(Dated: July 2, 2018. File: ar-cl-excur-f2-6.tex)

Prospects of experimental studies of argon and chlorine isotopes located far beyond the proton drip line are studied by using systematics and cluster models. The deviations from the widespread systematics observed in $^{28,29}$Cl and $^{29,30}$Ar have been theoretically substantiated, and analogous deviations predicted for the lighter chlorine and argon isotopes. The limits of nuclear structure existence are predicted for $^{26}$Ar and $^{25}$Cl in the respective isotopic chains. By simultaneous measurements of protons and $\gamma$-rays following decays of such systems as well as their $\beta$-delayed emission, an interesting synergy effect may be achieved, which is demonstrated by the example of $^{30}$Cl and $^{31}$Ar ground state studies. Such synergy effect may be provided by the new EXPERT setup (EXotic Particle Emission and Radioactivity by Tracking), being operated inside the fragment separator and spectrometer facility at GSI, Darmstadt.

I. INTRODUCTION

Several states in proton ($p$) unbound isotopes $^{28}$Cl, $^{30}$Cl and $^{29}$Ar were reported recently. This work continues the research published in Refs. [1][4]. The systematics and cluster model studies in [1] allowed to interpret the data as observations of ground state (g.s.) in $^{28}$Cl, g.s. and three excited states in $^{30}$Cl, and one state in $^{29}$Ar (either ground or excited state). Also the reported spectrum of $^{31}$Ar allowed for prescription of the g.s. energy of this isotope by using the isobaric symmetry systematics. Together with the known $p$-unbound isotopes $^{14,15,16}$F, the studied argon and chlorine isotopes constitute the most deeply-studied chains in the whole $Z \leq 20$ nuclei region.

In this work we continue the “excursion beyond the proton dripline” of Ref. [1]. We intend to answer the question: What impact the obtained experimental results...
may have on our understanding of prospects to study the other nuclides located far (e.g., 2–5 mass units) beyond the driplines? Correspondingly, we discuss three main topics:

(i) The previously-published systematics of one-proton (1p) separation energies is extrapolated further into the unexplored region beyond the proton drip line. The obtained results for the experimentally observed cases (28–30Cl nuclides) are considerably different from the systematic trends available in the literature 3–5. We extrapolate this systematics to the lightest chlorine and argon isotopes in Section II. The smaller than expected values of decay energies suggest longer-living states, and, consequently, weaker limitations on the nuclear structure existence beyond the dripline.

(ii) We clarify the prospects of a limit of the nuclear structure existence by using the obtained information on the separation energies. We assume that a nuclear configuration has an individual structure with at least one distinctive state, if the orbiting valence protons of the system are reflected from the corresponding nuclear barrier at least one time. Thus nuclear lifetime may be used as a gauge of such a limit. It is clear that the very long-lived particle-emitting states are quasistationary. This means that they can be considered as stationary for majority of practical applications. For example, the lifetimes of all known heavy two-proton (2p) radioactivity cases (45Fe, 48Ni, and 54Zn) have 2p decay lifetimes of milliseconds. Thus, their 2p decays are so slow that weak transitions become their competitors with branching rati of dozens of percent 6. We may assume that modification of nuclear structure by continuum coupling is absolutely negligible for such states. In contrast, the continuum coupling becomes increasingly important for broad ground states beyond the driplines. For example, see the discussion connected with studies of the 10He g.s. in Ref. 6. This work demonstrated that the observed continuum properties of 10He can be crucially modified by peculiarities of initial nuclear structure of the reaction participants for the widespread experimental approaches (e.g. knockout reactions). Such a situation can be regarded as transitional to continuum dynamics, where observable continuum response is also defined by the reaction mechanism and initial nuclear structure. Here the properties, interpretable as nuclear structure of the reaction products, cannot be reliably extracted from measured data. For example, we may refer to the well-known tetra-neutron system in continuum 11, where such an ambiguity has been demonstrated by applying the realistic scenario of the tetra-neutron population. Within the topic of the above discussion, we predict the limits of nuclear structure existence to be near the 25Cl and 26Ar isotopes in Section III.

