Abstract

The adhesion of cell membranes is mediated by the binding of membrane-anchored receptor and ligand proteins. In this article, we review recent results from simulations and theory that lead to novel insights on how the binding equilibrium and kinetics of these proteins is affected by the membranes and by the membrane anchoring and molecular properties of the proteins. Simulations and theory both indicate that the binding equilibrium constant $K_{2D}$ and the on- and off-rate constants of anchored receptors and ligands in their ‘two-dimensional’ (2D) membrane environment strongly depend on the membrane roughness from thermally excited shape fluctuations on nanoscales. Recent theory corroborated by simulations provides a general relation between $K_{2D}$ and the binding constant $K_{3D}$ of soluble variants of the receptors and ligands that lack the membrane anchors and are free to diffuse in three dimensions (3D).

1 Introduction

Cell adhesion processes and the adhesion of vesicles to the membranes of cells or organelles depend sensitively on the binding constant and binding kinetics of the membrane-anchored receptor and ligand molecules that mediate adhesion. Since the binding equilibrium constant $K_{2D}$ and the on- and off-rate constants of these receptor and ligand molecules are difficult to measure in their natural two-dimensional (2D) membrane environment, a central question is how they are related to the binding equilibrium constant $K_{3D}$ and the on- and off-rate constants of soluble variants of the receptors and ligands that lack the membrane anchors and are free to diffuse in three dimensions (3D). The binding equilibrium constant $K_{2D}$ of membrane-anchored receptor and ligand molecules has units of area, while the binding constant $K_{3D}$ of soluble variants of these molecules has units of volume. Bell and co-workers therefore suggested the relation $K_{2D} = K_{3D}/l_c$ between the binding constants with a characteristic confinement length $l_c$ that balances the different units of these constants. However, experimental data for $K_{2D}$ and $K_{3D}$ of several receptor and ligand pairs lead to values of the confinement length $l_c$ that can differ by orders of magnitude, depending on whether $K_{2D}$ is determined with fluorescence methods or with mechanical methods. Fluorescence methods probe the binding equilibrium of receptors and ligands in equilibrated adhesion zones of cells and lead to values of $l_c$ of the order of nanometers. In contrast, mechanical methods probe the binding kinetics of anchored receptors and ligands during initial contacts and typically lead to values of $l_c$ between tens of micrometers and millimeters in cell adhesion experiments.

In this article, we review recent results from computational model systems and theory that provide general and novel insights into the relation between the binding equilibrium and kinetics of membrane-anchored receptor and ligand molecules in 2D and the binding of soluble variants of these molecules in 3D. A central aspect of these computational and theoretical results is that the relation between the binding equilibrium constants $K_{2D}$ and $K_{3D}$ involves four characteristic lengths, rather than a single confinement length $l_c$. Two of these four lengths are characteristic lengths of the receptor-ligand complex that reflect variations in the binding site, and how strongly the local membrane separation at the location of the complex is constrained by the complex. The remaining two lengths...
are the average separation and relative roughness of the apposing membranes and, thus, characteristic lengths of the membranes. The relative membrane roughness is the local standard deviation of the membranes from their average separation due to thermally excited shape fluctuations on nanoscales.

The binding equilibrium constant $K_{2D}$ strongly depends both on the average membrane separation and the relative membrane roughness, which helps to understand why mechanical methods that probe the binding kinetics of membrane-anchored proteins during initial membrane contacts can lead to values for $K_{2D}$ that are orders of magnitude smaller than the values obtained from fluorescence measurements in equilibrated adhesion zones [9]. In equilibrated adhesion zones that are dominated by a single species of receptors and ligands, the average membrane separation is close to the preferred average separation for receptor-ligand binding at which $K_{2D}$ is maximal, and the relative membrane roughness is reduced by receptor-ligand bonds [9,7]. During initial membrane contacts, in contrast, both the average membrane separation and relative membrane roughness are larger, which can lead to significantly smaller values of $K_{2D}$.

## 2 Characteristic lengths of membranes and membrane-anchored receptors and ligands

A membrane-anchored receptor can only bind to an apposing membrane-anchored ligand if the local membrane separation $l$ at the site of the receptor and ligand is within an appropriate range. This local separation $l$ of the membranes varies along the membranes, and in time because of thermally excited membrane shape fluctuations. Experiments that probe the binding equilibrium constant $K_{2D}$ or the on- and off-rate constants $k_{on}$ and $k_{off}$ imply averages in space and time over membrane adhesion regions and measurement durations. Our recent simulations and theories indicate that these averages can be expressed as [9,10]

