The compaction dynamics of a granular media subject to a sequence of vertical taps made of fluid pulses is investigated via Molecular Dynamics simulations. Our study focuses on three different levels: macroscopic (volume fraction), mesoscopic (Voronoi volumes, force distributions) and microscopic (grain displacements). We show that the compaction process has many characteristics which are reminiscent of the slow dynamics of glass forming systems, as previously suggested. For instance the mean volume fraction slowly increases in time and approaches a stationary value following a stretched exponential law, and the associated compaction time diverges as the tapping intensity decreases. The study of microscopic quantities also put in evidence the existence of analogies with the dynamics of glass formers, as the existence of dynamical heterogeneities and spatially correlated motion of grains; however it also shows that there are important qualitative differences, as for instance in the role of the cage effect. Correlations between geometry and dynamics of the system at the grain level are put in evidence by comparing a particle Voronoi volume and its displacement in a single tap.

I. INTRODUCTION

When subject to vertical vibrations granular materials can produce a variety of distinct phenomena, depending both on the driving parameters and on the container properties. A great deal of interest has been recently raised by the process of compaction under successive vertical taps. Experiments show that the density of a column of grains submitted to vertical tapping increases slowly in time with a law well fitted by a stretched exponential or logarithmic function, and that the characteristic compaction time grows abruptly as the driving intensity decreases. These observations have suggested an analogy with glass-forming systems, where the relaxation time diverges as the temperature is decreased; the analogy is corroborated by the fact that concepts like frustration and free volume, which are commonly used to explain the slow dynamics of supercooled liquids and other thermal systems, do also provide an insight in the physics of powder compaction.

However, contrary to supercooled liquids, granular materials are non-thermal systems as their typical energy scale, the energy required to rise a grain of its own diameter against gravity, is orders of magnitude larger than the thermal energy $k_B T$: each granular pack is in a mechanically stable state, which last as long as there is no external perturbation. Therefore even though the dynamics induced by a sequence of vertical taps becomes slower and slower as the tapping intensity decreases, important qualitative differences may exist between slow granular dynamics and glassy dynamics.

Here we investigate analogies and differences between granular dynamics and glassy dynamics by performing molecular dynamics (MD) simulations of a granular system subject to a sequence of vertical taps where, in order to explore a wide range of volume fractions, the system is tapped via flow pulses as in the experiment of Schröter et al. We investigate the evolution of macroscopic quantities (volume fraction), mesoscopic quantities (Voronoi volumes, force distributions) and microscopic quantities (grain displacements), and we discuss how various static properties of a granular pack change during compaction. We found several analogies between the compation of granular media, and the slow dynamics of glass forming systems, as the divergence of the relaxation times, dynamical heterogeneities and spatially correlated motion; but we also show evidences of important qualitative differences, as in the role of the cage motion, which are put in evidence by the study of particle trajectories.

The paper is organized as follows. Sec.III presents the numerical model used. Then compation dynamics, investigated via the study of the time dependence of the volume fraction, and of the diffusion coefficient at stationarity, is discussed in Sec.IV. The evolution of structural properties of a compacting granular pack, the radial distribution function, the distribution of Voronoi volumes, and the distribution of interparticle forces, is presented in Sec.V. Sec.VI discusses the compaction dynamics at a grain level, showing the existence of dynamical heterogeneities and of spatially correlated motion of grains, and putting in evidence qualitative differences in the particle trajectories of compacting granular media and glass formers. Sec.VII also presents a connection between geometrical (Voronoi volumes) and dynamical (particle displacements) properties of the system. Finally, a conclusion summarizes the main results and perspectives.
II. NUMERICAL MODEL

We run Molecular Dynamics (MD) simulations of $N = 1600$ monodisperse spherical grains of diameter $d = 1\text{cm}$ and mass $m = 1\text{g}$. Grains, under gravity, are confined in a box with a square basis of length $L = 10\text{cm}$, with periodic boundary conditions in the horizontal directions. The bottom of the box is made of other immobile, randomly displaced, grains (to prevent crystallization). Simulations with 4 time more particles in a system with a square basis of length $2L$ give the same results, so we exclude the presence of finite size effect in our system.

