Abstract
Polythene is the most common plastic. The annual global production is around 80 million tones. It’s Ecthyma gangrenosum (EG) is an uncommon skin infection caused most commonly by Pseudomonas aeruginosa. It is characterized by a macule that rapidly changes into a gangrenous ulcer with a black eschar surrounded by erythema. We report a case of EG in a previously healthy woman treated with intracutaneous injection and topical gel of Wharton’s Jelly-derived MSCs (SWj-MSCs) secretome that showed a significant result in the wound healing process, and the patient was satisfied with the results.

Keywords: Ecthyma gangrenosum, secretome, stem cell, wharton’s jelly, wound healing

Introduction
Ecthyma gangrenosum (EG) is a skin infection caused by microorganisms such as bacteria (Pseudomonas aeruginosa, Staphylococcus aureus, Group A Streptococcus, Escherichia coli, Klebsiella pneumoniae, Serratia marcescens and Aeromonas hydrophila) and fungi (Candida albicans) but most commonly by Pseudomonas aeruginosa [1, 2]. EG usually targets immunocompromised subject’s body parts such as on the anogenital area, buttocks, extremities, abdomen, axillae, and rarely on the face. Despite this, it has the potential to affect previously healthy subjects [3]. The mortality rate varies between 35% and 90%, depending on the severity of the underlying sepsis, which can be as low as 15% in subjects without bacteremia. Septic shock, neutropenia, resistant microorganisms, and inadequate or delayed antibiotic treatment are all associated with increased mortality [2, 4]. Antibiotics such as third and fourth-generation cephalosporins, broad-spectrum penicillins, β-lactam antibiotics, and aminoglycosides can be used for EG treatment. Surgical debridement may be necessary to prevent further spread of infection for necrotic tissue and drainage of localized abscesses [1, 2, 5]. The secretome is a product secreted by MSCs that contains a variety of growth factors, cytokines, and chemokines that aid in the re-epithelialization, immunomodulation, angiogenesis, and ECM remodeling processes, thereby accelerating wound healing. This case report discusses the potential benefit of treating ecthyma gangrenosum with secretome. The secretome is used in conjunction with other therapies to support in wound healing [6].

Case Report
A 37-year-old woman presented with a 3-day history of a black wound on her left thigh near her groin. Initially, it looked like a red papule that was neither itchy nor painful. In 24 hours, this red papule turned blackish and increased in size. The patient had no history of immune system disorders and was not taking immunosuppressive drugs. On examination, the patient was hemodynamically stable, and there was no fever. On the dermatological examination on the left thigh, a necrotic ulcer covered with black eschar, measuring 17x7 cm, with a hyperemic edge, was found (fig.1). The patient was initially given intravenous third-generation cephalosporin for broad-spectrum coverage. The lesion was cleaned with NaCl, followed by applying topical antibiotics. Twelve days later, the black eschar became hard, and the erythema became less (fig. 2A). The patient consented to surgical debridement.
After that, the secretome of Wharton’s Jelly-derived MSCs (SWj-MSCs) was injected intracutaneously of the lesion (fig 2B). The patient also was given SWj-MSCs gel to be applied daily by herself at home. After two days, the patient came back to control; tissue regeneration and repair process had occurred. The lesion looked clean as the vessel contracted and the leaked blood coagulated (fig. 3). Sixteen days after the intervention, the formation of granulation tissue has appeared (fig. 4). Two weeks later, the lesion has got smaller in size, and granulation tissue was perfectly formed (fig. 5). The lesion had been getting better since then (fig.6), and one month later, it became a closed wound accompanied by scarring (fig. 7). The patient was very satisfied with the result.

Fig 5: Thirty days after the intervention: The lesion has got smaller in size, and granulation tissue was perfectly formed.
Discussion
Ecthyma gangrenosum (EG) is a rare type of skin infection that is most frequently caused by *Pseudomonas aeruginosa*. EG manifests clinically as a painless, erythematous macule that progresses to form a papule, pustule, nodule, or bulla. It develops to a gangrenous ulcer with a black eschar surrounded by erythema within 12 hours [7]. There have been two distinct forms of EG described. Bacteria spread hematogenously and infect the media and adventitia of blood vessels in the classic bacteremic form. Ischemic necrosis of the surrounding skin occurs as a result of perivascular invasion. In the second nonbacteremic form, the lesions occur at the site of direct inoculation into the skin. *Pseudomonas aeruginosa* produces protease, elastase, phospholipase C, and exotoxin A that are responsible for the direct tissue and vessel destruction leading to ulcerative lesions [5, 8, 9].