$$K_{2D} = \int K_{2D}(l)P(l)dl \quad (1)$$

$$k_{on} = \int k_{on}(l)P(l)dl \quad (2)$$

where $K_{2D}(l)$ and $k_{on}(l)$ are the binding equilibrium constant and on-rate constant as functions of the local membrane separation $l$, and $P(l)$ is the distribution of local membrane separations that reflects the spatial and temporal variations of $l$. The single-peaked functions $K_{2D}(l)$ and $k_{on}(l)$ are maximal at the preferred local separation of the receptors and ligands for binding, and have characteristic widths that depend on the anchoring, length, and flexibility of the receptors and ligands [9,10]. The off-rate constant follows from Eqs. (1) and (2) as $k_{off} = k_{on} / K_{2D}$. Our simulations also show that the distribution $P(l)$ of the local separation is well approximated by the Gaussian distribution

$$P(l) \approx \exp\left[-(l-\bar{l})^2/2\xi^2\right] / (\sqrt{2\pi}\xi) \quad (3)$$

in situations in which the adhesion of two apposing membranes, or membrane segments, is mediated by a single type of receptors and ligands [9,10]. Here, $\bar{l} = \langle l \rangle$ is the average separation of the membranes or membrane segments, and $\xi = \sqrt{\langle(l-\bar{l})^2\rangle}$ is the relative roughness of the membranes. The relative roughness is the standard deviation of the local membrane separation $l$, i.e. the width of the distribution $P(l)$. The distribution $P(l)$ describes both the spatial and temporal variations of the local membrane separation $l$ of two apposing membranes, or membrane segments. Related temporal averages for the on-rate constant $k_{on}$ and off-rate constant $k_{off}$ at fixed membrane locations have been employed by Bihr et al. [32].

The Eqs. (1) and (3) illustrate three characteristic lengths of the binding constant $K_{2D}$. These lengths are the width $\xi_{TS}$ of the single-peaked function $K_{2D}(l)$, which reflects how strongly the local separation $l$ is constrained by a receptor-ligand (RL) complex, and the average separation $\bar{l}$ and relative roughness $\xi_{\perp}$ of the membranes. A fourth characteristic length that affects the relation of the binding constants $K_{2D}$ and $K_{3D}$ in our theory is the ratio $V_b/A_b$ of the translational space phase volume $V_b$ of a bound soluble receptor in 3D and the translational phase space area $A_b$ of a bound membrane-anchored receptor in 2D, relative to their ligands (see Section IV).

Similarly, three characteristic lengths of the on-rate constant $k_{on}$ are the width $\xi_{TS}$ of the single-peaked function $k_{on}(l)$, which reflects variations of the local separation $l$ in the transition-state (TS) complex for binding, the average membrane separation $\bar{l}$, and the relative membrane roughness $\xi_{\perp}$, according to Eqs. (2) and (3).

In equilibrated membrane adhesion zones that are dominated by a single type of receptors and ligands, the average membrane separation is close to the preferred average separation of these receptors and ligands for binding. Our simulations indicate that the relative membrane roughness $\xi_{\perp}$ then is determined by the concentration [RL] of
the receptor-ligand bonds, which constrain the membrane shape fluctuations:

\[ \xi_\perp \simeq 0.2 \sqrt{\frac{k_B T}{\kappa_{\text{eff}}}} / \sqrt{[\text{RL}]} \]  

(4)

Here, \( \kappa_{\text{eff}} = \kappa_1 \kappa_2 / (\kappa_1 + \kappa_2) \) is the effective bending rigidity of the two apposing membranes with bending rigidities \( \kappa_1 \) and \( \kappa_2 \), and \( k_B T \) is the thermal energy, the driving force of membrane shape fluctuations. For a concentration \( [\text{RL}] \simeq 100/\mu m^2 \) of receptor-ligand bonds and for typical values of the bending rigidities \( \kappa_1 \) and \( \kappa_2 \) of lipid membranes \([34, 35]\) and cell membranes \([36, 37]\) between 20 \( k_B T \) and 80 \( k_B T \), we obtain estimates for the relative membrane roughness \( \xi_\perp \) between 3 nm and 6 nm from Eq. (4). For a four times larger bond concentration \( [\text{RL}] \simeq 400/\mu m^2 \), these roughness estimates are decreased by a factor of 2, according to Eq. (4). For a four times smaller bond concentration \( [\text{RL}] \simeq 25/\mu m^2 \), the roughness estimates are increased by a factor of 2, compared to the bond concentration \( [\text{RL}] \simeq 100/\mu m^2 \). The scaling relation (4) results from the fact that the membrane shape fluctuations on the relevant lateral length scales up to \( 1/\sqrt{[\text{RL}] \simeq 10 \text{ or } 100 \text{ nanometers} \), are dominated by the bending energy of the membranes. In contrast, the overall shape of cells on length scales of micrometers is dominated by the membrane tension and the cell cytoskeleton. The bending energy dominates over the membrane tension \( \sigma \) on length scales smaller than the crossover length \( \sqrt{\kappa/\sigma} \), which adopts values of 100 or a few 100 nanometers for typical values of the bending rigidity \( \kappa \) and tension \( \sigma \) of cell membranes \([36]\).

