results in Table II with other works shows that for similar inputs we obtain numbers which are compatible with those presented in Refs. [7] and [32].

C. The number of $J/\psi$’s

The number of $J/\psi$’s produced in the plasma can be obtained from Eqs. (34) and (35). We must change the upper limit of integration in $m^2$ introducing a kinematical cut-off, i.e., making the replacement $\infty \rightarrow 4m_D^2$. In doing so,
we rename the superscripts in Eqs. (34) and (35) to $gg \rightarrow J/\psi$ and $q\bar{q} \rightarrow J/\psi$. Moreover we introduce the CEM multiplicative factor $F_{J/\psi}$ and arrive at:

$$\frac{dN_{QGP}^{AA\rightarrow J/\psi}}{dx_F} = f_s F_{J/\psi} \left[ \frac{dN_{gg\rightarrow J/\psi}}{dx_F} + \frac{dN_{q\bar{q}\rightarrow J/\psi}}{dx_F} \right]$$

(39)

and

$$N_{QGP}^{J/\psi} = \int_0^1 dx_F \frac{dN_{QGP}^{AA\rightarrow J/\psi}}{dx_F}$$

(40)

The color evaporation model has an "intrinsic efficiency" given by the fractional factor $F_{J/\psi}$ above, which was fixed [18,15] in the analysis of $p-p$ reactions to be $F_{J/\psi} \approx 0.02 = 2\%$. It is by no means obvious that the same value should hold for $A-A$ collisions. For simplicity, we shall assume that $F_{J/\psi}$ is universal and holds even for in-plasma production. The "screening factor" $f_s$ is thus the only free number introduced here. It gives the probability that a $J/\psi$ formed inside the plasma survives the passage through the medium. In other words, $f_s$ accounts for dynamical screening, in which gluons in the plasma destroy the charmonium bound state. It varies from 0 to 1. A literal interpretation of [1] or [8] would imply $f_s = 0$. We will however tolerate a small value of $f_s$ and examine the consequences. In fact, it is impossible to say what a "realistic" value of $f_s$ would be. Our choices, based on some numerical estimates, are in the following interval:

$$10^{-3} \leq f_s \leq 10^{-2}$$

(41)

If $f_s < 10^{-3}$ we do not observe any visible effect of the in-plasma production. On the other hand, $f_s = 10^{-2}$, which can be interpreted as meaning that 1% of the in-plasma born $J/\psi$'s can survive as bound states, can be taken as an upper limit, beyond which, rather than taking small fluctuations into account we would be really challenging the well established concept of screening.

IV. FINAL THERMAL J/ψ PRODUCTION

We will also, for completeness, consider the case where the $J/\psi$'s produced in the early stage of the collision traverse the plasma being destroyed and then “regenerated” [3]. We call them “thermal”. As has been discussed in the literature [17,35], regenerated $J/\psi$'s follow a thermal distribution with the temperature of the quark-hadron phase transition $T_c \approx 170$ MeV:

$$\frac{dN_{thermal}^{AA\rightarrow J/\psi}}{dx_F} = \frac{\pi^{1/2} V_0 A}{2} \int_0^{p_T^s} dp_T^2 \exp \left[ -\frac{1}{T_c} \left( x_F^2 s/4 + p_T^2 + m_{J/\psi}^2 \right)^{1/2} \right]$$

$$= \text{const} \exp \left[ -\frac{1}{T_c} \left( \sqrt{x_F^2 s/4 + m_{J/\psi}^2} \right) \right] \left[ 1 + \frac{1}{T_c} \sqrt{x_F^2 s/4 + m_{J/\psi}^2} \right]$$

(42)

where the constant in front of the integral will be fixed later through the normalization condition:

$$N_{th}^{J/\psi} = \int_0^1 dx_F \frac{dN_{thermal}^{AA\rightarrow J/\psi}}{dx_F}$$

(43)