Two grains in contact interact via a normal and a tangential force. The former is given by the spring-dashpot model, while the latter is implemented by keeping track of the elastic shear displacement throughout the lifetime of a contact \[12\]. The model is the one described in \[13\] with a restitution coefficient, $e = 0.8$. We use the linear model instead of the more realistic Hertzian model \[14\] as this latter is characterized by a coefficient of restitution which goes to zero as the relative velocity of the impacting particles decreases \[12\]. This feature makes computationally expensive the simulation of a granular system reaching a mechanically stable state.

The system is immersed in a fluid and, starting from a random configuration, it is subject to a dynamics made of a sequence of flow pulses where the fluid flows through the grains (see Fig.1), as in the experiment of Ref.\[2\]. In a single pulse the flow velocity, directed against gravity, is $V > 0$ for a time $\tau_0$; then the fluid comes to rest. We model the fluid-grain interaction as in Refs.\[15,16\] via a viscous force proportional to the fluid grain relative velocity: $F_{fg} = -A(v - V)$ where $v$ is the grain and $V = (0,0,V)$ is the fluid velocity. The prefactor $A = \gamma(1 - \Phi_l)^{-3.65}$ is dependent on the local packing fraction, $\Phi_l$, in a cube of side length $3d$ around the grain, and the constant is $\gamma = 1 \text{Ns/cm}^2$ \[16\].

During each pulse, grains are fluidized and then come to rest under the effect of gravity $g$. The system is considered to be still when the kinetic energy per grain is below $10^{-5} \text{mgd}$. All measures below are recorded when the pack is at rest.

The dynamics of dry granular media subject to vertical vibrations is determined by two parameters, the amplitude and the frequency of vibrations. In the system we are investigating here there are also two parameters, the tap duration $\tau_0$ and the fluid velocity $V$.

III. DYNAMICS

A. Volume fraction

When subject to a sequence of flow pulses a granular system compactifies (or expands) until it reaches a stationary state which depends on the driving parameters \[2\]. Fig.2 shows the evolution of the volume fraction $\Phi$ (measured in the bulk of the system) with the number of flow pulses for systems subject to a tap dynamics with tap length $\tau_0 = 0.03\text{s}$ and various values of the fluid velocity $V$. Each curve is obtained by averaging over 32 independent realizations. Similar curves are obtained with different values of $\tau_0$.

The time evolution of the volume fraction is well described by a stretched exponential law,

$$\Phi(t) = \Phi_\infty - (\Phi_\infty - \Phi_0) \exp\left(-\frac{t}{\tau^c}\right),$$  \hspace{1cm} (1)

with $c \simeq 1$. This is in agreement with experimental results of Philippe et. al. \[1,3\], which have investigated the relaxation dynamics of dry granular media subject to vertical taps in a system with a height to width ratio similar to ours. On the contrary Nowak et. al. \[3,4\] have investigated a system with a larger height to width ratio, finding logarithmic compaction.

As in previous experiments of both vibrated \[1,3,6,18\] and fluidized \[2\] granular systems, when the tapping intensity decreases the system compactifies more. This is clearly illustrated in Fig.3 where we show the dependence of the volume fraction reached at stationarity on

![Fig. 1: (Color online) We study the compaction process of a granular media subject to flow pulses. During each pulse (tap), of duration $\tau_0$, fluid flows with velocity $V$ through the granular media. Before applying a flow pulse we wait until the granular media comes to a rest.](image1)

![Fig. 2: (Color online) Temporal evolution of the mean volume fraction $\Phi$ for $\tau_0 = 0.03\text{s}$ and the reported values of fluid velocities $V$. The data obtained via simulations of a larger systems (4 times more particles) evidence the absence of finite size effects. Dashed lines are fit to a stretched exponential law.](image2)

the fluid velocity $V$ for various values of the tap length $\tau_0$. As one could have expected the final stationary state depends both on $V$ and $\tau_0$. However it is possible to show numerically [19] that the final state can be characterized by one thermodynamical parameter, supporting the idea of a statistical mechanics description of granular media at rest [9, 20, 21, 22] originally proposed by S.F. Edwards [23].