If the relative membrane roughness \( \xi_\perp \) is much smaller than the widths \( \xi_{\text{RL}} \) and \( \xi_{\text{TS}} \) of the functions \( K_{2D}(l) \) and \( k_{\text{on}}(l) \), the binding of membrane-anchored receptors and ligands is only weakly affected by \( \xi_\perp \). Such situations may occur in focal contacts or adherens junctions, which consist of clusters of integrin and cadherin complexes, respectively \([4, 38–41]\). In cell adhesion zones of immune cells and in the equilibrated adhesion zones probed with fluorescence methods \([15, 21]\), in contrast, the relative membrane roughness is likely of the same order or larger than \( \xi_{\text{RL}} \) and \( \xi_{\text{TS}} \). The computational model systems
and theory described in the next sections indicate that
the binding equilibrium and kinetics of the membrane-
anchored receptors and ligands is then strongly affected
both by the relative membrane roughness \( \xi_\perp \) and the aver-
age membrane separation \( l \). If the relative membrane
roughness \( \xi_\perp \) is significantly larger than \( \xi_{RL} \) and \( \xi_{TS} \), the
binding equilibrium constant \( K_{2D} \) and on-rate constant
\( k_{on} \) are both inversely proportional to \( \xi_\perp \) at the preferred
average separation for binding \( [9][10] \). Together with Eq.
(4), these inverse proportionalities lead to a quadratic de-
pendence of the bond concentration \([R]\) and the overall
reaction rate on the concentrations \([R] \) and \([L] \) of unbound
membrane-anchored receptors \( R \) and ligands \( L \), which
reflects the binding cooperativity caused by the membrane
roughness on nanoscales \( [3][10] \).

### 3 Results from computational model systems of biomembrane adhesion

We have recently developed two computational model sys-
tems to investigate the binding of anchored receptors and
ligands in their 2D membrane environment and the bind-
ing of soluble variants of the receptors and ligands that
are fully mobile in 3D \( [7][10] \). First, we have developed
a coarse-grained molecular model of biomembrane adhe-
sion \( [7][10] \) (see Fig. 1(a)). In this model, lipid molecules
consist of three hydrophobic head beads and two hy-
drophobic tails of four beads each, and the receptors and
ligands are represented as cylindrical rods of beads, which
are either anchored rather rigidly to a cylindrical trans-
membrane domain, or more flexibly to lipid molecules.
We have investigated the binding equilibrium and kinetics
of both these transmembrane and lipid-anchored re-
cipients and ligands with molecular dynamics (MD) sim-
ulations, as well as the binding equilibrium and kinetics
of soluble variants of the receptors and ligands that lack
the membrane anchors. Related coarse-grained molecu-
lar models of biomembranes have been previously used
to investigate the self-assembly \( [42][45] \), fusion \( [46][51] \),
and lipid domains \( [52][56] \) of membranes as well as the dif-
fusion \( [57][58] \), aggregation \( [59] \), and curvature genera-
tion \( [60][61] \) of membrane proteins with MD simulations.

Second, we have developed an elastic-membrane model
of biomembrane adhesion in which the membranes are
represented as discretized elastic surfaces, and the recep-
tors and ligands as anchored rigid or semi-flexible rods
that diffuse continuously along the membranes and ro-
tate around their anchoring points \( [9] \). Using Monte
Carlo (MC) simulations, we have determined both the
binding constant \( K_{2D} \) of these anchored receptors and
ligands as well as the binding constant \( K_{3D} \) of soluble
variants of the receptors and ligands. In previous elastic-
membrane models of biomembrane adhesion, determin-
ing both \( K_{2D} \) and \( K_{3D} \) and the molecular characteris-
tics affecting these binding constants has not been pos-
sible because the receptors and ligands are not explicitly
represented as anchored molecules. Instead, the bind-
ing of receptors and ligands has been described implic-
ily by interactions that depend on the membrane sep-
oration \( [32][62][69] \). In other previous elastic-membrane
models, receptors and ligands are described by concen-
tration fields rather than individual molecules \( [70][79] \), or
receptor-ligand bonds are treated as constraints on the
local membrane separation \( [53][80][83] \).

An important aspect for the binding of membrane-
anchored receptors and ligands is the flexibility of the
membrane anchoring. In our computational model sys-
tems, the anchoring flexibility of unbound membrane-
anchored receptors and ligands can be described by the
harmonic anchoring energy

\[
V_{\text{anchor}} = \frac{1}{2} k_a \theta_a^2 \tag{5}
\]

with anchoring strength \( k_a \) and anchoring angle \( \theta_a \), which
is the angle between the direction of the receptors and lig-
ands and the local membrane normal. An anchoring angle
of zero thus corresponds to a perpendicular orientation
of the receptors and ligands relative to the membrane.
For our coarse-grained molecular model of biomembrane
adhesion, the effective anchoring strength \( k_a \) can be
determined by fitting the anchoring-angle distributions of
unbound receptors and ligands observed in the MD sim-
ulations, which leads to the values \( k_a \approx 2.5 \ k_B T \) for our
lipid-anchored receptors and ligands and \( k_a \approx 23 \ k_B T \)
for our transmembrane receptors and ligands \( [10] \). In our
elastic-membrane model of biomembrane adhesion, the
anchoring energy \( [3] \) of receptors and ligands is part of
the overall configurational energy of the model, and the
anchoring strength \( k_a \) thus can be ‘set’ as a parameter.
We have performed MC simulations with the three values
\( k_a = 4, 8 \) and 16 \( k_B T \).