V. FINAL STATE INTERACTIONS

In sections II, III and IV we discussed $J/\psi$ production. After being produced these states will suffer interaction with the free partons of the plasma and later with the hadronic comovers. In [4], the final state interactions (FSI) were incorporated (to the rate analogous to our (13)) by the introduction of the multiplicative suppression factors $S_{FSI}^{COM}$ and $S_{FSI}^{QGP}$, for interactions with comovers and QGP partons respectively. We shall adopt here the same procedure. In fact, in the case of the initial QCD production, since we are using the same formalism, for the sake of comparison we shall later borrow the final corrected expression from [4]. In the case of (40), the $J/\psi$ dissociation by partons within
the plasma is already taken into account by the “screening factor” $f_s$. If the charmonium state survives the plasma phase, it will interact with hadronic comovers and (40) will be multiplied by the suppression factor [36,4]:

$$S_{FSI}^{COM} = \exp \left[-\sigma_{nco} \ln \left( \frac{n_{co}}{n_{f_o}} \right) \right]$$

(44)

where $n_{co}$ is the comover density, $n_{f_o}$ is the freeze-out density ($= 1.15 fm^{-2}$) and $\sigma_{nco} \simeq 1 - 4$ mb is the charmonium-hadron cross section [12,13]. The above expression depends on the impact parameter, on the collision energy and on time at which the charmonium interacts with a given comover. Moreover, since $n_{co}$ is a function of the rapidity, it will depend also on $x_F$. However, restricting the analysis to central collisions and to a fixed ($\sqrt{s}$) energy, the suppression factor tends to be constant, as concluded in [3,36,37]. For simplicity we shall take here the average of the values quoted in these works:

$$S_{FSI}^{COM} = 0.25$$

(45)

Final state interactions with comovers will be included in the thermal production differential rate (42) in the same way and with the use of (45).

VI. FEYNMAN MOMENTUM DISTRIBUTIONS

In Fig. 1 we show, for Au − Au ($\sqrt{s} = 200$ GeV) (1a) and Pb − Pb ($\sqrt{s} = 17$ GeV) (1b) collisions, the results obtained with (13) (dash-dotted line), (39) (solid line) and (42) (dashed line). For the QCD distribution, we have used the nuclear parton distribution functions (PDF) parametrized as in [38]. In doing so, the proton PDF’s were taken from [39] (GRV98 LO). We also used $m_c = 1.2$ GeV, $m_D = 1.87$ GeV and $\kappa = 2$. With these choices the total number of produced $J/\psi$’s is determined. In computing (39) we have used $T_0 = 0.7$ fm and $T_0 = 550$ MeV, for Au + Au and $T_0 = 1$ fm and $T_0 = 300$ MeV for Pb + Pb collisions. $T_c$ was taken to be 170 MeV.

In each figure all curves are normalized to the same number of produced $J/\psi$’s, which is given by (15). In Fig. 1 we have used the parton distributions of [38], obtaining $N_{J/\psi} \simeq 0.09$ at RHIC and $N_{J/\psi} \simeq 0.001$ at SPS.

Although the normalization is still artificial (it overestimates the number of $J/\psi$’s produced in QGP) it anticipates our main claim: QGP production will create a peak at $x_F \approx 0$. Even if suppressed, it will leave a signal. Moreover, this may happen at RHIC and at SPS as well.

In order to further investigate the differences between the three $J/\psi$ production mechanisms we will study the relation between the measured number of $J/\psi$’s and the naive expectation based on what we know from $pp$ collisions. Experimentally this ratio is easily constructed from the measured $x_F$ spectra in $A + A$ and $p + p$ collisions. Theoretically, the numerator can be written in terms of our theoretical prejudices.