(iii) The experimental setup, used in Refs. 3–5, is a pilot version of the EXPERT (EXotic Particle Emission and Radioactivity by Tracking) setup planned by the Super-FRS Experiment Collaboration of the FAIR project, see Refs. 11, 12 and Fig. III. The tracking system for light ions and γ-ray detector were installed downstream of the secondary target in the internal focal plane of the fragment separator FRS at GSI, Darmstadt (see the details in Ref. 1). The first half of FRS was set for production and separation of 31Ar ions, and the second half was used as a spectrometer for heavy-ion decay products. The optical time projection chamber (OTPC) installed at S4 can study beta-delayed particle emission and radioactive particle decays of heavy fragments living long enough to pass through the 30 m of S2-S4 second half of the FRS. In this paper we demonstrate that the complementary measurements performed by all components of the EXPERT setup can be combined together, which allows for synergy effect in studies of the above-mentioned unbound nuclear systems. Such an effect is demonstrated in Section IV by example of 30Cl and 31Ar studies.

The unit system $\hbar = c = 1$ is used in this work.

II. CHLORINE AND ARGON ISOTOPIC CHAINS FAR BEYOND THE PROTON DRIPLINE

The isotopes between $^{32}$Cl and $^{28}$Cl have been studied in Ref. 1 by applying the two-body cluster $^4S+p$ model. The major parameters of the model (potential and charge radii of the sulphur core nucleus) were systematically varied (see Table I in 1). The Thomas-Ehrman effect 13, 14, especially pronounced in the $s$-$d$ shell nuclei is well accounted in such a model. As a result, the...
The chlorine isotopic chain is given in Figure 5 (a). For spectrum is quite “poor”: it contains just one known $^{25}$Cl g.s. at $E_r = -S_p = 6.0 - 6.3$ MeV. By adding Coulomb interaction to this potential we obtain the $^{25}$Cl g.s. at $E_r = -S_p = 6.0 - 6.3$ MeV. The systematics of proton separation energies $S_p$ for the chlorine isotopic chain is given in Figure 5 (a). For illustration here we use the data compiled in NNDC database [3], the standard AME2012 evaluation [6], and the recent isobaric multiplet mass evaluation [7].

On the basis of the developed $S_p$ systematics for the chlorine isotopic chain, we can turn to the systematics studies of the argon isotopic chain. Following the approach of Ref. [1] we apply the systematics of odd-even staggering energies (OES)

$$2E_{OES} = S_{2p} - 2S_p,$$

see Figure 4. For the chlorine isotopic chain beyond the dripline there is the trend of overbinding because of Thomas-Ehrman shift (TES). For the argon isotopic chain there should be competition of two trends:

| Isotope | $S_{2p}$ | $S_{3p}$ | $S_{4p}$ |
|---------|----------|----------|----------|
| $^{26}$S | $-1.3$   | $2.0$    | $2.1$    |
| $^{25}$S | $-3.0$   | $-5.3$   | $-3.5$   |
| $^{24}$S | $-6.0$   | $-8.1$   | $-5.4$   |
overbinding because of TES (Coulomb displacement energy decrease because of increase of the valence orbital size) and underbinding due to E_{OES} reductions (pairing energy decrease because of increase of the valence orbital size). This effect has been already emphasized in Ref. [2]. Thus for the limiting estimates of the $S_{2p}$ in the argon isotopic chain we use the upper and lower estimates of $S_{p}$ shown in Fig. 5(a) subtracted from the full $2E_{OES}$ value and 1/2 of this value. The obtained results are shown in Fig. 5(b).

To conclude this section, the smaller than conventionally-expected separation energies $S_{p}$ and $S_{2p}$ are predicted in this work for the chlorine and argon isotopes far beyond the proton dripline. Such a general decrease should result in longer lifetimes of their ground and low-lying excited states, and consequently it may affect limits of existence of nuclear structure beyond the proton dripline.

III. LIMITS OF NUCLEAR STRUCTURE EXISTENCE FOR CHLORINE AND ARGON ISOTOPIC CHAINS

On of the fundamental tasks of nuclear science studies is determination of the limits of existence of individual states in nuclear systems. The lifetime can be chosen as a quantitative criterion of the nuclear structure formation.