The Figs. 2 and 3 illustrate MC results for the bind-
ing constant of membrane-anchored receptors and ligands
from two different simulation scenarios \( [9] \). In the first
scenario, the two apposing membranes are parallel and
planar (see Fig. 2(a)). The local separation \( l \) of the mem-
branes is then identical at all membrane sites and, thus,
identical to the average separation \( \bar{l} \) of the membranes.
By varying the membrane separation \( l \) in this scenario, we
Figure 2: (a) Snapshot from a MC simulation with parallel and planar membranes. (b) and (c) Ratio $K_{2D}/K_{3D}$ of the binding constants of membrane-anchored and soluble receptors and ligands versus local membrane separation $l$ for different anchoring strengths $k_a$ and complex lengths $L_0$ of the receptors and ligands of our elastic-membrane model of biomembrane adhesion. The data points represent MC data, and the lines theoretical results based on Eqs. (7) and (8). The binding constant $K_{3D}$ of soluble variants of the receptors and ligand is determined by the binding potential of the receptors and ligands and does not depend on the complex length $L_0$.

Figure 3: (a) Snapshot from a MC simulation with fluctuating membranes. (b) and (c) Ratio $K_{2D}/K_{3D}$ of the binding constants of membrane-anchored and soluble receptors and ligands versus relative membrane roughness $\xi_\perp$ of two equilibrated fluctuating membranes with preferred average separation for different anchoring strengths $k_a$ and complex lengths $L_0$ of the receptors and ligands. The data points represent MC data, and the lines represent theoretical results based on Eqs. (1), (7), and (8).
obtain the binding constant $K_{3D}$ as a function of the local membrane separation $l$ from MC simulations in which the receptors and ligands diffuse along the planar membranes and rotate at their anchor points. In the second scenario, the two apposing membranes are flexible, and the local membrane separation $l$ varies because of thermally excited shape fluctuations of the membranes (see Fig. 3(a)). These variations can be quantified by the relative roughness $\xi_L$ of the membranes, which is the standard deviation of the local separation. In this scenario, the membranes are ‘free to choose’ an optimal average separation $l_0$ at which the overall free energy is minimal, and we obtain $K_{3D}$ as a function of the membrane roughness $\xi_L$ at the average membrane separation $l = l_0$ from MC simulations that differ in the numbers of receptors and ligands, and in the membrane tension. In both MC simulations scenarios, the binding constant of the membrane-anchored receptors and ligands is obtained as $K_{2D} = \langle RL \rangle_{2D}/\langle R \rangle_{2D} \langle L \rangle_{2D}$ from the average area concentrations $\langle RL \rangle_{2D}$, $\langle R \rangle_{2D}$, and $\langle L \rangle_{2D}$ of the bound receptor-ligand complexes, unbound receptors, and unbound ligands observed in the simulations. The binding constant of soluble variants of the receptors and ligands can be obtained as $K_{3D} = \langle RL \rangle_{3D}/\langle R \rangle_{3D} \langle L \rangle_{3D}$ from the volume concentrations of the receptors and ligands observed in MC simulations. The binding constant $K_{3D}$ is determined by the binding potential of our model, and does not depend on the length of the complexes [9].

As a function of the local separation $l$, the binding constant $K_{2D}(l)$ is maximal at a local membrane separation $l_0$ that is slightly smaller than the length $L_0$ of the receptor-ligand complexes, and is asymmetric with respect to $l_0$ (see Fig. 3(b) and (c)). This asymmetry reflects that the receptor-ligand complexes can tilt at local separations $l$ smaller than $l_0$, but need to stretch at local separations larger than $l_0$. The maximum of the function $K_{2D}(l)$ decreases with increasing length $L_0$ of the rigid receptor-ligand complexes (see Fig. 3(b)), and strongly increases with increasing anchoring strength $\kappa_0$ of the receptors and ligands (see Fig. 3(c)). The width of the function $K_{2D}(l)$ increases with decreasing anchoring strength $\kappa_0$. These features of the function $K_{2D}(l)$ can be understood from our general theory presented in the next section, which agrees with the MC data without any fit parameters (see full lines in Fig. 2).