Mesenchymal Stem Cells (MSCs) are one type of stem cells that can differentiate into a variety of tissue-specific cell types. Due to the proliferative and regenerative capabilities of stem cells, they are currently an effective alternative therapy for skin diseases. MSCs can be isolated from a variety of tissue types, including bone marrow, adipose tissue, skeletal muscle, dental pulp, amniotic membrane, amniotic fluid, and umbilical cord [10, 11]. MSCs contribute to the cutaneous wound healing process by expediting wound closure, accelerating re-epithelialization, improving tissue granulation, inducing angiogenesis, reducing inflammation, and increasing ECM remodeling. These beneficial effects are apparently mediated by paracrine signaling. Certain cells, such as epithelial cells, endothelial cells, keratinocytes, and fibroblasts, respond to MSC paracrine signaling. MSC paracrine signaling controls a variety of cellular responses to environmental changes, including cell survival, proliferation, migration, and gene expression, via the secretion of bioactive molecules such as cytokines, chemokines, and growth factors, collectively referred to as secretome. (Fig. 8) [12–14].
The secretome is present in the medium used to culture the stem cells; this medium is referred to as conditioned medium (CM). Secretome has several advantages over stem cells in terms of processing, storing, packaging, and transportation. Numerous studies have shown that MSC-CM contains growth factors that aid in the regeneration of damaged organ tissues, with a particular emphasis on proliferation, most notably epidermal growth factor (EGF), basic fibroblast growth factor (bFGF), and hepatocyte growth factor (HGF). It has been demonstrated that it accelerates wound healing by increasing the proliferation and migration of preexisting skin cells through PI3K/Akt or FAK-ERK1/2 signaling. In addition, proangiogenic proteins that contribute to angiogenesis are also found, such as Vascular Endothelial Growth Factor (VEGF), Platelet-Derived Growth Factor (PDGF), Angiopoietin-1 (Ang-1), Ang-2, angiostatin, CXCL16, granulocyte-macrophage colony-stimulating factor (GM-CSF), monocyte chemotactic protein-1 (MCP-1), matrix metalloproteinase (MMP)-8 and MMP-9. Besides that, the secretome contains anti-inflammatory cytokines (Transforming Growth Factor-Beta 1(TGF-β1), Interleukin-6 (IL-6), IL-10, IL-27, IL-17E, IL-13, and IL-12p70), as well as pro-inflammatory cytokines (IL-1β, IL-8 / CXCL-8, and IL-9) that also make a significant contribution to wound healing [6,13,15]. Antimicrobial effect can be achieved by secreting antimicrobial peptides (AMPs) and expressing molecules such as 3-dioxygenase (IDO), indoleamine-2, and interleukin (IL)-17. MSC have been shown in several studies to be capable of directly killing certain bacteria, including Pseudomonas aeruginosa, Klebsiella pneumoniae, Staphylococcus aureus, and Escherichia coli. By interfering with the integrity of the bacterial cell membrane or by enhancing chemotaxis and chemokine induction, the mechanisms are outlined below. Cathelicidin LL-37, human-defensin 2 (hBD-2), hepcidin, and lipocalin 2 are all AMPs expressed by human MSCs (Lcn2). AMP is one of the critical components produced by MSCs that aid in the control or elimination of bacterial infection and the regulation of inflammatory responses [16-18]. Wharton's Jelly-derived MSCs (Wj-MSCs), one of the MSC sources derived from the umbilical cord, are considered to be more beneficial than adult mesenchymal stem cells. Without using an invasive method or additional surgery, Wj-MSCs are isolated from extraembryonic tissues discarded following delivery. Due to their non-tumorigenicity and immunomodulatory properties, they can be allotransplanted without rejection to regenerate organs such as the liver, bone, fat, heart, cartilage, neural, pancreas, blood vessels, and skin components [11,19]. Wj-MSCs release anti-inflammatory, proangiogenic, and other molecules that can promote wound healing, such as IL-10, TGF-β, Prostaglandin E2 (PGE2), IDO, and TNFα-stimulated gene-6 (TSG-6), VEGF, bFGF, IL-6, PDGF, Placental Growth Factor (PIGF), Ang-1, MCP-1, and HGF [11,20]. According to several studies, Wj-MSCs increase re-epithelialization, fibroblast proliferation, neovascularization, and collagen deposition, all of which can accelerate wound closure. Wj-MSCs can be used as an alternative therapy option in wound healing to stimulate wound repair [11,21].

**Conclusion**

Echyma gangrenosum is a skin disease that begins as an erythematous macule and rapidly progresses to a gangrenous ulcer with a black eschar surrounded by
erythema. Due to its proliferative and regenerative potentials, as well as its strong antimicrobial effect, Secretom of Warthon Jelly Mesenchymal Stem cell therapy may be an alternative therapy for EG. A case of EG in a previously healthy woman treated with intracutaneous injection and topical gel of Wharton's Jelly-derived MSCs (WJ-MSCs) demonstrated a significant improvement in the wound healing process, and the patient was satisfied with the results.