FIG. 4. Odd-even staggering energies $2E_{OES} = 2S_N - S_{2N}$ for the isotones leading to $^{28}\text{Ar}$ (a) and $^{27}\text{Ar}$ (b) are shown by dotted line. The OES energies for the mirror isobar are given by solid line. Gray line is provided to guide the eye: this is solid line shifted down by constant values of about 0.5 MeV. The blue and red diamonds correspond to certain prescriptions of two-proton decay energy $E_T$ indicated in legends and giving odd-even staggering energies equal either its systematic value or half of this value.

FIG. 5. Separation energies $S_{2p}$ for the chlorine isotopic chain (a) and $S_{2p}$ for Ar chain (b) from [1] are shown by the solid black line plotted opposite the right axis. The thick gray lines plotted opposite the left axes show with offset the neutron/two-neutron separation energies for the mirror isotope chains. The systematic evaluations from [5] and [7] are given by red dashed and green dash-dotted lines. The results of this work and [1] based on cluster model and $E_{OES}$ systematics are shown by blue dotted lines (there are two lines for upper and lower limiting estimates). The experimental values for $^{29}\text{Cl}$ and $^{30}\text{Ar}$ are shown by red diamonds, while the results of [1] are given by red circles.

Let us consider the situation of a system formed by a potential barrier. Let us assume that in order to form a nuclear state, there should be at least one reflection of the valence nucleon from the barrier. Then the potentials for $^{A}\pi+p$ channel used in [1] and this work may help in estimations of such a limit for the chlorine isotopes by using the classical oscillation frequency

$$\nu = \left( \frac{2}{\int_{r_1}^{r_2} \frac{dr}{v(r)}} \right)^{-1} = \left( \int_{r_1}^{r_2} dr \sqrt{\frac{2M}{E-V(r)}} \right)^{-1},$$

where $r_1$ and $r_2$ are two inner classical turning points. For energies $E$ varying from 0 to $\sim 90\%$ of the barrier
FIG. 6. Internal normalizations for the ground states of $^{27-29}$Cl isotopes as a function of proton decay energy $E_r$. The gray solid curve shows the excitation spectrum of $^{26}$Ar obtained in three-body model as a function of two-proton decay energy $E_T$. One curve is given for both $^{29}$Cl and $^{27}$Cl, as the g.s. energies of these isotopes are predicted to be almost equal in Ref. [3].

height the estimate is $\nu \approx 1 - 3$ MeV. Thus we can assume that the systems with widths exceeding $3 - 5$ MeV have shorter lifetimes than those needed for formation of the nuclear state.

The width values of the chlorine isotopes can be estimated from the calculated excitation spectra which are illustrated in Fig. 6. For this purpose, we have used the internal normalization $N(E)$ for two-body continuum wave function $\psi(kr)$

$$N(E) = \int_0^\infty dr |\psi(kr)|^2,$$

as a measure of the resonance formation. This is done in contrast to conventional scattering phase shifts which could not provide a firm signature of a resonance formation in the case of very broad nuclear states ($\Gamma \gtrsim 1$ MeV). One may see in Fig. 6, that $s$-wave states in chlorine isotopes become quite broad already in $^{27}$Cl ($\Gamma \gtrsim 3$ MeV). However, the $d$-wave states remain reasonably narrow ($\Gamma \sim 1.5$ MeV) even in $^{25}$Cl with its quite high decay energy $E_r \sim 6$ MeV.

In Fig. 7 we provide the upper limit width estimates for the Ar isotopes. They are performed in a “direct decay” R-matrix model from Ref. [5], where each proton is assumed to be in a resonant state of the core+$p$ subsystem with resonant energy $E_{j1}$. The differential of the decay width is given by

$$\frac{d\Gamma_{j1j2}}{d\varepsilon}(E_T) = \frac{E_T\langle V_3\rangle^2}{2\pi} \frac{\Gamma_{j1}(\varepsilon E_T)}{(\varepsilon E_T - E_{j2})^2 + \Gamma_{j2}^2(\varepsilon E_T)/4} \times \frac{\Gamma_{j2}}{((1 - \varepsilon)E_T - E_{j2})^2 + \Gamma_{j2}^2((1 - \varepsilon)E_T)/4},$$