The MC data in Fig. 3 and the corresponding MD data of Fig. 4 illustrate that the binding constant $K_{2D}$ of receptors and ligands anchored to fluctuating membranes decreases with increasing relative membrane roughness $\xi_L$ at the optimal average membrane separation $l_0$ for binding. In Fig. 3 the ratio $K_{2D}/K_{3D}$ of the binding constant, the inverse ‘confinement length’, varies between 0.2 and 10 nm$^{-1}$, depending on the relative roughness $\xi_L$ of the membranes and on the anchoring strength and length of the receptors and ligands.

In Fig. 4 the values of $K_{2D}/K_{3D}$ range from 0.5 to 5 nm$^{-1}$, depending on the relative membrane roughness $\xi_L$ and on whether the receptors and ligands have a transmembrane anchor or a lipid anchor. The MD data points in Fig. 4 result from a variety of membrane systems that differ in membrane area, in the number of receptors and ligands, or in the membrane potential [9]. The roughness depends on the area $L_x \times L_y$ of the membranes in the MD simulations because the periodic boundaries of the simulation box suppress membrane shape fluctuations with wavelength larger than $L_x/2\pi$ where $L_x = L_y$ is the linear membrane size. In membrane systems with several anchored receptors and ligands, the roughness is affected by the number of receptor-ligand bonds because the bonds constrain the membrane shape fluctuations. For the small numbers of receptors and ligands in our MD simulations, the binding constants can be determined from the times spent in bound and unbound states [7,10].

The binding kinetics of the transmembrane and lipid-anchored receptors and ligands of our coarse-grained molecular model of biomembrane adhesion can be determined from the frequencies of binding and unbinding events observed in MD simulations [7]. The binding potential is identical for both types of receptors and ligands and has no barrier to ensure an efficient sampling of binding and unbinding events of receptors and ligands in our simulations. The kinetics of these events is then strongly enhanced compared with protein binding events in experiments [19,21,90,86]. However, this rate enhancement does not affect our main results, which concern the dependence of the rate constants and equilibrium constant on the membrane separation and roughness. At the preferred average separation $l_0$ for binding, the 2D on-rates of the anchored receptors and ligands decrease with the relative membrane roughness, while the 2D off-rates increase with the relative roughness [7,10]. For our transmembrane receptors and ligands, the 2D off-rate $k_{off}$ increases from about 90/ms to about 140/ms with an increase of the relative membrane roughness from 0.5 nm to 1.8 nm for the membrane systems of Fig. 4(a). For our lipid-anchored receptors and ligands, the 2D off-rate $k_{off}$ increases from about 245/ms to about 290/ms with an increase of the relative membrane roughness from 0.2 nm to 1.7 nm for the membrane systems of Fig. 4(b). The 3D off-rate of soluble variants of these receptors and ligands with the same binding potential is $k_{off} \approx 400$/ms. This 3D off-rate
is slightly larger than the off-rates of the lipid-anchored receptors and ligands, and about 3 to 5 times larger than the off-rates of the transmembrane receptors and ligands at the preferred average separation for binding. These results appear to indicate that the 2D off-rates of the receptors and ligands in our coarse-grained molecular model are smaller than the 3D off-rate due to constraints on the rotational motion from membrane anchoring, which are more pronounced for our transmembrane receptors and ligands. 2D off-rates that are slightly smaller than 3D off-rates have also been observed for the binding of T-cell receptors and ligands that agrees with the results from our computational model systems. In this theory, the binding constants $K_{2D}$ and $K_{3D}$ of membrane-anchored and soluble receptors and ligands can be calculated from the translational and rotational free-energy change upon binding. As a function of the local membrane separation $l$, the binding constant $K_{2D}$ has the general form

$$K_{2D}(l) \approx \sqrt{3\pi K_{3D}} \frac{A_b \Omega_{RL}(l)}{V_b \Omega_R \Omega_L}$$

in this theory. Here, $\Omega_R$, $\Omega_L$, and $\Omega_{RL}(l)$ are the rotational phase space volumes of the unbound receptors R, unbound ligands L, and bound receptor-ligand complex RL relative to the membranes, and $A_b$ and $V_b$ are the translational phase space area and translational phase space volume of the bound ligand relative to the recep-
tor in 2D and 3D. The ratio \( V_b/A_b \) in Eq. \((1)\) represents a characteristic length for the binding interface of the receptor-ligand complex and can be estimated as the standard deviation of the binding-site distance in the direction of the complex \( \theta \). The rotational phase space volumes of the unbound receptors and ligands can be calculated as \( L = L_0 = 2\pi \int_0^{\pi/2} \exp(-\frac{1}{2} k_0 \theta_a^2/k_B T) \sin \theta_a d\theta_a \). The remaining, theoretically ‘challenging’ term in Eq. \((1)\) is the rotational phase space volume \( L_{RL}(l) \) of the bound complex, which determines the shape of the function \( K_{2D}(l) \).