B. Compaction time

The relaxation time $\tau$ which appears in Eq. 1 is a measure of the number of flow pulses required by the system to reach stationarity. The experiments of Ref. [5] have investigated a range of parameters $V, \tau_0$ where the system reaches a stationary state after few flow pulses. On the contrary, the experiments of Bideau et al. [1] have investigated a range of parameters where the compaction dynamics of the system is glassy like. They report a relaxation time following an Arrhenius behavior with the inverse maximum acceleration of the pack, $\tau \propto \exp (1/T)$. In the system under investigation here the relaxation time also evidences the existence of a glassy dynamics of the system, as it diverges with a power law with decreasing fluid velocity,

$$\tau \propto V^{-\beta} \tag{2}$$

with $\beta \approx 1.17 \pm 0.04$, as shown in Fig. 4 (for data with tap length $\tau_0 = 0.03$ s). The same behavior is observed for different values of the tap length $\tau_0$.

C. Stationary dynamics

After having applied a long sequence of pulses up to reach the stationary state, we have computed the mean square displacement,

$$\langle r^2(t) \rangle = \frac{1}{N} \sum_i (\mathbf{r}_i(t + t_w) - \mathbf{r}_i(t_w))^2, \tag{3}$$

with $\mathbf{r}_i(t)$ position of grain $i$ after $t$ taps, and $t_w$ waiting time which depends on the driving conditions ($t_w \approx 3\tau$). From the mean square displacement, shown in Fig. 5 we have extracted the diffusion coefficient $D \langle \langle r^2(t) \rangle \propto Dt \rangle$ which decreases with the fluid velocity as a power law, $D \propto V^{\beta}$, with the same exponent observed for the dependence of the relaxation time on the fluid velocity (Fig. 5). This suggest the existence of relation $\tau \propto D^{-1}$ relating the compaction time and the diffusion coefficient at stationarity, which is illustrated in the inset of Fig. 5 (lower panel).

The mean square displacement evidences the absence of a subdiffusive regime in the slow dynamics of granular media subject to flow pulses, a signature of the cage effect in supercooled liquids. In Sec. V we will show that particles may be constrained in a cage, but that the escaping time is too small (few taps) in order to affect the mean square displacement.

IV. STRUCTURE EVOLUTION

A. Radial distribution function

The radial distribution function $g(r)$ is the probability distribution of finding the center of a particle in a given position at a distance $r$ from a reference sphere. Since it contains information about long range interparticle correlations, it is a common tool in the characterization of packing structures. Here we study how the radial distribution functions, which we normalize as usual is such a way that $g(r) \to 1$ for $r \to \infty$, evolves during compaction.
distribution function on the volume fraction has been ob-

eral structure of the system, only specified by its volume

densities, and numerically by L.E. Silbert

right panel: the inverse diffusion coefficient (measured

cm/s). Right panel: the inverse diffusion coefficient (measured

displacement (in the stationary state) for $\tau_0 = 0.03$ s and fluid velocities

similar dependence of the secondary peaks of the radial

diagram shows $g(r)$ at different times during compaction ($\tau_0 = 0.03$ s, $V = 0.2$ cm/s); similar results are found with different values of $\tau_0$ and $V$. The first strong peak at $r = d = 1$ cm corresponds to the high probability of a having a neighbor in contact. This peak characterizes all dense systems of hard particles, as a consequence of their impenetrability. In a granular media at rest under gravity it is enhanced by the fact that, in order for the system to be stable, each grain must contact other grains. The following two maxima, as shown in the inset, appears at $r = \sqrt{3}d$ and $r = 2d$. Both of them increase with the volume fraction indicating an increasing organization of the packing (not necessarily related to the formation of ordered structures [25]). A similar dependence of the secondary peaks of the radial distribution function on the volume fraction has been observed experimentally by T. Aste at al. [25], which have investigated via x-ray tomography packs with different densities, and numerically by L.E. Silbert at al. [13].

In a granular pack of monodisperse spheres of volume fraction $\Phi$ the mean volume occupied by a particle is $V_{p}/\Phi$, where $V_{p}$ is the volume of a particle. When the system is in a disordered state there will be both particles occupying a larger volume, and particles occupying a smaller one. It is therefore instructive to investigate what is the probability that a given particle occupies a volume $v$, and how this probability changes during compaction.