where $j_i$ is the angular momentum of a core+$p_i$ subsystem. This model can be traced to the simplified Hamiltonian of the three-body system in which the nucleons interact with the core, but not with each other. The model approximates the true three-body decay mechanism and also provides a smooth transition to the sequential decay regime [13, 20]. The matrix element $\langle V_3 \rangle$ can be well approximated by

$$\langle V_3 \rangle^2 = D_3[(E_T - E_{j2} - E_{j3})^2 + (\Gamma_{ph}(E_T))^2]/4],$$

where the parameter $D_3 \approx 1.0 - 1.5$ (see Ref. [20] for details) and $\Gamma_{ph}(E_T)$ should provide smooth width behavior around $E_T \sim E_{j1} + E_{j2}$. The assumed R-matrix parameters for the widths

$$\Gamma(E) = \frac{\theta^2}{2Mr_c^2} P_i(E, r_c, Z),$$

in the chlorine isotopes are given in Table I. It was shown in [3] that the calculation has a significant sensitivity only to the general decay parameters $\{E_T, E_r, \Gamma\}$.

For the width estimates in Fig. 7 we consider initial structure and decay of the Ar isotopes via $[s^2]_0^2$ configurations with $s$-wave resonance parameters inherited from two-body model calculations for the chlorine isotopic chain. Such an assumption guarantees that this is an upper limit width estimate (see discussions in [3, 13, 20]). This does not work for $^{26}$Ar. The $^{25}$Cl which is core+$p$ subsystem of $^{26}$Ar has very “poor” spectrum with just one low-energy $d$-wave state. For that reason we make $[d^2]_0^2$ estimate for $^{26}$Ar decay, but to cross check it we make three-body calculations of excitation function in a full three-body model: it is known that for $2N$ decays of higher orbital configurations accounting for $N$-$N$ final state interaction may lead to a drastic decrease of the lifetime [21]. The three-body calculations are totally analogous to the calculations of $^{28}$O g.s. in Ref. [13] with the added Coulomb interaction in the $p$-$p$ and core-$p$ channels. The corresponding excitation function is shown in Fig. 8 and the estimated width value is also given in Figure 7.

To conclude this Section, relatively narrow states, which presumably can be interpreted in terms of nuclear structure, are predicted in the chlorine and argon isotopic chains down to $^{26}$Ar and $^{25}$Cl isotopes. These are

| $A$ | $l$ | $r_c$ | $\theta^2$ | $E_r$ | $\Gamma_r$ |
|----|----|------|-------|-----|-------|
| 26 | 2  | 3.31 | 1.0   | 6.0 | 0.5   |
| 27 | 0  | 3.55 | 1.5   | 5.1 | 3.3   |
| 28 | 0  | 3.60 | 1.5   | 4.2 | 2.2   |
| 29 | 0  | 3.64 | 1.5   | 1.6 | 5.7 x 10^{-3} |
| 31 | 0  | 3.73 | 1.5   | 0.5 | 5.3 x 10^{-6} |
| 31 | 2  | 3.73 | 1.0   | 0.5 | 3.6 x 10^{-8} |
FIG. 7. Widths and lifetimes of $^{29}$Ar–$^{26}$Ar as functions of decay energy estimated in a direct decay model. The obtained decay energy of $^{26}$Ar is indicated by black circle. The energies predicted in this work are indicated by red-cyan circles. The magenta arrow points to the $\{E_T, \Gamma\}$ position evaluated for the $^{26}$Ar isotope within the three-body model, see Fig. 6. The hatched area indicates the lifetime range where the nuclear structure begins to “dissolve”.

located on $N = 8$ shell closure and the lighter systems along these chains are not expected to exist. Population of such exotic systems is far beyond the reach of any modern experiment. However, we want to emphasize that there exists a rich, often not considered, research field far beyond the proton dripline which does not seem to be exhausted in the observable future.