As a starting point, we assume that all $J/\psi$’s are produced directly and we show in Fig. 2 the following ratio:

$$R_I(x_F) = \frac{1}{\pi T_A} \frac{d^2N_{QCD}+J/\psi}{dx_F} - \frac{dN_{QCD}+J/\psi}{dx_F}$$

(46)

where the denominator is given by the product of (8) with the nuclear overlap function $T_{AA}(b = 0) = 29.9$ mb$^{-1}$ at RHIC and $= 30.4$ mb$^{-1}$ at SPS. The numerators were obtained with (12), (13) and the nuclear parton distribution functions (PDF) parametrized as in [38] (solid line) and as in [40] (dashed line). In the first case the proton PDF were taken from [39] (GRV98 LO) whereas in the second case they were taken from [41] (MRST LO). With this last set of parton distributions $N_{J/\psi} \simeq 0.06$ at RHIC and $N_{J/\psi} \simeq 0.001$ at SPS.

$R_I$ shows essentially the effect of shadowing in the low $x$ region. We can see that if no effect is present, other than shadowing, $J/\psi$ spectrum produced in $AA$ collisions is just a constant times the corresponding $pp$ spectrum. As it can be seen this constant may change a lot with the PDF. This constancy in the region $x_F < 0.1$ will be important for the subsequent discussion. This figure shows also that the value of the constant decreases when we go from SPS to RHIC collisions. This same behavior was found in [4].

In Figure 3 we present the $x_F$ distribution of the in-plasma produced $J/\psi$’s. The screening factor will be fixed to $f_s = 10^{-2}$. The curves are obtained with expression (39) normalized to the largest (solid line) and to the smallest (dashed line) number of $J/\psi$’s. These normalization constants correspond to the choices 2.7 and 0.16, in the last line of Table II. Fig. 3a and 3b correspond to RHIC and SPS collisions respectively.

If we believe that all production is mainly direct plus some small plasma component, then (46) acquires the form:
where, for the moment, we neglect the final state interactions discussed in the previous section. If the screening in the plasma is so strong that \( f_s = 0 \), then \( R_{III} = R_I \approx \text{const} \). If, however, there is a small \( J/\psi \) survival probability, for example \( f_s = 10^{-2} \), there will be a noticeable change in \( R_{III} \). This is illustrated in Fig. 4, where we see a pronounced deviation from a flat behavior in the low \( x_F \) region if there is a contribution from the plasma. This interesting feature is due to nature of plasma production, which is peaked at \( x_F \approx 0 \). In Fig. 4 the two upper lines correspond to the largest plasma \( J/\psi \) production (\( N^{J/\psi}_{QGP} = 2.7 \)) and the lower two lines to the smallest plasma contribution (\( N^{J/\psi}_{QGP} = 0.16 \)). The screening factor is kept fixed to \( f_s = 10^{-2} \). In all cases solid and dashed lines mean the same PDF’s as in Fig. 2.

Figs. 4a and 4b refer to \( Au + Au \) at RHIC and to \( Pb + Pb \) at SPS respectively. We can clearly see that deviations from unity happen more strongly for RHIC collisions.

The above situation has to be regarded as an extreme case, in which \( J/\psi \)'s are produced via parton fusion (with shadowing taken into account) in the initial state of the nucleus-nucleus collision and then just escape from the fireball, without further nuclear or comover suppression.

We now consider the opposite extreme case, where all \( J/\psi \)'s are formed in the final state. Final state here means that the original \( J/\psi \)'s are totally destroyed by plasma screening and re-created at the final stage of the fireball life (at \( T = T_c \approx 170 \text{ MeV} \)) by coalescence and then just “emerge ready” during the fireball life, obeying the thermal distribution (42). This scenario is supported by the calculations performed in [3,17,42]. Assuming this production mechanism the ratio defined above is modified to:

\[
R_{III}(x_F) = \frac{\frac{dN^{AA-J/\psi}_{FISI}}{dx_F}}{T_{AA}(b = 0)\frac{dN^{pp-J/\psi}_{QGP}}{dx_F}} + \frac{\frac{dN^{AA-J/\psi}_{QGP}}{dx_F}}{T_{AA}(b = 0)\frac{dN^{pp-J/\psi}_{QGP}}{dx_F}}
\]