To this end one has to operatively define what is the volume occupied by a particle: by using the Voronoi tessellation (as in [25] we define the volume $v_{i}$ occupied by particle $i$ as the volume of the convex polyhedron which contains all points closer to particle $i$ than to any other particle. Fig. 7a shows the distribution $P(v)$ of the Voronoi volumes of a system tapped with $\tau_0 = 0.03$ s and $V = 0.2$ cm/s, after 1, 10, 100 and 300 taps. These are slightly asymmetric distributions with exponential tails (Fig. 7a, inset). The asymmetry is a standard feature of the Voronoi distribution: for an ideal gas in one dimension, for instance, $P(v) \propto v \rho^2 (1 - \rho)^{v}$, where the Voronoi volume $v$ of a given atom is half of the distance between its left and right nearest neighbors. As the system compacts both the mean value $\langle v \rangle$ and the standard deviation $\sigma_{v}$ of the distribution decrease. However the distribution retains its functional form: when $\sigma_{v} P(v)$ is plotted versus $(v - \langle v \rangle)/\sigma_{v}$ all of the different curves scale on the same master curve, as shown in Fig. 7b. This scaling suggests the existence of a single geometrical structure of the system, only specified by its volume fraction, and tell us that there are no dramatic structural changes during compaction.

The same scaling of the distribution of Voronoi volumes has been observed by F.W. Starr et al. [25] in MD simulations of a glass-forming polymer melt, and is ver-

in Fig. 7c. The discrepancy which may be due to the fact that Ref. [26] investigates a thermal system, while Ref. [25] investigates a polydisperse system, needs further investigation.

C. Force distribution

Since the work of Mueth et al. [27] interparticle force distributions have become a standard tool for the characterization of granular packs. There are now experiments, numerical simulations and theories (see [28] and references therein) finding an exponential decay at high forces. This exponential decay is the signal of an heterogeneous structure of the system: while most of the interparticle normal forces have magnitude close to the mean value, there are also interparticle normal forces of much higher magnitude. Moreover, these high forces have been shown to be spatially related, giving rise to the well known force chains.

We have studied the evolution of the probability distribution of normal forces during compaction. In order to avoid the effect of gravity (due to the absence of vertical walls the mean vertical stress depends on the depth) we have computed the probability distribution of the normal forces between grains contacting in a point at a height \( z \) enclosed in a thin horizontal slice (\( z > 8 \) cm and \( z < 10 \) cm). Similar results are observed when selecting different horizontal slices of our system. Fig. 8 shows the force probability distribution after 1, 10, 100, and 300 taps (corresponding to volume fractions in the range 0.576 – 0.616). Since the distributions collapse on the same curve normal forces appears not to be affected by the density of the system (in the range we have investigated). We conclude that the force distribution is rather insensitive to the density of the granular pack, as also observed in Ref. [33] and in [34] (where it is show

FIG. 8: (Color online) The distribution of interparticle normal forces decay exponentially at high forces, it appears to be insensitive on the packing fraction of the system.
A simple explanation of the decreasing of the compressional force with the Voronoĭ volume can be obtained via the following argument. Consider two contacting particles at a distance \( l \). Their interparticle force decreases with \( l \) and particularly in our case, due to the computational model used, \( f = k(d - l) \), where \( d \) is the diameter of a particle. On the other hand the Voronoĭ volume \( v \) of one of these particles increases with \( l \). Assuming \( v \propto l^3 \), one obtains \( f \propto (d - v^{1/3}) \), i.e. a decrease of the compressional force with the Voronoĭ volume. The data of Fig. 9 are consistent with \( \alpha = 3 \), as expected for dimensional reasons. However a reliable estimate of \( \alpha \) is difficult to obtain as Voronoĭ volumes vary in a small range.

V. GRAIN MOTION

In this section we investigate how a granular pack moves during a single tap. We consider a system subject to a tap dynamics with \( \tau_0 = 0.03 \) s and \( V = 0.2 \) cm/s, and compare the state reached after the application of \( n \) taps, with the state reached after the application of one more tap (with \( n = 1, 10, 100, 300 \)).

Particularly we investigate the distribution of particle displacements, the heterogeneity of particle motion, and the correlation between a particle displacement and both its Voronoĭ volume and the compressive force acting on it.