IV. SYNERGY EFFECT IN THE EXPERT SETUP

The experimental setup used in the works \[1\] is a pilot version of the EXPERT (EXotic Particle Emission and Radioactivity by Tracking) project proposed for the physics program of the Super-FRS Experimental collaboration of the FAIR facility, see Refs. \[11, 12\]. The EXPERT setup will be located mainly in the middle of the Super-FRS fragment separator which first part will produce and separate ions of interest and the second part will measure momenta of heavy-ion decay products with high precision. The EXPERT setup is being tested at the FRS fragment separator at GSI (Darmstadt). It consists of the following devices, see Fig. 1 \(i\) charged-particle tracking system based on microstrip silicon detectors ($\mu$SSD) located downstream of the secondary target in the S2 middle focal plane of FRS, \(ii\) Optical time projection chamber (OTPC) at the end of FRS, \(iii\) $\gamma$-ray detectors around the secondary target GADAST. Important part of the EXPERT initiative is \(iv\) the use of the second half of FRS as a high-resolution spectrometer. This feature provides unique \{A, Z\} identifications for a number of possible long-lived (i.e., with $T_{1/2} \gtrsim 100$ ns) heavy-ion reaction products and their implantation into the OTPC for radioactivity studies.

The instruments \(i\)–\(iii\) can be operated as independent devices and each of them has scientific value of their own. However, for studies of nuclear systems beyond the dripline, the elements of EXPERT operated together provide an important synergy effect which has not been discussed so far. Let us demonstrate such a synergy effect by example of the $^{30}$Cl and $^{31}$Ar g.s. studies.

Figure 8 shows the constrains that can be imposed on the ground state energies of $^{30}$Cl and $^{31}$Ar connected with different types of measurements and theoretical considerations given below. They are partly based on the lifetime estimates for these isotopes found in Fig. 2. First, let us explain the Fig. 9. The lifetime of $^{30}$Cl is calculated for $^{28}$S$^+_p$, s-wave decay in R-matrix model. The lifetimes of $^{31}$Ar ground and first excited states are estimated in R-matrix-type direct decay three-body model, see Eq. (1), Table 2 and discussion around them. The calculations are performed assuming the $|s^2\rangle$ and $|sd\rangle$ configurations in the $^{28}$S$^+_p$+$p$ channel, respectively. For the $^{31}$Ar first excited state the $2p$ decay energy $E_T \sim 1$ MeV is expected, while for $^{30}$Cl g.s. the expectation is $E_T \sim 0.5$ MeV \[1\]. Therefore for this state the turnover from true $2p$ to sequential $2p$ decay is expected at $E_T \gtrsim E_r$. These decay modes are characterized by very different behavior of width as a function of energy. We have estimated three lifetime curves for the $^{31}$Ar first excited state corresponding to the assumed $^{30}$Cl g.s. energies of 0.4, 0.55, 0.7 MeV, which are shown in Fig. 9 by the red dotted curves.
One should note that the widths of states are estimated for the fastest possible s-wave proton emission from 30Cl as well as the fastest \( |s^2| \)-wave 2p decay from 31Ar g.s. We have also assumed that the first process in the decay of the 31Ar first excited state is the emission of the s-wave proton, which is a very conservative estimate because the 30Cl g.s. has presumably an s-wave configuration. So, the more realistic lifetime limitations could be even more stringent than those provided below.

Now we turn to description of the obtained limits on decay energies of 31Ar and 30Cl, which are illustrated in Figure 8.

(i) The horizontal and vertical hatched bands correspond to the energies directly inferred from the measurements by \( \mu \)SSD tracking system as discussed above in this work and in Ref. 1.

(ii) The diagonal hatched band is provided based on the systematics of OES energies of Fig. 13 (a) from Ref. 1. We assume that isobaric symmetry for 31Ar is a good assumption giving \( 2E_{\text{OES}} = 0.915 \) MeV. In Fig. 8 we assume that some deviation from this value (–300 keV) is possible but not too much and \( 2E_{\text{OES}} = 0.615 \) MeV is taken as the lower limit.

(iii) The ions of 30Cl were not observed at the final focal plane of FRS. This means that the lifetime of 30Cl is shorter than the time-of-flight (ToF) through the S2–S4 section of FRS which is around 150 ns. We use the ToF value of 50 ns as the limit estimate. This imposes the corresponding lower-limit estimate \( E_\tau > 160 \) keV, see the green arrow in Fig. 8 and the magenta horizontal dotted line in Fig. 8.