(47)

where, for the moment, we neglect the final state interactions discussed in the previous section. If the screening in the plasma is so strong that \( f_s = 0 \), then \( R_{III} = R_I \approx \text{const} \). If, however, there is a small \( J/\psi \) survival probability, for example \( f_s = 10^{-2} \), there will be a noticeable change in \( R_{III} \). This is illustrated in Fig. 4, where we see a pronounced deviation from a flat behavior in the low \( x_F \) region if there is a contribution from the plasma. This interesting feature is due to nature of plasma production, which is peaked at \( x_F \approx 0 \). In Fig. 4 the two upper lines correspond to the largest plasma \( J/\psi \) production (\( N^{J/\psi}_{QGP} = 2.7 \)) and the lower two lines to the smallest plasma contribution (\( N^{J/\psi}_{QGP} = 0.16 \)). The screening factor is kept fixed to \( f_s = 10^{-2} \). In all cases solid and dashed lines mean the same PDF’s as in Fig. 2.

Figs. 4a and 4b refer to \( Au + Au \) at RHIC and to \( Pb + Pb \) at SPS respectively. We can clearly see that deviations from unity happen more strongly for RHIC collisions.

The above situation has to be regarded as an extreme case, in which \( J/\psi \)'s are produced via parton fusion (with shadowing taken into account) in the initial state of the nucleus-nucleus collision and then just escape from the fireball, without further nuclear or comover suppression.

We now consider the opposite extreme case, where all \( J/\psi \)'s are formed in the final state. Final state here means that the original \( J/\psi \)'s are totally destroyed by plasma screening and re-created at the final stage of the fireball life (at \( T = T_c \approx 170 \text{ MeV} \)) by coalescence and then just “emerge ready” during the fireball life, obeying the thermal distribution (42). This scenario is supported by the calculations performed in [3,17,42]. Assuming this production mechanism the ratio defined above is modified to:

\[
R_{III}(x_F) = \frac{S_{COM}^{\text{FISI}} \frac{dN^{AA-J/\psi}_{FISI}}{dx_F}}{T_{AA}(b = 0)\frac{dN^{pp-J/\psi}_{QGP}}{dx_F}} + \frac{S_{COM}^{\text{QGP}} \frac{dN^{AA-J/\psi}_{QGP}}{dx_F}}{T_{AA}(b = 0)\frac{dN^{pp-J/\psi}_{QGP}}{dx_F}}
\]

(48)

where \( S_{COM}^{\text{FISI}} = 0.25 \). When discussing thermal production a crucial aspect is how to normalize the distribution (42). The most straightforward procedure would be to normalize it in such a way that the total number of quarks in the final state would match the number of charm quark pairs produced initially and computed with the help of perturbative QCD. However, as we can see from Table I and also from the recent and comprehensive analysis performed in Ref. [18], already at the \( p + p \rightarrow c \bar{c} + X \) level there is some uncertainty in the cross section coming from choices of the quark masses, renormalization scales and parton density parametrizations. A further source of uncertainty arises when we go from \( pp \) to \( AA \) collisions and introduce shadowing effects. Moreover, in a very recent calculation of thermal charm production [42], already taking into account the first PHENIX data [28], it was shown that, to explain the overall magnitude of the data, one needs to increase the NLO QCD \( c \bar{c} \) yield by a factor 2.8. In view of this lack of precise knowledge, in our study we will normalize the integral of Eq. (42), \( N_{th}^{J/\psi} \) in two different ways:

I) \( N_{th}^{J/\psi} = 3 N_{QCD}^{J/\psi} \);  II) \( N_{th}^{J/\psi} = 0.5 N_{QCD}^{J/\psi} \)

(49)

where \( N_{QCD}^{J/\psi} \) is given by Eq. (15), which, in turn, will be evaluated with two different nuclear parton distributions.