We have found that the rotational phase space volume \( L_{RL}(l) \) of the bound receptor-ligand complex can be calculated from an effective configurational energy \( H_{RL} \) of the bound receptor-ligand complex. In our computational model systems, the binding angles and binding angle variations of the rigid, rod-like receptor and ligand molecules are small compared to their anchoring-angle variations. A receptor and ligand then have an approximately collinear orientation in the complex, and approximately equal anchoring angles \( \theta_a \). The effective configurational energy is then

\[
H_{RL}(l, \theta_a) \simeq k_a \theta_a^2 + \frac{1}{2} k_{RL}(l/\cos \theta_a - L_0)^2 \tag{7}
\]

The first term of this effective energy is the sum of the anchoring energies \( k_a \) of the receptor and ligand in the complex, and the second term is a harmonic approximation for variations in the length \( L_{RL} \) of the receptor-ligand complex, i.e. in the distance between the two anchoring points of the complex. For parallel membranes with separation \( l \) and approximately identical anchoring angles \( \theta_a \) of the RL complex in these membranes, the length of the complex, i.e. the distance between the two anchoring points in the membranes, is \( L_{RL} \simeq l/\cos \theta_a \). With the effective configurational energy \( H_{RL} \), the rotational phase space volume of the bound complex can be calculated as \( \Omega_{RL} \simeq 2\pi k_0 \int_0^{\pi/2} \exp(-H_{RL}(l, \theta_a)/k_B T) \sin \theta_a d\theta_a \), which leads to

\[
K_{2D}(l) = 2\pi c_{2D} \int_0^{\pi/2} e^{H_{RL}(l, \theta_a)/k_B T} \sin \theta_a d\theta_a \tag{8}
\]

with \( c_{2D} = \sqrt{8\pi K_{3D} A_b / (V_0 \Omega_R \Omega_L)} \).

The theoretical result for \( K_{2D}(l) \) of Eq. \((8)\) agrees with MC data for our elastic-membrane model of biomembrane adhesion without any fit parameters (see lines in Fig. \(9\)). For our elastic-membrane model, the effective spring constant \( k_{RL} \) and preferred length \( L_0 \) of the receptor-ligand complex in the effective configurational energy \( \Omega_{RL} \) can be calculated from standard deviations of the binding angle and binding-site distance and from the lengths of the receptors and ligands. By combining the Eqs. \((1)\), \((4)\), and \((8)\), we obtain general results for the binding constant \( K_{2D} \) of receptors and ligands anchored to fluctuating membranes that agree with MC data without fit parameters (see lines in Fig. \(9\)). Our general theory for the binding constant \( K_{2D} \) thus captures the essential features of the ‘dimensionality reduction’ from 3D to 2D due to membrane anchoring.

In analogy to Eq. \((7)\) for the bound receptor-ligand complex, we have postulated the effective configurational energy

\[
H_{TS}(l, \theta_a) \simeq k_a \theta_a^2 + \frac{1}{2} k_{TS}(l/\cos \theta_a - L_{TS})^2 \tag{9}
\]

for the transition-state complex of the binding reaction of membrane-anchored receptors and ligands, with the same anchoring strength \( k_a \) as in Eq. \((7)\). This effective configurational energy reflects that a receptor and ligand molecule can only bind at appropriate relative orientations and separations. The effective spring constant \( k_{TS} \) for the length variations of the transition-state complex is smaller than the corresponding spring constant \( k_{RL} \) of the RL complex, because the variations in the binding-site distance and binding angle, which affect the effective spring constants, are larger in the transition state \( \theta_b \).

The preferred effective length \( L_{TS} \) of the transition-state complex, in contrast, is in general close to the preferred length \( L_0 \) of the bound RL complex. In analogy to Eq. \((8)\), the on-rate constant is

\[
k_{on}(l) \simeq 2\pi c_{on} \int_0^{\pi/2} e^{-H_{TS}(l, \theta_a)/k_B T} \sin \theta_a d\theta_a \tag{10}
\]

for a given separation \( l \) of the planar and parallel membranes. The integration over the angle \( \theta_a \) in Eq. \((10)\) can be interpreted as an integration over the transition-state ensemble of the binding reaction. The on-rate constant \( k_{on} \) of receptors and ligands anchored to fluctuating membranes can then be obtained from an average over the local membrane separation \( l \) (see Eq. \((2)\)). This average over local separations for the on-rate constant \( k_{on} \) relies on characteristic timescales for membrane fluctuations that are significantly smaller than the timescales for the diffusion of the anchored molecules on the relevant length scales \( \Omega_R \). In contrast, the average in Eq. \((4)\) for the binding constant \( K_{2D} \) is independent of these timescales because \( K_{2D} \) is an equilibrium quantity that does not depend on dynamic aspects.