A. Particle trajectory and cage motion

Fig. 10 shows a typical trajectory of a particle during compaction. As observed in colloidal systems the trajectory is characterized by period of time in which the particle is confined in cages formed by its neighbors. Cage motion has also been observed before in experiment of granular materials subject to continuous vibrations \( 29, 30, 31, 32 \). The typical linear size of the cage is roughly \( 0.05d \), where \( d = 1 \) cm is the diameter of the particles. A similar ratio between cage size and particle size has been observed in \( 30 \). However there is an important qualitative difference between the motion of a particle in colloidal suspension and other glass forming systems, and that observed in our system. In glass forming systems a particle spend most of its time rattling inside a cage,
from which it escape via infrequent cage-breaking rearrangements. Here we observe the opposite behavior: particles usually diffuse, and sometimes they get trapped in a cage. This unusual property of the trajectory is put in evidence by the study of the distribution of the angle α formed by the displacements $\Delta_n$ of a particle during tap $n$, and the displacement $\Delta_{n+1}$ of the same particle during the following tap. Figure 11 shows the distribution of $\cos(\alpha)$, which is strongly peaked near 1. This is a clear indication that particles usually move along straight lines (as also confirmed by Fig. 10), and that cage motion is negligible: for a particle rattling in a cage two consecutive displacements have opposite direction, and $\cos(\alpha) \approx -1$.

The absence of cage motion is due to the driving mechanism. During a tap the system expands, cages break, and it is easier for the grains to move one with respect to the other.

**B. Particle displacements**

Here we investigate the evolution of the distribution of particle displacements during a single tap. After the application of a flow pulse to our system (and the following relaxation) a particle $i$, initially located in $\vec{r}_i$, will be in a new position $\vec{r}'_i + \Delta_i$, where $\Delta_i$ denotes its displacement. We examine below the probability that a particle makes a given displacement $\Delta$. Due to presence of gravity, which breaks the up-down symmetry of the system, it is convenient to separate the vertical component of the displacement, $\Delta z_i$, from the horizontal ones, $\Delta x_i$ and $\Delta y_i$. As $\Delta x_i$ and $\Delta y_i$ have the same, even distribution, we have studied the evolution of the distribution of $\Delta h = |\Delta x| + |\Delta y|$. In order to follow the dynamics of the system, in Fig. 12 we have plotted the probability distribution of $\Delta z$, $P_z(\Delta_z)$, (upper panel) and of $\Delta h$, $P_h(\Delta_h)$, (lower panel) during tap number 1, 10, 100 and 300.

During the compaction process displacements with $\Delta z < 0$ are more probable than those with $\Delta z > 0$. Therefore, as shown in Fig. 12 (upper panel), $P_z(\Delta_z)$ is asymmetrical. The asymmetry of the distribution decreases as the system compactifies and after 300 taps, when stationarity is almost attained, $P_z(\Delta_z)$ appears to be nearly symmetric. Accordingly the value of $\Delta z$ where $P_z(\Delta_z)$ has its maximum increases, starting from a negative value, until it reaches zero. Also, it is apparent that as the system compactifies the variance of the distribution decreases. The probability of a large vertical displacement to occur is smaller in a dense rather than in a fluffy system. This is also true for the probability of large horizontal displacements, as shown in Fig. 12 (lower panel).
An important feature of the probability of both vertical and horizontal displacements is the nearly exponential decay at large displacements. This is an indication of the fact that, while during a tap most of the particles are subject to small displacements, very few of them may move much more. We conclude that the system is characterized by a heterogeneous dynamics. This is a well known property of thermal systems, like liquids or colloids (see Ref. [37] for a review), which appears upon cooling the system near the glass transition. For instance, in colloidal systems the exponential tail of the particle displacement distribution has been experimentally observed by Weeks et. al. [36].

The probability distribution function of particles displacements can be further analyzed via the study of the excess-kurtosis

$$\alpha^{(i)}_2 = \frac{\langle (\Delta_i - \langle \Delta_i \rangle)^4 \rangle}{3\langle (\Delta_i - \langle \Delta_i \rangle)^2 \rangle^2} - 1, \quad i = h, z, \quad (6)$$

a comparison between the second and the fourth central moment of the distribution, which is zero for a gaussian distribution. We have first considered the excess-kurtosis as obtained from the probability of particle displacements in a single tap: $\alpha^{(h)}_2$ and $\alpha^{(z)}_2$ fluctuate from tap to tap, and their mean values are $\alpha^{(h)}_2 = 2.8 \pm 0.1$, $\alpha^{(z)}_2 = 4.3 \pm 0.2$. This positive values indicate that the probability distribution of particle displacements is more peaked with respect to a gaussian distribution. Then, we have considered the excess-kurtosis of the probability distribution of the horizontal and vertical components of $\vec{r}_i(n) - \vec{r}_i(n_0)$, the total displacement of a grain after tap $n_0$, where $n_0 = 100$ correspond to the compaction time. As expected form the central limit theorem at long times this excess-kurtosis is zero: Fig. 13 shows, interestingly, that in our system the excess kurtosis approach zero with a monotonic decay. This is in sharp contrast with the observations made in glass forming system, as in Ref. [34], where a peak is observed at the $\alpha$ relaxation time, i.e., when cage rearrangements occur. Therfore Fig. 13 confirms the marginal role played by cage motion in our system.