(iv) The 31Ar isotopes were implanted into the OTPC in order to study \( \beta \)-delayed proton emission \( \beta p \). No events of 2p decay of 31Ar were observed. A non-observation limit value is less than the obtained branching ratio of \( 7(2) \times 10^{-4} \) for the \( \beta \)-delayed decay channel of 31Ar. This means that the 31Ar g.s. energy is \( E_T < 0.4 \) MeV, see blue arrow in Fig. 8 and vertical violet dotted line in Fig. 8. Otherwise, the prompt 2p emission from 31Ar becomes faster than its \( \beta \)-decay.

(v) The estimated lifetime curves for 2p decay of the 31Ar first excited state are given in Fig. 9. It is clear that if the lifetime of 31Ar with respect to 2p emission is longer than \( \sim 1 \) fs, than the preferable decay branch for this state will be \( \gamma \)-deexcitation to the ground state. Since the 2p decay of the 31Ar first excited state was really observed, then the lifetime limitations indicated by red arrows in Fig. 9 infer synchronous limitations both on proton decay energy \( E_\tau \) for 30Cl g.s. and two-proton decay energy \( E_T \) for the 31Ar first excited state. The latter is transferred into \( E_T \) for the 31Ar g.s. in Fig. 8 by subtracting 0.96 MeV as assumed from isobaric symmetry with 31Al in Ref. 1 (inclined black dotted line). As example, consider the \( E_\tau = 0.7 \) MeV curve in Fig. 8. It provides \( E_T = 1.21 \) MeV limit and thus leads to black dotted line passing through point \{0.21, 0.7\} in Fig. 8.

(vi) Analogous information could be in principle inferred from non-observation of \( \gamma \)-rays from the \( \gamma \)-decay of the 31Ar first excited state in GADAST (inclined red line in Fig. 8). The statistics in the current experiment was not sufficient to make this information significant, but in general case it could provide additional cross-check of consistency for the different types of the data.

All in all, the limitations shown in Fig. 8 lead together to a dramatic reduction of the area admissible for the correlated 30Cl vs. 31Ar g.s. energies compared to the data provided by the \( \mu \)SSD tracking detectors of the EXPERT only. We should state here that the confidence in the results for 30Cl and 31Ar g.s. energies is strongly enforced by the synergy analysis presented here.

V. SUMMARY

In this work we base on the data concerning the most remote from the proton dripline 30–28Cl and 31–29Ar isotopes, which allow for the further advances in studying an unknown domain beyond the proton dripline.
The main results of this work are:
(i) The systematic studies of the chlorine and argon isotopic chains beyond proton dripline have been performed. Large Thomas-Ehrmann shifts were revealed for the $^{30}\text{Cl}$ and $^{30}\text{Ar}$ isotopes in Ref. [2], and here we report further increased values in the $^{28}\text{Cl}$ and $^{30}\text{Cl}$ isotopes. The predictions for the very remote from the dripline isotopes $^{27}\text{Cl}$ and $^{28}\text{Ar}$ are provided by the elaborated models. For these isotopes, the Thomas-Ehrmann effect becomes less important as (a) the isobaric mirror partners of these nuclides are located in proximity of the neutron dripline and (b) the ground states are $d$-wave states which are less prone to modification by the Thomas-Ehrmann shift.
(ii) The obtained decay energies for the experimentally observed cases ($^{28-30}\text{Cl}$ nuclides) [1] are considerably different (smaller) from the systematic trends available in the literature. The extrapolations to even lighter chlorine and argon isotopes also continue this trend. Smaller decay energy systematics means “survival” of the nuclear structure for even more remote from the dripline particle-unstable systems. The limits of nuclear structure existence for the proton-rich edge of chlorine and argon isotope chains are predicted to be in $^{28}\text{Ar}$ and $^{29}\text{Cl}$.
(iii) Amazingly small $2p$-separation energy of 6(34) keV of the $^{31}\text{Ar}$ ground state reported in the preceding article [1] has been explored in addition by using the complementary data available in the setup and relevant theoretical speculations. The synergy effect for the measurements by different detectors of the EXPERT setup was demonstrated, which provides more confident conclusions for the decays of $^{30}\text{Cl}$ and $^{31}\text{Ar}$ isotopes.