The effective configurational energies \((7)\) and \((9)\) describe the bound complex and the transition-state complex of membrane-anchored receptors and ligands as ef-
flective harmonic springs that can tilt. In contrast, classical theories describe these complexes as simple harmonic springs \(^{[22, 88, 89]}\). As functions of the local membrane separation \(l\) and the binding constant \(\kappa_2D(l)\) and on-rate constant \(\kappa_{on}(l)\) then have a symmetric, Gaussian shape in this classical theory (see Appendix). However, the MC data of Fig. 2 illustrate that the function \(K_{2D}(l)\) is clearly asymmetric, in agreement with Eq. (8) of our theory. In Fig. 5 both our theory (full lines) and the classical theory (dashed lines) are compared to data from MD simulations \(^{[10]}\). In these simulations of our smallest model system with membrane area \(14 \times 14 \text{ nm}^2\) and a single lipid-anchored receptor and ligand, the average separation \(\bar{l}\) of the membranes is varied by varying the number of water beads between the membranes. The relative membrane roughness in this system is determined by the membrane area and attains the value \(\xi_\perp \approx 0.54 \text{ nm}\). Our theoretical results (full lines) are in good agreement with the MD data. The results for the classical theory (dashed lines) deviate from the data because they do not reflect the asymmetry of \(K_{2D}\) and \(\kappa_{on}\) as functions of the average membrane separation \(\bar{l}\), which results from the asymmetry of \(K_{2D}(l)\) and \(\kappa_{on}(l)\).

For a relative membrane roughness \(\xi_\perp\) that is much larger than the widths \(\xi_{RL}\) and \(\xi_{TS}\), of the functions \(K_{2D}(l)\) and \(\kappa_{on}(l)\), the distribution \(P(l)\) of local membrane separations \(l\) is nearly constant over the range of local separations \(l\) for which \(K_{2D}(l)\) and \(\kappa_{on}(l)\) are not negligibly small. The Eqs. (1) and (2) of our theory then simplify to \(^{[9, 10]}\)

\[
K_{2D} \simeq \bar{\epsilon}_{2D} \kappa_{3D} \frac{\xi_\perp}{\xi_\perp} \exp \left[ - \left( \bar{l} - \bar{l}_0 \right)^2 / 2 \xi_\perp^2 \right] \tag{11}
\]

with \(\bar{\epsilon}_{2D} = \kappa_{a} A_b / \left( \sqrt{2 \pi} k_B T \pi k_{RL} V_b \right)\) and

\[
\kappa_{on} \simeq \bar{\xi}_{on} \frac{\bar{\xi}_\perp}{\xi_\perp} \exp \left[ - \left( \bar{l} - \bar{l}_{TS} \right)^2 / 2 \xi_\perp^2 \right] \tag{12}
\]

with \(\bar{\xi}_{on} = \sigma_{on}(k_B T)^{3/2} / (k_B \sqrt{\pi} k_{TS})\) for a Gaussian distribution \(P(l)\) of the local membrane separation \(l\) (see Eq. (3)). Here, \(\bar{l}_0\) and \(\bar{l}_{TS}\) are the preferred average separations for large roughnesses. For such large roughnesses, the dependence of \(K_{2D}\) and \(\kappa_{on}\) on the average separation \(\bar{l}\) is dominated by the shape of the distribution \(P(l)\), and the asymmetry of \(K_{2D}(l)\) and \(\kappa_{on}(l)\) are ‘averaged out’ in Eqs. (11) and (12). At the preferred average separations for binding, i.e. at the average separations for which the Gaussian functions in Eqs. (11) and (12) are maximal, the binding constant \(K_{2D}\) and on-rate constant \(\kappa_{on}\) can be estimated.
$k_{on}$ are inversely proportional to the relative membrane roughness $\xi_{\perp}$.

In our theory, the widths $\xi_{RL}$ and $\xi_{TS}$ of the functions $K_{2D}(l)$ and $k_{on}(l)$ depends on the anchoring strength $k_a$ of the receptors and ligands, and the preferred lengths and effective spring constants of the bound complex and the transition-state complex [9,10]:

\begin{align}
\xi_{RL} &\simeq \sqrt{(k_B T / k_{RL}) + (k_B T L_0 / 2k_a)^2} \\
\xi_{TS} &\simeq \sqrt{(k_B T / k_{TS}) + (k_B T L_{TS} / 2k_a)^2}
\end{align}

For the lipid-anchored receptors and ligands of our coarse-grained molecular model, these widths are $\xi_{RL} \simeq 2.1$ nm and $\xi_{TS} \simeq 2.2$ nm. For the transmembrane receptors and ligands, we have $\xi_{RL} \simeq 0.38$ nm and $\xi_{TS} \simeq 0.8$ nm. For the receptors and ligands of our elastic-membrane model, the width $\xi_{RL}$ of the function $K_{2D}(l)$ ranges between 1.3 nm and 5.0 nm, depending on the anchoring strength $k_a$ and complex length $L_0$ of the receptors and ligands. For receptor-ligand complexes of length $L_0 = 40.3$ nm, we have $\xi_{RL} \simeq 5.0$ nm, 2.5 nm, and 1.3 nm for the anchoring strengths $k_a = 4k_BT$, $8k_BT$, and $16k_BT$. For receptors and ligands with anchoring strength $k_a = 8k_BT$, we have $\xi_{RL} \simeq 1.3$ nm, 2.5 nm, and 3.8 nm for the complex lengths $L_0 = 20.4$ nm, 40.3 nm, and 60.3 nm.