In Fig. 5 we plot the ratio \( R_{III} \). The two lower (upper) panels refer to \( Pb + Pb \) (\( Au + Au \)) data measured at SPS (RHIC). In the two left (right) panels we use the Eskola et al. [38] (Hirai et al. [40]) nuclear parton distributions. Inside each of the panels, the two upper curves are obtained with I) \( N_{th}^{J/\psi} = 3 N_{QCD}^{J/\psi} \) and the two lower curves with II) \( N_{th}^{J/\psi} = 0.5 N_{QCD}^{J/\psi} \). Finally, solid and dashed lines represent the maximal and the minimal contribution from the QGP component Eq. (39). Although \( f_s = 10^{-2} \) it is easy to see that choosing a smaller value for the screening factor would move the solid lines to the dashed ones, since they contain already a very small number of “in-plasma” born \( J/\psi \)'s.

In Fig. 5 we see that there is already a rise of \( R_{III} \) at decreasing values of \( x_F \), but this rise has the shape of a plateau (as anticipated in the introduction), starting from \( x_F \approx 0.01 \). If the screening is less effective, \( f_s = 10^{-2} \), then we find a deviation from the plateau at RHIC energies, as in Figs. 5a and 5b, but do not observe any visible effect at SPS energies, as in Figs. 5c and 5d. From these last figures we conclude that in-plasma production can hardly be detected at SPS since the \( x_F \) distribution is always dominated by the thermal (plateau-like) contribution. On the other hand, it should be remarked that if a plateau is found experimentally, this is interesting in itself, being a strong evidence in favor of the statistical hadronization model, which implies plasma formation.
Now we come back to the prediction made in [4], namely that the initially produced $J/\psi$’s after the interaction either with hadronic comovers or with the plasma will disappear around $x_F \simeq 0$ giving place to a dip in this region. We can split Eq. (47) into two pieces, the first one containing initial production and the second containing the plasma contribution. In order to include the suppression resulting from the final state interactions predicted in [4], we replace the first piece by a parametrization of $R_{AB}(x_F, b = 0)$, Eq. (3) of [4], keeping our plasma contribution the same and construct a new version of (47):

$$R_{IV}(x_F) = R_{AB}(x_F) + \frac{S_{COM}^{FSI} dN_{QGP}^{AA\rightarrow J/\psi}}{S_{FSI}^{FSI} dN_{QGP}}$$

50

This quantity, plotted in Fig. 6 is a more realistic version of $R_{II}$ (plotted in Fig. 4). As in previous figures solid and dashed lines correspond to the nuclear parton densities of Refs. [38] and [40] respectively. Figs. 6a and 6b correspond to RHIC and SPS collisions respectively. Following the same convention employed in Fig. 4, in each panel the two upper curves represent the largest QGP contribution, whereas the two lower curves represent the smallest QGP contribution. Comparing Figs. 4 and 6 we can see that the inclusion of FSI changes the results, decreasing the strength of the low $x_F$ enhancement. Nevertheless, the effect of in-plasma production remains quite visible. Notice that the lowest line crosses the origin of the horizontal axis ($x_F \simeq 0$) at 0.16. This is still far above the point predicted in [4], of 0.055.

We discuss now two more conservative scenarios, i.e., with less QGP production. First, we consider the lower part of Fig. 6a, amplifying the scale and allowing for smaller values of the screening factor $f_s$ ($f_s = 10^{-3}$). This amplification is shown in Fig. 7a. In spite of the uncertainties in the calculations, our results in this figure, being still larger than the one found in [4] (the dash-dotted line), suggest that an enhancement in $R_{IV}$ in the low $x_F$ region might be seen if QGP would be formed. Finally, we compute again the QGP production rate, using the same inputs except for the initial temperature of the plasma, which we take to be $T_0 = 300$ MeV. At these smaller temperatures the screening factor must be larger and we choose it to be $f_s = 0.1$. This is shown in Fig. 7b with the same conventions used in the previous figures. As it can be seen, our lowest line is still above the result of [4].