Our results put in evidence a very smooth behavior of the particles displacement distribution. Particularly we have not observed any ‘rare event’ (displacement of the order of 0.4 particle diameters), recently observed by Ribière and coworkers [35] in the study of a granular system undergoing compaction. This is probably due to the different driving mechanism of the systems. In shaken system, in fact, grains move one with respect to the other mainly when the pack settle downs and a shock wave propagates upwards; in our system, on the contrary, there is not a shock wave propagating as grains settle down slowly, and relative grain motion occurs during the tap.

C. Spatial heterogeneous dynamics

In supercooled liquids and dense colloidal systems the dynamics is heterogeneous as there are both slow and fast particles. Moreover, fast particles are known to be spatially correlated as they appear to form clusters [36, 37, 38]. Here we show that the exact same tendency characterizes a granular system subject to vertical taps, as suggested in Refs. [39, 40].

In order to characterize the spatially heterogeneous dynamics [38, 41, 42] one usually resorts to a four-point time-dependent density correlation function and to its fluctuations (susceptibility). This latter measures the correlated motion between pairs of particles. As this motion is decorrelated on short and long times, the susceptibility show a well defined maximum at a given time. Unfortunately we cannot follow this line here as many averages are needed in order to get clear data on the fluctuations, and our simulations are computationally too expensive. Moreover during compaction the system is not in a stationary state. In order to measure the degree of spatially heterogeneous dynamics we have therefore used a different method, based on the comparison between our system and a random one, as discussed below.

We apply $k$ flow pulses ($k = 1, 10, 100, 300$) to our system (who reaches volume fraction 0.576, 0.596, 0.612, 0.616) and we determine the $n_p$ particle having experienced the largest displacement during the last tap. Here $n_p = pN$, were $N = 1600$ is the total number of particles, $p = 1\%, 2\%, 5\%$ and $10\%$. When these fast particles are drawn, as in Fig. 14 it is apparent that they form clusters, an clear evidence of the spatially heterogeneous dynamics. We have quantified the degree of heterogeneity of the system as follows. After every tap we have determined the $n_p$ faster particles of the system, and determined the number $s_p$ of couples of these particles made of neighboring particles (we consider two particles to be neighbor if...
FIG. 14: Granular compaction is characterized by a spatially heterogeneous dynamics. After the $k$th tap ($k = 1, 10, 100, 300,$ and volume fraction $\Phi = 0.576, 0.596, 0.612, 0.616$) we plot the position of the $n_p$ particles which have experienced the largest displacement during the last tap, with $n_p = pN$ and $p = 1\%, 2\%, 5\%$ and $10\%$.

the distance between their center is smaller than 1.2 particle diameters). Then we have computed the same quantity $\delta_p^{\text{random}}$ in the case of $n_p$ randomly selected particles of the system. A measure of the degree of
spatial heterogeneous dynamics is given by

\[ \xi_p = \frac{s_p - s_{\text{random}}}{s_{\text{random}}} \] (7)

Clearly \( \xi_p \simeq 0 \) for an homogeneous systems, \( \xi_p > 0 \) if faster particles form clusters, while \( \xi_p < 0 \) if faster particles tend to be apart. Fig. 15 shows the evolution of \( \xi_p \) with the number of taps. In all cases \( \xi_p > 0 \), signaling the presence of an heterogeneous dynamics. When the system approaches the steady state, and compaction stops, \( \xi_p \) fluctuates around a plateau which varies with \( p \) between 0.5 and 1.5. These are very high values, indicating a high degree of spatial heterogeneity of the system.