5 Conclusions and outlook

The computational model systems and theories reviewed in this article indicate that the relative roughness $\xi_{\perp}$ of two adhering membranes plays an important role for the binding of membrane-anchored receptors and ligands. For concentrations [RL] of receptor-ligand bonds around 100/µm², the relative membrane roughness $\xi_{\perp}$ obtained from Eq. [4] is of the same magnitude or larger than the characteristic lengths $\xi_{RL}$ and $\xi_{TS}$ of the receptors and the ligands in our computational model systems, which reflect how strongly the local separation of the membranes is constrained by the receptor-ligand and transition-state complexes. The binding constant $K_{2D}$ and on-rate constant $k_{on}$ of the receptors and ligands then decreases with increasing relative membrane roughness $\xi_{\perp}$ in equilibrated membrane adhesion zones in which the average separation $l$ of the membranes is close to preferred average separation $l_0$ of the receptors and ligands for binding.

In the next years, experimental model systems of biomembrane adhesion may confirm the effect of the relative membrane roughness $\xi_{\perp}$ on the binding constant $K_{2D}$ of membrane-anchored receptors and ligands. In such model systems, the adhesion of reconstituted membranes is mediated by anchored adhesion proteins [68,90,100], by anchored saccharides [101,102], or by anchored DNA [103,106]. The roughness-dependence of $K_{2D}$ can be confirmed by demonstrating that $K_{2D}$ increases with the concentration [RL] of bound receptor-ligand complexes, because the relative membrane roughness $\xi_{\perp}$ decreases with increasing bond concentration [RL]. Measuring the relative membrane roughness requires a spatial resolution in the nanometer range both in the directions parallel and perpendicular to the membranes, which is beyond the scope of current optical methods used to probe membrane shape fluctuations [107,108]. However, the relative membrane roughness can be measured in neutron scattering experiments on stacks of oriented membranes that interact via anchored molecules [102].

Our general theories for the binding constant $K_{2D}$ and binding kinetics of membrane-anchored molecules reviewed in this article are in good agreement with simulation data for our computational model systems. These theories identify characteristic properties of the receptor and ligand molecules and of the apposing membranes that determine the binding equilibrium and kinetics. In the general Eqs. [1] and [2], the molecular properties of the receptors and ligands, including their membrane anchoring, are reflected in the functions $K_{2D}(l)$ and $k_{on}(l)$, and the properties of the membranes are reflected in the distribution $P(l)$ of the local membrane separation $l$. The distribution $P(l)$ has the Gaussian shape [3] with the average membrane separation $l$ and relative membrane roughness $\xi_{\perp}$ as characteristic lengths if the adhesion is dominated by a single type of receptors and ligands [9,10]. In our detailed theories for $K_{2D}(l)$ and $k_{on}(l)$ reviewed in Section IV, the receptor-ligand complex and the transition-complex are described as elastic springs that can tilt, which results in asymmetric, non-Gaussian functions $K_{2D}(l)$ for $k_{on}(l)$. Our theoretical results for the ratio of the binding constants $K_{2D}$ and $K_{3D}$ of membrane-anchored and soluble receptors and ligands agree with MC data without any fit parameters (see Figs. 2 and 3), which indicates that our theory captures the essential features of the ‘dimensionality reduction’ from 3D to 2D due to membrane anchoring, for both planar and fluctuating membranes. Other theories concern the binding of receptors and ligands anchored to essentially planar membranes [43], the binding of DNA immobilized on opposing nanoparticle surfaces [109,110], or the binding of flexible receptor and ligand polymers [111,113].
Appendix: Gaussian theory for membrane-anchored receptors and ligands

In classical theories [32, 88, 89], the effective configurational energies $H_{RL}$ and $H_{TS}$ of membrane-anchored receptor-ligand and transition-state complexes depend only on the membrane separation $l$. In harmonic approximation, such effective configurational energies lead to Gaussian functions

$$K_{2D}(l) = K_{2D}^{\text{max}} \exp \left[-(l-l_K)^2/2\xi_K^2\right]$$

$$k_{\text{on}}(l) = k_{\text{on}}^{\text{max}} \exp \left[-(l-l_K)^2/2\xi_K^2\right]$$

(15) and (16). Negative values of $\bar{l}_K$ imply that the off-rate constant $k_{\text{off}}$ is monotonously decreasing at positive average separations for $\xi_K > \xi_K$, and monotonously decreasing at such average separations for $\xi_K < \xi_K$. Because the membranes cannot intersect, the average separation $\bar{l}$ of the membranes does not attain negative values.