VII. CONCLUSIONS

In this paper we have considered $J/\psi$ production in nucleus-nucleus collisions by three different mechanisms: direct (primordial parton fusion) ii) thermal (statistical coalescence at hadronization) and iii) QGP (in-plasma parton fusion). As already discussed in [3] i) and ii) are just two extreme cases. In realistic simulations, for a fixed number of $c\bar{c}$ pairs and of $J/\psi$’s, these last are gradually destroyed, giving origin to the “regenerated” component ii). Component iii) is reconsidered here after being forgotten for long time. Our main point was that, even being small, contribution iii) is very strongly peaked around $x_F \simeq 0$ and can thus become visible if enough plasma is formed.

With this in mind we defined the ratio (46) and computed it assuming mechanism i) plus a small component of iii) (ratio $R_{II}$) and assuming mechanism ii) plus a small component of iii) (ratio $R_{III}$). In the first case it is completely flat without plasma contribution. A QGP contribution creates a big bump at $x_F < 0.01$. In the second case, without plasma contribution, we observe a step structure, with a plateau at $x_F < 0.01$. Switching on the plasma contribution creates a steeply falling curve. We believe that any of these features can be measured and will be very interesting for charm physics at RHIC.

In [4] it was suggested that the $x_F$ distribution to be measured at RHIC is flat and has a dip in the region $x_F \simeq 0$. Our calculations indicate that the inclusion of the “in-plasma born” $J/\psi$’s will fill this dip.

Of course, there are several improvements that one could do in the in-plasma production, as, for example, the use of a more sophisticated hydrodynamical expansion. Moreover, final state interactions of this component should be considered. Work along these lines is already in progress. Our findings in this work encourage us to pursue this program.

**TABLE II.** Number of “in-plasma” produced \( cc \) pairs and \( J/\psi \)’s in RHIC collisions. Numbers inside parenthesis are obtained with \( \kappa = 1 \) and the others with \( \kappa = 2 \). The initial temperature is 550 MeV in all cases.
FIG. 1. $J/\psi$ momentum distributions: direct QCD (13) (dash-dotted line), in-plasma (39) (solid line) and thermal production (42) (dashed line). All curves have the same normalization (see text). a) RHIC collisions; b) SPS collisions.

FIG. 2. Ratio $R_I(x_F)$: effect of shadowing in QCD direct production. The numerators were obtained with (13) and (12) and the nuclear parton distribution functions were taken from [38] (solid lines) and from [40] (dashed lines).
FIG. 3. In-plasma $J/\psi$ momentum distribution: a) Au + Au at RHIC; b) Pb + Pb at SPS. Solid (dashed) lines are obtained with the smallest (largest) charm quark mass and with $\alpha(M^2)$ ($\alpha(T)$). The curves are obtained with expression (39) and in both cases the screening factor ($f_s$) has been fixed to $10^{-2}$.

FIG. 4. Ratio $R_{II}(x_F)$: a) Au + Au at RHIC; b) Pb + Pb at SPS. Solid and dashed lines, as in Fig. 2, are obtained with the nuclear parton densities taken from [38] and [40] respectively.
FIG. 5. Ratio $R_{III}(x_F)$ calculated with (48); labels I and II represent the normalizations defined in (49); solid (dashed) lines are obtained with the largest (smallest) in-plasma contribution; a) and b) are for RHIC collisions and c) and d) for SPS collisions; in the two left (right) panels we use the Eskola et al. [38] (Hirai et al. [40]) nuclear parton distributions.

FIG. 6. Ratio $R_{IV}(x_F)$ computed with (50). a) RHIC collisions; b) SPS collisions; solid lines: parton densities of Ref. [38]; dashed lines: parton densities of Ref. [40].
FIG. 7. Ratio $R_{IV}(x_F)$ computed with (50) for RHIC collisions; solid lines: parton densities of Ref. [38]; dashed lines: parton densities of Ref. [40]; dash-dotted line represents the (parameterized) result for central collisions obtained by Hufner et al. [4].

7a) $T_0 = 550$ MeV; 7b) $T_0 = 300$ MeV.