**D. Volume-Displacement correlation**

It is well known than many equilibrium and transport properties of dense fluids depend on the space available for molecular motion. For instance the well known free volume theory developed by Cho and Turnbull 43 to explain the divergence (with a Vogel-Tamman-Fulcher law) of the relaxation time of many glass formers as the temperature is decreased, is based on the idea that the space available for molecular motion decreases with the temperature. It is therefore interesting to check for correlations between the displacement of a particle and its free volume in our granular system. There are many possible way to define the free volume of a particle. Here we approximate, for simplicity sake, we consider the free volume of particle \( i \) to be \( V^F_i = v_i - V_0 \), where \( v_i \) is the Voronoï volume of the particle (see Sec. 11.1) before the application of a tap, and \( V_0 = 4/3\pi(D/2)^3 \) its volume. The displacement \( \Delta_i \) of particle \( i \) \( (\Delta_i = (\Delta_{x_i}^2 + \Delta_{y_i}^2 + \Delta_{z_i}^2)^{1/2}) \) is the distance between the position of the particle before and after the application of the tap.

A possible connection between \( V^F_i \) and \( \Delta_i \) is suggested by the similarity between the the probability distribution functions of Voronoï volumes (see Fig. 7a), and that of particles displacements (Fig. 12). Both of them have an exponential tail at high values. Moreover they evolve in a qualitatively similar way (the variance and the mean value decrease) as the system compactifies.

In order to test this possible correlation we have computed during the \( n \)th tap (\( n = 1, 10, 100, 300 \)) \( (\tau_0 = 0.03 \text{ s, } V = 0.2 \text{ cm/s}) \) the mean value of the displacement \( \Delta \) of all the particles with free volume \( V^F \). The dependence of \( \Delta \) on \( V^F \) is shown in Fig. 16. This figure puts in evidence the existence of an almost linear correlation between Voronoï volumes and particle displacements, with \( \partial \Delta / \partial v \simeq 0.01/0.2 = 0.05 \text{ cm}^{-2} \): the larger the Voronoï volume of a particle, the bigger its displacement.

**E. Force-Displacement correlation**

In the previous paragraph we have shown that there is a correlation between the displacement \( \Delta \) of a particle during a single tap, and its free volume. Fig. 17 investigates the correlation between displacement and compression \( C \) (see Eq. 4) of a particle. The figure puts in evidence that for small values of the compressional force there is a decreasing linear relation between displacement and compression of a particle, while for higher value of the compressional force the two becomes uncorrelated.
VI. CONCLUSIONS

We have reported results of a numerical simulations of a packing of monosize spheres submitted to vertical taps made of flow pulses as in the experiment of Ref. [5]. Our results relative to the dynamics of the systems confirms earlier experimental observation: as the intensity of vibration decreases both the value of the volume fraction reached at stationary and the compaction time increases [1, 3, 5, 6, 18]. The increase of the compaction time with the decreasing of the vibration intensity is dramatic as this appears to diverge with a power law when the fluid velocity goes to zero.

The analysis of the evolution of several structural quantities during compaction has revealed that this is not accompanied by any particular geometrical modification. The radial distribution function and the Voronoï volume distribution, for instance, smoothly change as the density of the granular system increases. In particular the collapse of the Voronoï volume distributions (sec. [V B]) evidences the presence of a single underlying geometrical structure in the system. Also, the probability distribution function of normal forces between grains do not change during compaction.

The analysis of the dynamics of compaction has revealed that this is characterized by dynamical heterogeneities. The probability that, during a tap, a particle makes a given displacement decreases exponentially with its size, resembling observations made in dense colloidal systems [36]. Similarly we have observed that, during a tap, faster particle tend to form cluster, as observed both in colloidal [36] and in glass-forming [38] systems.

There is, however, a marked difference between a typical trajectory of a granular particle during compaction, and a typical trajectory of a particle in supercooled liquids. Precisely, in supercooled liquids a particle spend most of time in cages formed by its neighbors, and occasionally makes large displacement escaping from the cage. In our system, instead, particles usually diffuse, and sometimes are trapped in a cage. This different behaviour is due to the particular driving of our system as in our system, when the the flow in on the system expands and the grains are able to escape from their cages.

As the slowdown of the dynamics is related to the space available for particle motion, we have studied the correlation between the displacement of particle during a tap and its Voronoï volume, which is a rough estimate of its free volume. This analysis has shown that particles with larger Voronoï volumes are those who make larger displacements during a tap.
